attention of the whole world was directed to the subject of tuberculosis. Secondly, it seemed to him that the time was ripe for those who were especially interested in the study of the pathology of the skin to call the attention of the profession at large to the very great amplification of our knowledge of tuberculosis as it affected the skin. The additions to our knowledge of tuberculosis of the skin during the past twenty years had been enormous, but he was quite sure that the general profession had not sufficiently appreciated this fact. Comparing the textbooks published in 1880 with those published to-day, one would find in the former one-quarter or one-half a page devoted to a consideration of tuberculosis of the skin; whereas to-day one found as many as fifty or one hundred pages, and even more, necessary for a proper discussion of diseases of the skin of tuberculous nature. He said he was well aware that a multiplication of words did not mean always an increase in knowledge, but he was sure that many permanent and valuable additions had been made to the knowledge of tuberculosis as it affected the skin. Dr. Hartzell, referring to the two tables Dr. Robinson had presented, said that there were two groups of affections which were included under the term tuberculosis of the skin. Some of these had long ago passed from the region of debate; they were well established in the category of tuberculosis of the skin; their histological features, and especially the presence of the bacillus tuberculosis, left no doubt as to their proper place. The mere histological features of any lesion, however, were not sufficient to determine whether it belonged to tuberculosis of the skin or not; they were beginning to learn that there was no such thing as anatomical specificity, but only etiological specificity. Because several lesions presented closely allied morphology and symptomatology, it did not follow that they were due to the same cause. When one came to the so-called tuberculides there was still room for debate. They were by no means sure that they belonged to tuberculosis of the skin, for they had failed to demonstrate in those cases the bacillus of Koch. He wished it to be understood that he was not denying that these were cases of tuberculosis, but they were as yet far from certain about it. The failure to demonstrate the tubercle bacillus in these lesions must leave them in doubt as to the true nature of tuberculides. In the papulonecrotic tuberculide they had an affection usually associated with some fairly well demonstrable tuberculous condition elsewhere in the body; this was one of the chief reasons for regarding this as a tuberculide. All efforts to demonstrate the tubercle bacillus in those lesions had thus far failed, and some authors, notably the French, had attributed them to tuberculous toxins produced in foci remote from the skin. But if they were thus produced it would be very difficult to account for the comparative infrequency of the eruption in cases of visceral tuberculosis, in which tuberculous toxins must be abundantly present in the circulation. One of the peculiarities about several tuberculous eruptions was the tendency, in many cases, to localize themselves about joints; this was a very curious characteristic, and it had not received adequate explanation. In the papulonecrotic tuberculide the walls of the blood vessels were enormously thickened, thus encroaching upon the lumen of the vessel and leading to necrosis. There was in all probability some toxic substance which acted upon these vessels. Pityriasis rubra, which always terminated fatally, was in all probability a tuberculous affection, since in a large proportion of the cases autopsy disclosed visceral or glandular tuberculosis. A few years ago Brunsgard reported a case of universal dermatitis lasting for some months, and terminating fatally from bronchopneumonia; the autopsy revealed tuberculous foci in all the viscera and the lymphatic glands; tubercle bacilli were also found abundantly in the skin. He did not believe erythematous lupus to be tuberculous in nature. Most of his patients afflicted with this disease were in robust health, and many were living to-day after having had the disease for many years. In a case of erythematous lupus, in which death occurred from accident or acute disease, the most careful post-mortem examination conducted by some authors whose names he could not recall failed to show the smallest focus of tuberculosis. A few cases of this kind would completely refute the theory of the tuberculous character of this affection. Dr. Hartzell believed that this disease was due to a nontuberculous infection of some sort.

An important question was what was the relationship between cutaneous and visceral tuberculosis. Phthisis, for instance, frequently occurred with lupus vulgaris; but in how many cases did visceral tuberculosis follow as a result of the cutaneous affection? There were no accurate or reliable statistics on this point, which was a very important one. How much did a local tuberculosis menace the patient's life? We were apt to regard local tuberculosis as a rather benign affection. A second important question was, What was the relationship between bovine and other nonhuman tuberculosis and cutaneous tuberculosis? It seemed likely that tuberculosis verrucosa cutis was in a considerable number of cases due to the bovine bacillus, since it was especially frequent in butchers and others who frequently came in contact with animals. If Koch's contention that the bovine bacillus rarely found a favorable soil in the human being was true, it was rather curious that the same bacillus so often attacked the skin which was very unfavorable soil for the growth of the bacillus, as shown by its scanty numbers in cutaneous tuberculosis.

GENITOURINARY SECTION.

Stated Meeting, Held March 17, 1909.

DR. MARTIN W. WARE, CHAIRMAN.

A Case of Chancroidal Bubo, Followed by Femoral Thrombosis, Pyemia, and Death.—Dr. HERMANN FISCHER reported this case and showed the specimen. The patient was a man 34 years old, a salesman, who contracted a chancre about ten years ago, for which he received treatment for only eight days. He also gave a history of gonorrhea, without complications. Two years ago several ulcers of large size developed on the right leg, which disappeared under antiluetic treatment. At the same time the right inguinal glands became swollen, and this swelling never entirely subsided. A week before coming under observation these glands again became enlarged, and an abscess developed which was discharging pus when he entered the hospital. Examination showed a large ulcerated area, with inflamed, ragged, and indurated edges. The floor of this ulcer was occupied by an irregular mass of ulcerating glandular tissue, freely discharging pus. There was no elevation of temperature. The inguinal glands were extirpated, with the removal of all diseased tissue. The saphenous vein, which was firmly adherent to the mass, was ligated and cut. It was found to be thrombosed. Two days after the operation the patient's temperature suddenly rose to 104° F., and he passed a very restless night. The wound was dressed and found clean. On the fourth day after the operation he had a severe chill; this was repeated daily, and his temperature ranged between 100° and 105°, at one time reaching 107.4°. His pulse ranged between 130 and 140. On the 16th day he developed a septic pneumonia and died the same day. The autopsy showed multiple abscesses in both lungs, and a thrombosis of the femoral vein, the external iliac vein, and the inferior vena cava. An incision into this thrombus revealed pus.

Chancroidal Bubo Perforating into the Abdomen.—Dr. FISCHER also reported the case of an inguinal abscess,

of chancroidal origin, which burrowed its way along the femoral vein and had broken into the peritoneal cavity, causing peritonitis. Upon opening the abdomen, Dr Fischer found a large amount of purulent fluid in the pelvis and right iliac fossa. When pressure was exerted upon the swelling in the groin, it was noticed that a small jet of pus flowed into the abdomen from below Poupart's ligament and from the inner side of the femoral vessels. Upon further exploration he found an abscess membrane which projected into the abdominal cavity like the finger of a glove, the tip of which was perforated. The pus in the abdominal cavity was carefully sponged out, the swelling in the groin was incised, and both incisions were drained. After the operation the patient was rather septic for about a week, his temperature at one time reaching 106°. From that time on it gradually subsided, and his further convalescence was uneventful.

Litholapaxy, with Specimens. (Two Cases).—By Dr. George Knowles Swinburne. The first case was that of a man 54 years old, who gave a history of having had a stone removed from his kidney nine years ago. Subsequently, he developed symptoms of stone in the bladder, and its presence there was corroborated with the cystoscope and searcher. It was of the mulberry type, about the size of the end of an adult thumb, and required considerable force to crush it. Only a portion of it was removed at the first sitting, the remaining fragment being crushed and evacuated a week later.

The second case reported by Dr. Swinburne was that of a man of 60, who had given symptoms of stone in the bladder for over a year. In this case the stone was situated behind the prostate, so that it was impossible to grasp it with the jaws of the lithotrite in the regulation manner, so that time was lost by being obliged to seek the stone with the instrument. In order to effect its complete removal, about ten operations were necessary, which were done at intervals of a week. Both of these patients were operated on under cocaine anesthesia, and in no instance did any reaction follow the procedure. In the first case the urine cleared up within a week; in the second case it did not clear up until all the fragments had been removed. The speaker said he did not consider it necessary to complete the litholapaxy at a single sitting if there were any contraindications to so doing.

Dr. Victor C. Pedersen said that this patient illustrated how in some of these old subjects, notwithstanding beginning prostatic enlargement, one might enter the bladder repeatedly and do a good deal of work there without getting the disastrous renal crisis that one was so apt to fear.

Dr. Follen Cabot said that in the absence of any history of retention of urine and prostatic symptoms he did not think that this could be regarded as a true case of prostatic enlargement.

Dr. James Pedersen said that success after litholapaxy depended largely on the technical skill of the operator. Possessing that, the operation was possible, and was the operation of choice in many cases, in spite of an enlarged prostate, for example, and other possible contraindications.

The Chairman, Dr. Ware, thought that a certain amount of unnecessary risk was incurred by treating these patients with stone in the bladder as ambulant cases. It was well known that urethral fever might occur, even after a simple catheterization done under the most favorable auspices, and therefore to permit a patient to go about immediately after a litholapaxy was rather precarious.

Dr. Swinburne, in closing, said he would prefer to treat these cases in the hospital, but in the cases reported the patients would not consent.

Multiple Syphilitic Nodes of the Testis and Epididymis.—Dr. Victor C. Pedersen reported this case, which was one of multiple syphilitic nodes of the testis, epididymis, and chord, in which the lesions disappeared promptly after a dozen mercurial injections. This patient at first absolutely denied specific infection, and for a time the lesions were regarded as tuberculous.

Dr. F. Tilden Brown referred to the difficulty that was often met with in recognizing the true character of a testicular enlargement, and in the absence of a microscopic or pathological diagnosis he thought we should never fail to avail ourselves of the antisyphilitic test.

Dr. Ware said the history of these patients often counted for naught. He thought one could place some reliance on the use of tuberculin, and an observation of its general and local effects.

Dr. Pedersen, in closing, said the testis in this case was typical of tuberculosis, in regard to both the character and the multiplicity of the nodes. There were, however, no sinuses nor adhesions. The tuberculin test was not tried.

Two Cases of Epithelioma of the Penis, with Specimens.—Dr. Kingman B. Page reported these cases, in which he had amputated the penis for epithelioma. The first case was that of an Italian laborer, 65 years old, who, when he came under observation on March 15, 1908, gave no venereal history, but had been treated for syphilis until coming under observation, and said he had first noticed the growth two months before. It involved the superior surface of the prepuce, and the inguinal and femoral glands were enlarged and somewhat adherent to the skin. The penis was amputated, close to the pubis, and the glands excised. Two months later a recurrence was noticed in the prostate. From this point there was a rapid extension to the base of the bladder and the wall of the rectum, and by ulceration, the whole forming a huge cloaca. The man died of sepsis on July 4, 1908. The pathological report was carcinoma.

The second patient was a German cook, 56 years old. He gave an alcoholic and a probable specific history, and his physical condition was poor. The glands in both groins were enlarged, but movable. The penis was amputated on September 23, 1908, but the glands were not excised. When the patient was last seen, on February 6, 1909, he was in good condition and showed no evidences of a recurrence. Dr. Page said he had seen six cases of epithelioma of the penis, and of these, the longest duration of life after the primary operation was three and a half years. One survived the operation three and a half years, one two years; the others all died within less than a year, the shortest period being four months. Of 7,881 cases of primary cancer of all regions collected by Andrews, there were only 62 cases, or 1.27 per cent., affecting the penis. The majority of the patients were married. There were no cases of contact cancer, and no case in Jews.

Dr. Follen Cabot said that in all the cases of epithelioma of the penis that he had seen, the patients had a tight foreskin, and in most instances the disease was well advanced. These cases were apt to be confused with the lesions of venereal sores, and operation was thereby delayed. The speaker said that one of his patients was alive seven years after amputation; another four years.

Dr. Victor C. Pedersen recalled a case operated on at the New York Hospital by Dr. Robert F. Weir, where the patient was free from recurrence three and a half years after the operation. In that case on one groin Dr Weir did the so-called Lennander operation, by which, in addition to amputating the penis, Poupart's ligament was divided and the glands in the region of the common iliac vessels dissected out. In the other groin Dr Pedersen cleared the lymphaticus away just above Poupart's ligament within the abdomen, by passing beneath the ligament.

Fragment of Rubber Catheter Removed from the Bladder of a Prostatic.—Dr Page showed this specimen, which he had removed from the bladder of an old prostatic who had tried to catheterize himself. The frag-

ment was removed with the aid of an endoscopic tube and a stylet.

Diverticula of the Bladder.—Dr. Hermann Fischer in this paper said that diverticulum, double bladder, bladder-cells, cysts of the bladder, saccules, sacs, pouches and false bladder were terms that were used to designate an abnormality of the bladder, consisting of a receptacle of varying capacity, connected with the bladder by an orifice of variable diameter. These terms were formerly used interchangeably, without a clear or definite conception of the pathological condition to be designated, but in late years, since the pathology of these extra-vesical cavities had been studied more closely, it had been found that their origin and causative factors differed so widely that it was necessary to establish a definite nomenclature in order to avoid confusion. Morgagni was probably the first one to recognize the true nature of diverticula. He attributed their formation to a hypertrophy of the bladder wall, the true cause of which was in his opinion hypertrophy of the prostate. After discussing the various types of diverticula of the bladder, the author stated that the congenital type might be present for a long time before giving any discomfort. Some patients stated that they had suffered from "a weak bladder" as long as they could remember; others experienced symptoms for only a short time. The main symptom in all, at the outset, was frequent micturition. Later this was accompanied by pain, which might be situated in the abdomen, where it had the character of pressure or fullness, or it might only appear as a burning and stinging sensation during and at the end of micturition. After urinating there was in most cases a feeling as if the bladder was not completely emptied, and the desire to urinate persisted or came on again shortly after voiding. Some patients suffered from complete retention earlier or later in life. This complete retention might even be the first symptom of the anomaly. The urine became cloudy and contained mucopurulent material. At times hematuria might be present. These pathological findings made their appearance as soon as the urine in the diverticula stagnated and began to show ammoniacal fermentation. Then all the symptoms were aggravated, and stones might develop in the diverticulum and add to the misery of the patient. If the kidneys became implicated, as they often were in the later stages of the disease, symptoms of pyelitis and pyonephritis might develop, with septic temperature, an attack of uremia finally closing the scene. The treatment of diverticula of the bladder might be conservative, palliative, or radical. There were cases reported which had been made comfortable for years under careful catheterization, with the subsequent flushing of the bladder with various weak antiseptic solutions. Two different methods of operative procedure were at our disposal: 1. Drainage of the diverticulum and bladder through a suprapubic cystotomy, with or without the division of the septum. 2. Radical extirpation of the pouch, and suture of the bladder, with drainage.

Congenital Diverticula of Bladder, Demonstrated by Styletted Catheter and Radiography.—Dr. F. Tilden Brown, in connection with Dr. Fischer's paper, briefly reported a case of congenital diverticula of the bladder. This case was first regarded as one of reduplication of the ureter, and the true condition of affairs was finally demonstarted by the styletted catheter and radiography.

The discussion was continued by Drs. Cabot and Ware, and was then closed by Dr. Fischer.

New Model Composite Cystoscope.—Dr. F. Tilden Brown demonstrated this instrument. He also showed a modified urethroscope.

Glass Tubes for Suprapubic Drainage of the Bladder in Prostatic Surgery.—Dr. Follen Cabot, in showing these, said the advantages they possessed were that they were easily held in place and easily cleaned, and that they permitted a view of the flow of urine or blood through them. The tubes, having an inlet and outlet, allowed a very satisfactory method for continuous bladder washing.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held March 15, 1909.

The Corresponding Secretary, Dr. Frank C. Raynor of Brooklyn, in the Chair.

A Contribution to the Treatment of Cancers.—Dr. C. G. Am Ende, in this paper, first recalled the observation that some sheep thyroids, preserved in their natural condition, seemed to give better results in the treatment of certain goiters than the exsiccated material of commerce. This and other considerations led to the production of a fluid extract made from the gland, which possessed certain antitoxic properties, available to the fullest extent by its complete freedom from producing any cardiac or gastric disturbances, and manifested by restitution of bodily and mental vigor to patients suffering from exhaustion, and in a few cases almost complete prostration, of advanced carcinomatosis, so that they improved in health and in some instances were even able to again take up their previous occupations. When this extract was used in conjunction with the *x*-ray treatment, it seemed to enhance the efficacy of the latter, and the speaker reported cases in which, following this combined method of treatment, there was a disappearance of deep-seated, as yet soft tumors or edematous infiltrations, some quite large—a result not obtainable by the unaided use of the extract, nor by general consensus of opinion, by exposure to the *x*-rays alone. These tumors included metastatic developments in the thus-far healthy female breast subsequent to resection of the other. In offering the use of this thyroid extract as an adjunct to the *x*-ray treatment of cancer, Dr. Am Ende said he did not wish it to be understood that he was in any way heralding a so-called cancer cure, and he wished in no way to detract from the importance of early operative interference in malignant disease. The chief value of this method was in dealing with cancerous growths reappearing after operation.

Dr. J. Herman Branth said that some five years ago, in a paper read before this Association, he asserted that the *x*-rays were very helpful in the treatment of rodent ulcer and epithelioma—in fact, almost a certain cure. This had been confirmed by his experience since that time. He also asserted at the time that deep cancerous affections did not yield to this treatment, but at best were only retarded or brought to a standstill. This had also been confirmed by his later experience. At the meeting in October, 1908, he spoke of the benefits of the high frequency currents, and demonstrated that Houston and Maxwell were in error in their contention that these currents traveled on the surface. He proved by experiment and demonstration that just because of the high voltage, this current would all the more follow straight lines through the body, and that with the aid of a step-up transformer it could be made to pass through any and all insulators known. With this current he had treated epithelioma after raying, with great benefit to the patient. For this treatment he had devised an adjustable spark gap, for which he had received credit in France, where they called it by his name. In Heidelberg they now used a crude affair, unadjustable, and therefore not applicable, excepting with anesthesia, because of the pain it gave rise to. Nevertheless, this spark was followed by the same good result. In Heidelberg they called it "fulguration," and all cases of cancer were treated by this method after operation. Dr. Branth said he called his

method the high-frequency high-tension spark. This series of spark gaps enabled one to have absolute control over the intensity of the current, from the mildest to the strongest. He believed this current to be of greater effect than the *x*-rays in the treatment of glandular tumors of the neck. To warts and moles he applied the high-frequency spark with a pointed vacuum tube. Warts disappeared after from one to three applications; pigmented moles required more prolonged treatment, but all disappeared readily without leaving a scar. Applications for a longer period than two minutes were apt to leave keloidal scars. Electrical applications could not be measured and weighed like pharmaceutical remedies, and ripe experience was necessary to guide the operator and keep him within the bounds of safety.

Dr. Aspinwall Judd said that, while he was in thorough accord with many of Dr. Am Ende's conclusions, there were a few with which he was unable to agree. After ten years' experience with the use of the *x*-rays, the following conclusions briefly embodied his views regarding their value: About 90 per cent. of cases of epithelioma without glandular enlargement yielded very satisfactorily to the *x*-rays. Epithelioma with glandular enlargement, however, presented quite a different aspect, and his results in those cases had not been so good. He always advised the knife in dealing with tumors of that class. In endothelioma his results with the *x*-rays were very satisfactory. In sarcoma he had reported a series of thirty odd cases, all inoperable, in 40 per cent. of which the growth disappeared under the use of the rays, but in these cases there was always a recurrence. In one case the sarcoma had disappeared temporarily four times in the course of five years under the application of the rays. When these cases were inoperable the *x*-ray treatment was better than any other with which he was acquainted; when they were operable they belonged to the surgeon. Dr. Judd said that in recurrent carcinoma his results with the rays had been very satisfactory in cases where there was no glandular enlargement of a malignant nature. In primary deep-seated carcinoma he had obtain no results whatsoever, all the patients dying eventually of metastases, in spite of temporary improvement in some instances. In some of these cases the stimulating effect of the rays caused the rapid formation of metastases and hastened the fatal issue. In about 70 per cent. of these cases the pain was relieved by the rays. In lymphosarcoma and leukemia we simply destroyed the lymphatic cells and lymphatic structures. Caution should be exercised not to attempt to destroy these growths too rapidly; otherwise, we might get a collection of toxins in the body which would destroy the patient. By carefully watching the blood count, this danger could be avoided. Dr. Judd said he had used the hard tube in practically all of his cases. He had used Dr. Am Ende's extract in some of his more serious cases, and he had found that it added very materially to the efficacy of the *x*-ray treatment.

The Diagnosis and Treatment of Rheumatism in Children.—Dr. Le Grand Kerr, in this paper, said that in approaching the subject of rheumatism in children, we must leave behind us all preconceived ideas and deductions which we may have acquired from an experience with adult cases, for acute rheumatism in children was entirely different, in all of its clinical aspects, than the same disease in adult life. There was this chief difference between the adult and child types of rheumatism. In the former it was expressed as an acute polyarthritis, with the symptoms all massed, while in the latter its common occurrence was in monarthritic forms, with cardiac changes as a common manifestation, and the symptoms spread over a long period, so that often the history of the disease was the history of that child's life. The chief object in the child was the prevention of cardiac changes. Before these occurred there were present a multiplicity of symptoms which, when recognized, aided in the diagnosis. A child who had a rheumatic parent was very liable to develop the disease, and if both parents were rheumatic, the liability became almost a certainty. Among the nonarticular manifestations of the disease which were important for its early recognition, the speaker first mentioned tonsilitis. He said that, while not every tonsilitis was of rheumatic origin, fully one-third of the cases were of such genesis. Pain in the chest and exertional dyspnea (irrespective of disease of the heart) was an initial manifestation in 11 per cent. Chorea manifested itself as the initial symptom in 9 per cent. of the cases he had seen, and was severe in but one instance. So-called "growing pain" or myalgia was present in but 4 per cent. of the cases as an initial manifestation. Dr. Kerr said the time to treat rheumatism in children successfully was when any clinical manifestation, backed up by a positive family history, made us suspicious of the tendency to the disease. Joint involvement was the initial manifestation in 31 per cent. In children under two years of age the occurrence of rheumatism was possible, but highly improbable. When active symptoms were present the treatment and care of the child must be rigorous. There were several indications, these were etiological, pathological, and clinical. The etiological indications were absolute rest, both mental and physical. The avoidance of solid food for a few days, and the absolute abstinence from all meats or meat extractives for several days. Sugar must also be restricted to the lowest possible amount, or saccharin used in its stead. All foods which were rich in proteids should be restricted. The pathological indications were to combat the inflammation in the joint, which might be done by the stimulation of the cutaneous circulation, and to limit or prevent an extension to the heart, lungs, pleura, or meninges. Here was the place for elimination, and, with that end in view, the skin, kidneys and bowel must be kept active. Free water drinking should be encouraged. The clinical indications for treatment were hyperpyrexia, pain in the joints, to limit damage to the joints, tachycardia, profuse perspiration, and the resulting anemia and general debility. The salicylates occupied a well-deserved place in the treatment of rheumatism. They were palliative, however, and for the time overcame or modified the rheumatic manifestations. Their use could not be long continued in children, because of their prompt tendency to disturb digestion. Salicin was less objectionable than the salicylate of soda, and could be readily given in the dose of one grain for each year of the child's age and repeated every three hours. Along with the salicylates or immediately following the discontinuance of their use, bicarbonate of sodium should be given. In concluding his paper, the author again emphasized the importance of rest in the care of the rheumatic child, and said that the responsibility of the physician did not end with the diagnosis and treatment of an individual case. If there were other children in that family they must be protected. The parents must be made to realize that what to them seemed a slight illness might be but the beginning of a disease which would limit the usefulness of their child, narrow its activities, or possibly result in its premature death.

Dr. John Dorning said that unfortunately we knew little more about rheumatism to-day than we did fifteen years ago. Even then it was regarded as a disease of microbic origin, conflicting with the old chemical theory. If it is of bacterial origin, and we must admit that in some features it resembled an infection, we could not, at the same time, fail to recognize a predisposing factor in the constitutional diathesis of the child. As a general prophylactic measure, the speaker thought it was incumbent upon the family physician to pay some attention to the diet and general hygiene of the children under his care. During childhood, relatively, a greater percentage of

proteid was necessary for the growth of the body than was required in adolescence. It had, however, been his observation that many children received too large an amount of animal proteid, and they were also indulged too much with sugars, both of which rendered the system more vulnerable to rheumatic affections. The so-called growing pains should not be treated too lightly. In years gone by, when we knew less about scurvy, this affection was often mistaken for rheumatism. At the present time, however, a differential diagnosis was not difficult. Not infrequently, in rheumatism in children, our attention was not called to the case until some cardiac complication had developed. Prior to this the child's symptoms may have been comparatively insignificant; a slight tonsillitis, perhaps, with a persistent low grade of fever, loss of appetite and an increasing anemia. In the treatment of rheumatism in children, in addition to the usual medication, absolute rest was a most important factor. In some cases, the patient should be kept between blankets instead of sheets, as the skin was over-sensitive to cold. In the beginning, an exclusively fresh milk diet should be given, to which should soon be added cereals and fruits, and, later on, green vegetables. A general tonic treatment with iron and cod liver oil was indicated in many cases.

Dr. Thomas S. Southworth said that in the diagnosis of the obscure manifestations of rheumatism in children the family history was extremely valuable, if properly obtained, and it had been his custom for many years, in taking the history of children, to make inquiries as to the occurrence of rheumatism in the grandparents, parents and collateral relatives, carefully excluding senile arthritic changes. If the symptoms in a given case were at all suspicious of rheumatism, treatment should be promptly instituted. This consisted essentially of rest in bed, milk diet and the administration of salicylates and alkalies. Except the newer remedies of the salicylate class, the most marked advances that had been made in connection with the treatment of rheumatism in recent years had not been along therapeutic lines, but in the prompter recognition of the disease, and the more strict management of the case. As an alkali in these cases, Dr. Southworth said he preferred the bicarbonate of soda. He believed that alkalis should be given earlier than Dr. Kerr suggests and simultaneously with the salicylates, as they are the active and perhaps the sole measure for limiting the extent of the infection and its effects, together with absolute rest. The most serious complications were those connected with the heart, and these occurred in many cases where we least expected them. In such cases we may have myocardial as well as endocardial changes, and it was for that reason that prolonged rest was so important. During the convalescence of such a child, iron and tonics were more important than cardiac stimulants. He agreed with Dr. Dorning that the avoidance of chilling in these cases should not be lost sight of.

Dr. Homer Wakefield said he regarded this type of rheumatism as an acidosis. While in a large percentage of cases the alkalinity of the blood was not markedly reduced, yet the acidosis could be determined by the ammonia thrown down by the kidneys, which was often largely increased. In regard to the diet of these patients the injurious effects of sugar had already been referred to; this tended to acid fermentation, which was reduced by cutting out the sugars. Dr. Wakefield said it was his custom to give the alkalies on an empty stomach, half an hour before meals, and several years ago he had called attention to the fact that the salicylates, when given after meals, acted as antifermentatives, and, for that reason entirely, were very valuable in the treatment of rheumatism; whereas, if given at other times, they had very little effect. By controlling the acidosis with alkalies and preventing acid fermentation we obtain our best results in the treatment of rheumatism, and when this method was followed, cardiac complications did not occur. Alkalies should not be administered soon after meals, except to neutralize preformed gastric hyperacidity, and never to neutralize systemic acidosis. Sodium bicarbonate was the preferable form of alkali, and a teaspoonful before each meal should be continued until an alkaline urine was obtained.

Dr. Irving D. Steinhardt suggested the use of applications of ichthyol and iodine in acute cases.

Dr. P. W. Roberts said that in his orthopedic work it was very common to get a history of so-called growing pains, and that many of those children subsequently developed a tuberculous condition of the hip or knee.

Dr. Kerr, in closing, said he preferred local applications of water to the mixture of ichthyol and iodine. The latter made a rather nasty mess, while water was apparently equally efficacious; it was easily obtainable, and by restricting ourselves to these simpler remedies we could more readily secure the cooperation of the mother, which was a very important point. Replying to Dr. Roberts, the speaker said there were cases of myalgia due to bone or joint tuberculosis, but they could be readily demonstrated by a proper examination. In those cases there was restricted motion, and the child made an apparent muscular effort to keep the limb or joint immobilized. The duration of the pain was also a differential point.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

College of Physicians and Surgeons of British Columbia.

May, 1908.

ANATOMY.

1. (*a*) Describe the pleura. (*b*) Give the "reflections of the pleura" of the right side.
2. Name the bones which enter into the formation of the orbit, and give the articulations of any one of them.
3. (*a*) Give the muscles attached to the great trochanter of the femur. (*b*) Give the action and nerve supply of any two.
4. Trace the seventh nerve; what group of muscles does it supply?
5. Describe the ligaments of the ankle joint and the sternoclavicular joint.
6. Dissection necessary to expose the innominate artery.

CHEMISTRY AND PUBLIC HEALTH.

1. Antidotes—classify and give examples. What is the antidote in a case of acute arsenical poisoning? Give equation showing action.
2. In an analysis of drinking water you find chlorides 2 grs. per gallon. Discuss your results.
3. Describe minutely disinfection of a room occupied by an advanced and careless consumptive.
4. Cows' milk. (*a*) Discuss its merits as a food. (*b*) Show how it becomes dangerous for human use when improperly handled.
5. Differentiate between varioloid and chickenpox.

MATERIA MEDICA AND THERAPEUTICS.

1. Name two drugs in each of the following orders, stating doses and cases in which either would be used: Emetics, hypnotics, stimulants, diuretics, diaphoretics.
2. Doses and uses: Potassium bromide, strontium iodide, calomel, ichthyol, guaiacol.
3. State briefly in what disturbances of the circulatory system you would use digitalis, adrenalin, strychnine, ergot.
4. Write prescriptions: Acute bronchitis in adult. Acute rheumatism in adult. Acute nephritis, child, aged 12. Diabetes.
5. Describe treatment for typhoid fever.
6. Serum therapy: Nature and value as far as known.

MEDICAL JURISPRUDENCE.

1. Duties of a medical man when called to a case on which rape is alleged to have been committed.
2. Distinguish between acute alcoholism and acute mania.

3. A case of suspected poisoning. Describe proceedings.

4. Antidotes for: Carbolic acid, corrosive sublimate, chloral, arsenic, opium.

MIDWIFERY AND DISEASES OF WOMEN AND CHILDREN

1. What are the causes of delay, from slow dilatation, in the first stage of labor? Give the treatment in each case.

2. Describe the normal anatomy of the Fallopian tube. The varieties, causes, symptoms, prognosis, and treatment of salpingitis.

3. Enumerate the causes of hemorrhage before and after delivery. Give the varieties, causation, symptoms, and treatment of placenta prævia.

4. Name the varieties of displacement of the uterus. The causation and symptoms of retroflexion. Describe the operations performed for retroflexion.

5. Give the etiology, pathology, symptoms, complications, and treatment of a case of cerebrospinal meningitis.

PHYSIOLOGY.

1. Describe the cardiac nervous mechanism.
2. What do you know of renal secretion?
3. Discuss absorption in the digestive tract.
4. State the effect of cutting the third nerve.
5. Account for the different forms of aphasia.

SURGERY.

1. Empyema. Give its causes and treatment. Describe Schede's operation.

2. Prostatectomy. What conditions necessitate this? Describe the technique of the perineal method.

3. Coxalgia. Describe the various stages with symptoms of each, and appropriate treatment.

4. Describe Sayre's method for fractured clavicle. Give the principles of its action.

5. Hip-joint dislocations. Give the varieties, their symptoms and treatment.

THEORY AND PRACTICE OF MEDICINE AND MEDICAL PATHOLOGY

1. Epidemic cerebrospinal meningitis: Give etiology, symptoms, and differential diagnosis.

2. What is uremia? With what conditions may uremic coma be confused? Give differential diagnosis.

3. Mitral incompetency: Give physical signs and describe symptoms as they may arise.

4. Asthma: Give symptoms and treatment.

5. Give pathology, symptoms, and treatment of a case of tuberculous disease of the intestines.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

College of Physicians and Surgeons of British Columbia.

May, 1908

ANATOMY

1. "The *pleuræ* are two serous sacs enclosing and investing the lungs. Each pleura consists of a visceral and parietal layer. The *visceral* portion covers the lung, and the *parietal* layer lines the inner surface of the chest walls, the upper surface of the diaphragm, and the sides of the pericardium. The visceral and parietal layers of the corresponding pleura become continuous in front and behind the root of the lung; and below the root a fold, the *ligamentum latum pulmonis*, extends downward along the inner surface of the lung to the diaphragm. The mediastina are formed by the visceral layers of each side approaching one another toward the median line.

"The limits of the parietal pleuræ are as follows: Each extends upward into the neck, forming a domelike process over the apex of the lung about two inches above the first costal arch; from this the pleura passes downward and forward to the posterior aspect of the sternoclavicular joint of each side and meets its fellow in the midline at the manubriogladiolar articulation; they pass down together to level of fourth costal cartilages, where *right pleura* passes vertically to level of seventh right costal cartilage in midline; then outward, crossing ninth rib in midaxillary line; then downward and backward along eleventh rib to reach spine at neck of twelfth rib. Behind, it passes upward on the right side of the bodies of the vertebræ to the apex." (*Aids to Anatomy.*)

2. The bones which enter into the formation of the orbit are: The frontal, sphenoid, ethmoid, superior maxillary, malar, lacrymal, and palate. Of these, the *malar* articulates with. The frontal, sphenoid, temporal, and superior maxillary.

3. (*a*) The muscles attached to the great trochanter of the femur are. The Gluteus medius, Gluteus minimus, Pyriformis, Obturator internus, Obturator externus, Gemellus superior, Gemellus inferior, and Quadratus femoris.

(*b*) The *Quadratus femoris* rotates the thigh outward; it is supplied by branches from the sacral plexus.

The *Obturator internus* rotates the thigh outward; it is supplied by branches from the sacral plexus.

4. The *seventh or facial nerve* has its superficial origin in the upper end of the medulla oblongata, in the groove between the olivary and restiform bodies. It passes "forward and outward to enter the internal auditory meatus, it lies upon a groove on the auditory nerve, with portio intermedia of Wrisberg between, and at the bottom of the meatus it enters the aqueductus Fallopii, along which it runs first outward between cochlea and vestibule as far as hiatus Fallopii; then backward in internal wall of tympanum, just above fenestra ovalis, at the turn presenting a swelling, the *geniculate ganglion;* and finally it passes downward, to emerge from the bone at the stylomastoid foramen; it then passes outward and forward in the parotid, dividing behind the ramus of the jaw into *temporo-facial* and *cervico-facial* branches, which further subdivide and intercommunicate, forming the *pes anserinus.*" (*Aids to Anatomy.*)

It supplies the muscles of expression in the face, the muscles of the external ear, the Platysma, Buccinator Stylohyoid, and the posterior belly of the Digastric.

5. The *ligaments of the ankle joint* are: The anterior tibio-tarsal, posterior tibio-tarsal, internal lateral, and external lateral.

The *ligaments of the sternoclavicular joint* are: The anterior sternoclavicular, posterior sternoclavicular, interclavicular, costoclavicular, and interarticular fibrocartilage.

6.

CHEMISTRY AND PUBLIC HEALTH.

1. Antidotes are classified as:—(1) *Chemical antidotes*, which act by uniting chemically with the poison and thus converting it into a harmless or insoluble compound. *Example*: Albumin, in mercurial poisoning; sodium sulphate, in carbolic poisoning.

(2) *Physiological antidotes*, which act by combating one (or more) of the physiological actions of the poison. *Example*: Opium will counteract the dilated pupil caused by belladonna.

The antidote for acute arsenical poisoning is freshly prepared solution of ferric hydroxide. The equation showing the action is:

$$As_2O_3 + 2\,Fe_2(OH)_6 = Fe(OH)_2 + 5\,H_2O + Fe_3(AsO_4)_2$$

5. In *varioloid*: There is premonitory discomfort, noticeably pain in the back; there may be a marked initiatory fever; the rash does not appear till the third day, is shotty, is most marked on the face and wrists; vesicle formation is delayed, the vesicles have a central depression which is well marked: the fever subsides as the eruption appears.

In *chickenpox*: There is little or no premonitory discomfort; fever is slight; the eruption appears in about 24 hours, is not shotty, is scattered generally all over the body; vesicles form in a few hours, and umbilication appears late or not at all, and the vesicles rapidly become scabbed.

MATERIA MEDICA AND THERAPEUTICS.

1.

ORDERS	DRUGS	DOSE
Emetics.	1. Apomorphine hydrochloride.	gr. 1/10 (hypodermically.)
	2. Wine of ipecac.	℥ij—iv.
Hypnotics	1. Chloral hydrate.	gr xxx.
	2. Sulphonal.	gr xxx.
Stimulants	1. Aromatic spirit of ammonia.	ʒj.
	2. Strychnine sulphate	gr. 1/30.
Diuretics.	1. Potassium acetate.	gr xxx
	2. Citrated caffeine.	gr. v.
Diaphoretics	1. Pilocarpine hydrochloride	gr 1/5.
	2. Liquor ammonii acetatis.	ʒiv.

2. Potassium bromide, gr. xv.; strontium iodide, gr. vij; calomel, gr. j; ichthyol, gr x; guaiacol, ♏viij.

3. *Digitalis* is indicated in diseases of the heart, (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in nonvalvular cardiac affections; (4) in

irritable heart, due to nerve exhaustion. Digitalis is contraindicated in diseases of the heart (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong and arterial tension high.

Adrenalin is indicated in hemorrhage from different parts, in purpura and in hemophilia.

Strychnine is indicated in cardiac failure and when a cardiac stimulant is required.

Ergot is indicated in arterial hemorrhage (particularly postpartum hemorrhage), hemoptysis, aneurysms, and it also acts as a cardiac sedative.

4. *For acute bronchitis*:

℞. Vini ipecacuanhæ.....3ij
Liquoris potassii citratis.....3iv
Tincturæ opii camphoratæ.
Syrupi acaciæ.....aa ℥j Misce.
Signa—One tablespoonful three times a day.

For acute articular rheumatism:

℞. Sodii salicylatis.....3ijss
Fluidextracti glycyrrhizæ.
Tincturæ aurantii.....aa 3ijss
Aquæ chloroformi q.s. ad.....℥viij Misce.
Signa: Take two tablespoonfuls every four hours.

For acute nephritis, in a child, aged 12:

℞. Tincturæ jaborandi.....3iv
Sodii benzoatis.....3ii
Aquæ chloroformi q.s. ad.....℥iij Misce
Signa: One teaspoonful three times a day.

For diabetes:

℞. Codeinæ.....gr. xij
Extracti nucis vomicæ.....gr. iij
Extracti rhamni purshianæ.....gr. vj
Misce., et fiat massa in pilulas no. xij dividenda
Signa: Take one, three times a day.

6. "*Serum therapy* proper is the prophylactic and curative treatment of certain infectious diseases by the subcutaneous or intravenous administration of a blood serum containing an antibody which is specific to the particular disease." (Potter's *Materia Medica.*)

Examples: (1) Diphtheria antitoxin; dose, 3,000 units; immunizing dose, 500 units; indicated in diphtheria; (2) antitetanic serum; dose, 3ijss to v; indicated in tetanus; (3) antivenomous serum; dose, 3ijss to viij; indicated in snake bite.

MEDICAL JURISPRUDENCE.

1. The physician should note date and time when he is called; he should (with her consent) examine the female, and if possible also the accused, and note (1) marks of violence about the woman's genital organs; (2) wounds, bruises, or other marks of injury on the woman or on the accused; (3) blood stains and seminal stains on the person or clothing of either party; and (4) the presence of any venereal disease on either party.

He should be careful to say nothing, hear everything, and, above all, to avoid saying a rape has or has not been committed. The question of "consent" enters into the subject, and the physician has no means of knowing whether or no this was given.

3. "First of all, the physician should keep his suspicions to himself. In the next place, he should himself test the urine or feces, or both, and govern his treatment and his actions toward the patient and those surrounding the patient by the results of his examination. Should the case terminate fatally, he should at once communicate his suspicions to the prosecuting officer, and require a post-mortem investigation, which should, if at all possible, be conducted in the presence of the chemist who is to conduct the analysis.

"The following portions of the cadaver should be preserved:—The alimentary canal from the cardia to the middle of the rectum, *unopened*, and the contents enclosed by ligatures at the esophagus, duodenum, and lower end of gut; the liver, including the gall-bladder; one kidney; the spleen; a piece of muscular tissue from the leg; the brain, and any urine which may remain in the bladder.

"Any suspected food articles, and any obtainable vomited matter, are to be also preserved. All of these are to be placed in *clean* and *new* glass jars, closed with glass or cork covers or stoppers. Jars with metallic caps should never be used. Tapes or cords should be tied about the jar and cap, to which they should be attached by sealing wax bearing impressions of a seal, in such a manner that access can be had to the interior only after breaking the seals or cutting the tapes or cords. Great care must be exercised that no sealing wax can get into the jars. Each portion should be placed in a jar by itself." (Witthaus' *Essentials of Chemistry and Toxicology.*)

4. The *antidote* for *carbolic acid* is: A soluble sulphate, or alcohol; for *corrosive sublimate*, white of egg in moderate quantity; for *chloral*, there is no chemical antidote; for *arsenic*, freshly prepared ferric hydroxide; for *opium*, dilute solution of potassium permanganate.

MIDWIFERY, AND DISEASES OF WOMEN AND CHILDREN.

3. The following (from Gould and Pyle's *Cyclopedia of Medicine and Surgery*) is a useful classification of the hemorrhages in question:

A. Hemorrhages of Pregnancy: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) apoplexy of the decidua or placenta.

B. Hemorrhages of Labor: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) relaxation of the uterus; (4) laceration of the cervix; (5) rupture or inversion of the uterus.

C. Hemorrhages of the Puerperium: Caused by (1) retained secundines; (2) displaced uterus; (3) displaced thrombi; (4) fibroid tumors; (5) hypertrophied decidua; (6) carcinoma.

4. *The varieties of displacement of the uterus* are: Retroversion, retroflexion, anteversion, anteflexion, lateral version, lateral flexion, descent or prolapse, ascent, and malocation (to front, back, or one side).

The causes of retroflexion are: Distended bladder, retrouterine peritonitis; chronic cystitis; small fibroid in posterior wall of uterus; too long a period in the recumbent position after labor, or too tight bandaging; tight lacing; infection during puerperium; pressure of tumors; inflammations of uterus and its appendages; gonorrhea.

The symptoms of retroflexion are: Bladder disturbances; constipation and painful defecation; dysmenorrhea, or amenorrhea, or hemorrhages from the uterus; leucorrhea; sterility, or frequent abortion.

The operations performed for retroflexion are: Breaking up any adhesions that may be present, and then shortening the round ligaments (Alexander's operation, or some modification of it); suspension of the uterus (hysterorrhaphy, hysteropexy, ventral fixation, abdominal fixation or suspensio uteri); vaginal hysterorrhaphy is also done occasionally.

PHYSIOLOGY.

1. The *nerves which control the heart* are: (1) The pneumogastric nerve, which slows or inhibits the heart beats; (2) the sympathetic nerves, which accelerate or augment the beats; and (3) the intrinsic cardiac ganglia, which enable the heart to continue beating for some time after it is removed from the body.

2. The mechanism of the *secretion of urine by the kidneys* is twofold: (1) By filtration, most, if not all, of the fluid is eliminated, and also inorganic salts; this depends upon blood pressure, and takes place in the glomeruli. (2) By cell activity and selection, in the cells of the convoluted tubules, the urea and principal solids are eliminated.

3. Substances that may be absorbed in the *stomach* are: Water, alcohol, salts, sugars, and dextrins that may have been converted from starch by the ptyalin of the saliva, and proteoses and peptones resulting from peptic digestion of proteids.

In the *small intestine*, sugars, proteoses, peptones, fats, water, and salts are all absorbed.

In the *large intestine*, water, salt, sugars, proteids, and fats are all absorbed.

4. *Cutting the third nerve will produce*: Ptosis of the upper lid, external strabismus, slight prominence of the eyeball, dilatation of the pupil, and loss of the power of accommodation.

5. "The speech areas, four in number and in kind, are in the left hemisphere in righthanded persons and in the right in lefthanded persons. There are two types of aphasia, which is the loss of the power of speech, known as motor and sensory aphasia. The motor speech center lies in the posterior part of the third frontal convolution (Broca's convolution), just in front of the center of the muscles of speech (hypoglossal and facial nerve centers). A lesion of the motor speech center causes motor aphasia, in which there is a loss of the word-forming power, although the tongue is movable and the patient may understand spoken and written language and knows what he wants to say. It is as if memory of the motor combinations essential to produce speech were lost.

"The power of writing is usually lost with motor speech. The probable location of its cortical center is in the posterior two-thirds of the first, and perhaps in the second, temporal convolution. A lesion here causes 'word deafness,' a sensory aphasia in which the memory of the sounds of words is lost so that they are not understood, though hearing may be normal.

"The visual speech center lies in the posterior part of the

angular gyrus in the outskirts of the higher visual or the visuopsychic field. Word-blindness (alexia), or the loss of memory of printed or written language, is caused by a lesion here, though sight itself may be normal.

"Thus the basis of language is a series of memory pictures (1) of the sound of words; (2) of their appearance; (3) of the effort necessary to enunciate them, and (4) to write their symbols. As these memory pictures are connected with each other and with others that make up the concept by subcortical asssociation fibers passing between them, a lesion in any of these association tracts also leads to a defect of speech." (Woolsey, *Applied Surgical Anatomy.*)

SURGERY.

1. Empyema.—*Causes:* Wounds, injuries, pleuropneumonia, direct extension of a suppurative process in the lung, abdomen, or neck. The bacteria will vary with the cause; diplococcus pneumoniæ is the commonest; tubercle bacillus, staphylococcus, streptococcus, colon bacillus may also be present.

Treatment: Aspiration, drainage, irrigation, resection of ribs (Estlander's operation), or resection of chest wall (Schede's operation).

2. *Conditions which necessitate prostatectomy*: Marked enlargement of the prostate gland (when catheterization is painful, difficult, or impossible; when cystitis is imminent, and when the patient is comparatively young).

3. Coxalgia.—There are three stages. The first is the stage of synovitis, prior to the development of pus in the joint. The second is the stage of destruction of cartilage and ligaments, and continues till the development of pus outside the joint. The third is the stage of destruction of the bone.

Symptoms of first stage: Night cries; lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain; swelling; and deformity (either real or apparent).

Symptoms of second stage: Abduction; limping; pain, which is worse at night; apparent lengthening of the limb; abscess; atrophy of thigh muscles; flexion of thigh; effusion into hip joint; and there may be crepitation in the joint.

Symptoms of third stage: Flexion, adduction, and shortening of the limb; the joint may be dislocated or ankylosed, or suppuration may occur.

4. *Sayre's method for fractured clavicle*: "Sayre's dressing consists of two strips of adhesive plaster three and a half inches wide and two yards in length. The first strip is looped around the arm just below the axillary margin and is pinned or sewed with the loop sufficiently open not to constrict the arm. The arm is then drawn downward and backward until the clavicular portion of the pectoralis major muscle is put sufficiently upon the stretch to overcome the action of the sternocleidomastoid muscle, and in this way draws the sternal fragment of the clavicle down to its place. The strip of plaster is then carried completely around the body and pinned or stitched to itself on the back. The second strip is next applied, commencing on the front of the shoulder of the sound side; thence it is carried over the top of the shoulder diagonally across the back, under the elbow, diagonally across the front of the chest to the point of starting, where it is secured by pinning or sewing. A slit is made in this strip to receive the point of the elbow. Before the elbow is secured by the plaster it should be pressed well forward and inward." (Wharton's *Minor Surgery, and Bandaging.*) The action of the dressing is simply to press the shoulder upward and backward.

5. Hip Joint Dislocations.—*Varieties—Backward*: (1) On to the dorsum ilii; (2) on to the sciatic notch. *Forward*: (3) On to the obturator foramen; (4) On to the pubis.

Dorsal dislocation: Head of femur lies on the dorsum ilii, and can be felt in the buttock. The obturator internus is ruptured in most cases. The short rotator muscles are lacerated. The trochanter lies well above Nelaton's line and approximated to the anterior superior iliac spine. The leg is shortened two to three inches. The iliotibial band is relaxed. The leg is flexed, adducted, and inverted. The femur crosses the lower third of the opposite thigh. The toe rests on the opposite instep. A hollow exists in Scarpa's triangle.

Sciatic dislocation: Similar to the above, except in the following:—The obturator internus tendon is intact and lies over the neck of the femur, holding it down in the sciatic notch. Shortening amounts only to one inch or less. The axis of the femur crosses the opposite knee. The great toe rests on the dorsum of the opposite great toe.

Treatment of the backward dislocations: Flex the knee and thigh in position of adduction. Abduct the thigh and evert simultaneously. Bring the leg down straight. "Lift up, bend out, roll out."

Obturator dislocation: The head of the bone lies on the obturator externus in the obturator foramen. The adductor muscles are lacerated. The trochanter is obscured, the iliotibial band is tense. The leg is lengthened, the toes point forward and outward. Flexion, abduction, and rotation outward are well marked. The head of the femur is felt in the perineum. The capsule is torn in its lower part. Pain referred to the distribution of the obturator nerve.

Pubic dislocation: Similar to the above except: The femoral head is felt under Poupart's ligament. The leg is shortened about one inch. Abduction and eversion are more marked, the toes pointing outward.

Treatment of forward dislocations: Thigh is flexed in a position of abduction. Adduct the thigh and then invert it. Bring the thigh down straight. "Lift up, bend in, roll in." (From Groves' *Synopsis of Surgery.*)

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION
Alabama*	W. H. Sanders, Montgomery	Montgomery July 13
Arizona*	Ancil Martin, Phoenix	Phoenix July 5
Arkansas*	F. T. Murphy, Brinkley	Little Rock July 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco Aug 3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver July 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven July 13
Delaware	J. H. Wilson, Dover	Dover June 15
Dist. of Col'bia	Geo. C. Ober, Washington	Washington July 13
Florida*	J. D. Fernandez, Jacksonville	Tallahassee May 19
Georgia	E. R. Anthony, Griffin	Atlanta Oct. 12
Idaho*	W. F. Howard, Pocatello	Boise Oct. —
Illinois	J. A. Egan, Springfield	East St. Louis May 11
Indiana	W. T. Gott, Crawfordsville	Indianapolis May 25
Iowa	Louis A. Thomas, Des Moines	Des Moines June 1 Iowa City June 8
Kansas	D. P. Cook, Clay Center	Kansas City June 10
Kentucky	J. N. McCormick, Bowling Green	Louisville
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans May 20
Maine	Wm. J. Maybury, Saco	Augusta July 1
Maryland	J. McP. Scott, Hagerstown	Baltimore June 15
Massachusetts*	E. B. Harvey, State House, Boston	Boston May 11
Michigan	B. D. Harison, 205 Whitney	Detroit May 24

W. Virginia	H. A. Barbee, Point Pleasant	Charleston July 13
Wisconsin	J. V. Stevens, Jefferson	Madison July 13
Wyoming	S. B. Miller, Laramie	Laramie June 23

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Michigan.—According to the *Journal of the Michigan State Medical Society*, the Michigan Board of Medical Examiners has notified the several medical colleges upon its recognized list, that in future it will require a demonstration of an applicant's fitness to do practical refractive work, in addition to the usual written paper upon diseases of the eye, ear, nose, and throat. The examination on this subject will be conducted by a specialist, and will constitute an integral part of the examination, and failure to obtain 50 per cent. of possible standing will subject the applicant to refusal of license.

Alabama.—Last year examination by the county boards was abolished, and State board examinations were made compulsory. It is interesting to note that the failures under the former were less than 10 per cent of those who applied; whereas under the one State board there are over 60 per cent. of failures.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ATEMKUREN. Von Dr. Med. HENRY HUGHES. 8vo; 58 pages, paper. Curt Kabitzsch, Würtzburg, Germany.

FORMULAIRE DE CONSULTATIONS MÉDICALES ET CHIRURGICALES. Par LEMOINE & GÉRARD. 12mo, 916 pages, leather; 7 francs. Vigot Frères, Paris, France.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending May 1, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	590	181
Diphtheria	337	56
Measles	1,389	37
Scarlet Fever	326	11
Smallpox		
Varicella	191	
Typhoid Fever	19	11
Whooping Cough	62	13
Cerebrospinal Meningitis	3	6
Malarial Fever		
Totals	2,917	315

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending April 30, 1909:

SMALLPOX—UNITED STATES

		CASES.	DEATHS.
Alabama, Dallas County	Feb. 20–Apr. 12	12	
Salma	Feb. 28–Apr. 12	26	
California, San Francisco	Apr. 3–10	1	
District of Columbia, Washington	Apr. 10–17	2	
Georgia, Macon	Apr. 11–18	4	
Illinois, Danville	Apr. 4–18	13	
Galesburg	Apr. 10–17	2	
Springfield	Apr. 2–16	6	
Indiana, Fort Wayne	Apr. 6–17	2	
Indianapolis	Apr. 11–18	1	
Lafayette	Apr. 12–19	1	
Iowa, Davenport	Apr. 11–18	1	
Kansas, Kansas City	Apr. 10–17	15	
Wichita	Apr. 3–10	2	
Kentucky, Newport	Mar. 30–Apr. 10	14	
Louisiana, New Orleans	Apr. 3–17	7	4 imported
Massachusetts, Taunton	1 case erroneously reported by local health officer, January 9.		
Michigan, Saginaw	Apr. 3–10	6	
Minnesota, Duluth	Apr. 8–15	3	
Minneapolis	Mar. 27–Apr. 10	6	
Missouri, St. Louis	Apr. 3–17	3	
Montana, Butte	Mar. 23–30	1	
	Apr. 6–13	1	imported
New Jersey, Camden	Apr. 10–17	4	
Haddonfield	Mar. 26–27	2	
Plainfield	Apr. 3–10	2	
Ohio, Ashtabula	Apr. 10–17	3	
Cincinnati	Apr. 9–16	7	
Cleveland	Apr. 9–16	1	
Tennessee, Knoxville	Apr. 10–17	2	
Nashville	Apr. 10–17	2	
Texas, Galveston	Apr. 2–16	6	
San Antonio	Apr. 10–17	5	
Washington, Spokane	Mar. 27–Apr. 10	6	
Wisconsin, Appleton	Apr. 12–19	1	
La Crosse	Apr. 10–17	3

NEWER CONCEPTIONS OF CARDIAC ARRHYTHMIAS AND THEIR TREATMENT.

By THOMAS E. SATTERTHWAITE, M.D.,
NEW YORK

UNTIL quite recently physicians have relied mainly on the radial pulse, as felt by the finger, to contradistinguish the various forms of arrhythmias.

But the newer instruments of precision have been enlarging our field of vision, the sphygmograph, the polygraph, and to some extent the *x*-ray, enabling us not only to locate with a gradually increasing degree of certainty the sources of these irregularities, but also to classify them on a more scientific basis.

To understand, however, the present aspect of these matters, some of the work that has been done on the heart by physiologists and anatomists during the last twenty-seven years must be reviewed.

The first important move was made by Gaskell, who in 1882[1] demonstrated that the heart muscle has five separate physiological activities or functions. His propositions have now been accepted by physiologists generally. These functions are as follows:

1. Rhythmicity, *i. e.* the faculty of rhythmically initiating a stimulus.
2. Irritability or excitability, the faculty of receiving a stimulus.
3. Contractility, or the power of responding to a stimulus.
4. Conductivity, or the power of conveying a stimulus.
5. Tonicity, or the power of maintaining the tone of the heart.

It is on these postulates that the present classifications of cardiac arrhythmias is based.

Clinically speaking, however, the physiological or pathological disturbances of these functions are not always clearly distinguishable, for one reason, because they may occur together and then are not always or easily separable. In the matter of excitability and tonicity, too, we have as yet no criteria for determining abnormalities of function. And yet very often there can be seen a predominating disturbance of function sufficient to distinguish each form clinically from its fellows; while there is reason to believe from the progress that has recently been made, that far greater accuracy is going to be attained, and before very long.

Already we have learned enough from sphygmographic and polygraphic tracings, studied in conjunction with other objective and some subjective signs, to enable us to classify clinically at least five different forms of arrhythmias.

But before taking up this subject it is necessary to realize that there are two theories to explain the heart's action, the neurogenic and the myogenic. Let us examine some of the aspects of the former.

That the heart of many vertebrates acts rhythmically after removal from the body is certain. Now, following the known fact that the sinus,* auricle, and ventricle contract in serial order one after the other, it came to be assumed, very naturally, by the adherents of the neurogenic theory that the sinus was first stimulated into contraction by the intracardial nerves, then the auricle, and lastly the ventricle; so that there was a regular peristalsis of the heart chambers, like the peristalsis recognized in the group of muscles concerned in swallowing. The inhibitory and accelerator influences were also naturally relegated to the intracardial nervous system. So, too, it was assumed that the cardiac nerves arising in the central nervous system might have a positive as well as negative influence on the intracardial system; that is, that they might regulate the speed of the heart, making it fast or slow, according to the needs of the moment. This theory would then accord with known physiological laws, and there would be two systems of nerves controlling the activities of the heart. From this point of view the heart muscle would be a passive instrument on which the nervous system played.

According to the myogenic theory, on the other hand, there is an autochthonous origin of the cardiac contractions. The muscle cells originate the movement and conduct it onward. And this theory is based on such facts as these, viz.: that rhythmic contractions occur in portions of the cardiac muscle, such as the apex of the heart, which do not contain a single ganglion cell. Another fact is that, in some vertebrates, the embryonic heart beats before the development of the cardiac nerves has taken place; and this is in harmony with the known fact that the cilia of cells operate independently of nervous influences.

On physiological grounds, therefore, there is excellent reason to conclude that contractions may arise independently of nerve influences in the heart muscle cells.

Now this automatic action belongs to the entire heart, though it is best seen about the sinus, perhaps in the muscle cells of the venæ cavæ, or of the coronary veins, from which it proceeds downward to the auricle and then to the ventricle. And yet it is possible, under artificial stimulus, to make the wave of contraction pass in any direction. That the conduction can be accomplished by the nerves in an opposite direction to their usual course is difficult to conceive. Besides, if only a very small bridge of muscle connects two bundles of the heart muscle, and the muscle is cut zig-zag, the contraction will still take place; all of which facts support the evidence that muscle can conduct the impulse. In fact, this function of the muscle is necessary to support the theory of "extra-systoles" which will be considered

*In using the word sinus, it will include not only the sinus, but the mouths of the coronary and great veins or parts immediately adjacent.

in this article. In this connection it may be said that when the stimulating substance has stored up enough muscular energy to cause a contraction, a "muscular explosion," as it is called, occurs at systole. It abolishes the excitability and contractility, but it destroys at the same time the stimulating energy itself.

New energy is therefore necessary, and it is rapidly regenerated at that particular spot in the heart to the point of effective strength, sufficient to give the predominant rate of contraction for the whole heart. This rate is known as the "spontaneous rhythm." And yet artificial stimulation of other parts of the heart wall may cause artificial waves of contraction to start from these centers, throwing out of action, temporarily, the regular spontaneous rhythm. And such an artificial wave will give rise to what are now known as "extra-systoles," to be described at greater length further on.

But now that these influences are recognizable, the relation of the nerves to stimulus production comes into less prominence. That they do act on the heart is certain, however. For example, the attention of the mind to a task quickens the pulse. The most rapid form of pulse I ever saw was in a case of Graves disease, where the nervous system was profoundly involved. That there is also an arrhythmia due to the penumogastric is proved by the fact that when, in such cases, a small dose of atropine (gr. 1/60), which paralyzes the nerve, is given, the arrhythmia will be stopped. This point will be referred to again.

So that all these evidences of the influence of the nerves on the heart must be recognized equally well with the power of the muscle fibers, among the influences that govern cardiac action.

Before proceeding further along these lines it is necessary to call attention to some of the newer anatomical facts relating to the heart. In the first place, at an early stage in embryonic life the heart is a tube at whose posterior end—the *sinus venosus*—the veins of the body unite. Out of this tube pouches develop which eventually become the auricles and ventricles, the original tube still remaining to connect them. Eventually, from this sinus the ends of the inferior and superior venæ cavæ are formed, a portion of the right auricle and the coronary sinus. At the same time, the primitive cardiac tube gets to be transformed from a tube into a connecting band (the auricular-ventricular bundle, His' bundle, or Gaskell's bridge), uniting the auricles and ventricles.

*All the tracings except Fig. 4 were taken by Dr. T. B. Barringer, Jr., who also furnished the descriptions.

Now, after the primitive cardiac tube, as a pump, has been replaced by the auricles and ventricles, the origin of the normal or physiological heart-beat remains at or about this sinus; though as a matter of fact the impulse may start from other parts of the heart, provided the stimulation is greater in degree than at the sinus, as has been said.

Further, it has been shown, experimentally, that after separating sinus from auricle, and auricle from ventricle, that though stimulation will cause auricular and ventricular contractions, they will be independent of one another. Now for the newer anatomical discoveries. The remains of the sinus were discovered recently by Keith and Flack at the mouths of the venæ cavæ, though previously Keith,* Stanley, Kent, and His had found the rudiments of the primitive tube (eventually the bundle) spreading over the auricle into the ventricle. The bundle arises from a node (Tawara's node) situated in the right auricular wall near the mouth of the coronary sinus.

Tawara, in Jena, and also Keith and Flack of London,[2] were able to trace the bundle of His from the anterior edge of the coronary vein to the auricular-ventricular septum, where it pierces the septum, there dividing into two branches, to be distributed to either side of the septum, from which they extend down to the lower third of the ventricular cavities, where they divide into numerous branches.

Fig. 1.*—Pneumogastric, Sinus or Fundamental Arrhythmia—Polygraphic tracings taken March 27, 1909, at Bellevue Hospital, from a uremic patient with Cheyne-Stokes respiration, in the service of Prof. W. Gilman Thompson. During the apneic period shown in the upper respiratory tracing, the radial pulse became more regular and frequent. In the respiratory phase following the apneic period the pulse at first was less frequent and quite irregular, but gradually assumed its former speed and regularity. This arrhythmia is characterized by a lengthening of the diastolic interval. It is an example of the respiratory type of arrhythmia, and is caused by pneumogastric influence. It can be inhibited by atropine.

Now Keith is one of the majority who hold that the origin of the heart's action is to be referred to the sinus, where it sets the pace of the heart's rhythm, the impulse passing to the auricle and ventricle, and then to the bulbus cordis (corresponding in the adult mammalian to the infundibulum of the right ventricle).

In this connection it may be said that Koch* holds to the view that the heart's action originates in the mouths of the coronary veins. He studied this matter from the pathological and anatomical points of view. Erlanger and Blackman believe it originates either in the mouths of the coronary veins or in the mouths of the venæ cavæ.

(1) The first irregularity to be considered is a variation from the normal, to be called here *Pneumogastric arrhythmia*, but known to some as *Fundamental* or *Sinus* irregularity, on the theory that the normal or spontaneous rhythm starts at the sinus.

It is a variation in rhythm within normal bounds. There is in this form of arrhythmia a varying length of the cardiac cycle, mainly in the diastolic interval, while the pulse beats are of equal or nearly

*In 1903.

equal size, without "imperfect systoles" or "missed beats." With the quickening of the pulse-rate the shortening of the cardiac cycle is almost entirely at the expense of the diastolic interval. The length of the diastolic interval, therefore, is the chief characteristic of this kind of irregularity. It is seen in the "Pulsus Paradoxus" of Kussmaul, caused by a deep inspiration or swallowing. It is not uncommon in young people, when it assumes the so-called juvenile type. It may also occur in adult life, though as a matter of fact there are apt to be trifling irregularities even in health. From this it is evident that the pneumogastric plays a prominent in part in the causation of this form of varying rhythmicity. Thus in the reflex stimulation of the pneumogastric, where the patient has swallowed something, the heart is quickened for some beats and then slows up. The same effect is produced by hurried breathing. This variation of normal regularity is easily recognized. Even the finger feels that the pulse varies with inspiration, but the beats are tolerably equal in length.

Premature contractions of auricle and ventricle or node occur in response to a stimulus from some part of the heart other than the sinus, but where otherwise the sinus or fundamental rhythm is still maintained. This (2) *extra-systolic arrhythmia* is easily recognizable in a polygram as a "premature or dwarf beat" in the radial pulse, followed immediately by an abnormally long pause (Fig. 2). If, as happens occasionally, it is preceded and followed by a beat of normal length, the extra-systole is then said to be "interpolated." The extra-systole appears at irregular or regular intervals. But the wave may be so weak that it is not recognized by the finger on the radial, though shown in the sphygmogram. It may be appreciable in the apex beat as well (Fig. 2). In such instances the ventricle has contracted to the extent of producing an extra-systole, but without sufficient force to convey the wave to the radial.

Examples of this form of arrhythmia are seen in the "deficient" or "intermittent" pulse of the older classifications. The irregularities are best differen-

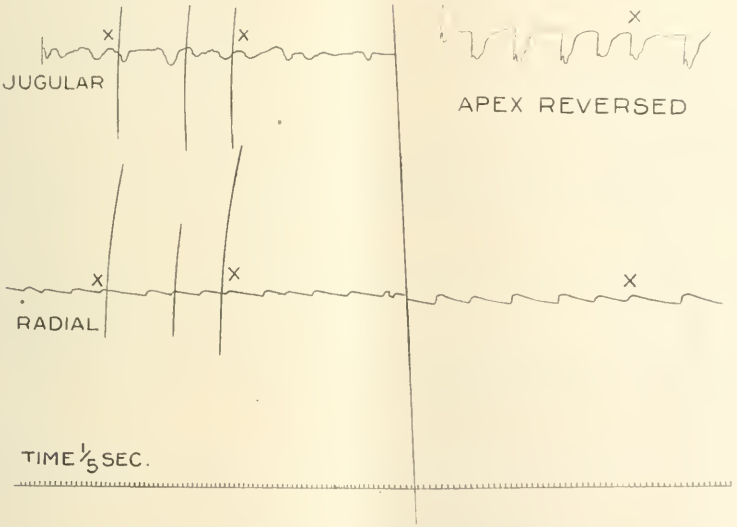

FIG. 2.—Extra-Systolic Arrhythmia of the Ventricular Type—Polygraphic tracings taken from a patient with mitral stenosis, tricuspid regurgitation and auricular paralysis. At three points in the radial pulse (XXX) the irregular cardiac rhythm is interrupted by extra-systoles. Inasmuch as the duration of the pulse period preceding and that following the extra-systole is equal to two normal pulse periods, the extra-systole originates probably in the ventricle. The apex-beat gives a reverse tracing, because formed by the right ventricle

In the polygraphic tracings it is seen that the auricular and ventricular waves have their natural relation in point of time.*

In Fig. 1 the temporary apnoea is associated with Cheyne-Stokes respiration. Medicinally, it is said to have been caused by an overdose of digitalis; it is also said to be found in neurasthenia and in brain diseases; follows febrile attacks and occurs in tuberculosis and in the paroxysmal form of the frequent pulse. No great importance is to be necessarily attached to this condition of mere sinus irregularity, because it is simply a variation in rhythmicity within normal bounds and functional in character, depending on a temporarily disturbed condition of the heart; or upon an underlying systemic affection; or temporary disturbance of the functions of the nerves.

*The illustrations of this article were drawn from the originals, or tracings of them, by the Central Bureau of Engraving, New York City, and then reduced in size.

tiated by a polygram giving the simultaneous tracings of the radial and jugular, or radial and apex beat. The extra-systole, however, is, as a rule, easily recognizable in auscultation. The regular sequence of events is interrupted by two short, sharp sounds (if very faint, only one sound may be heard) followed by a long pause.

The explanation according to MacKenzie is this: The extra-systole is produced by a stimulus starting in the remains of the primitive cardiac tissue in the auricle, ventricle, or the auricular-ventricular node (Tawara's) independently of the sinus or fundamental rhythm which starts in the sinus.

So far as the *ventricular extra-systole* (Fig. 2) is concerned, it is assumed that the origin of the stimulus arising in a ventricle is in the auriculo-ventricular bundle on the distal side of the auriculo-ventricular node.

In the *auricular extra-systole* (Fig. 3) MacKenzie

thinks the stimulus arises in the primitive tissue incorporated in the auricle, the exact site of which has not been determined. It is important to know that it is only by a polygram that the auricular can be differentiated from the ventricular extra-systole.

In some cases the extra-systoles may originate in the bundle of His, as a result of sclerotic changes in those branches of the coronary that supply the auriculo-ventricular node and bundle, causing secondary changes in their substance and increased excitability of this tissue.

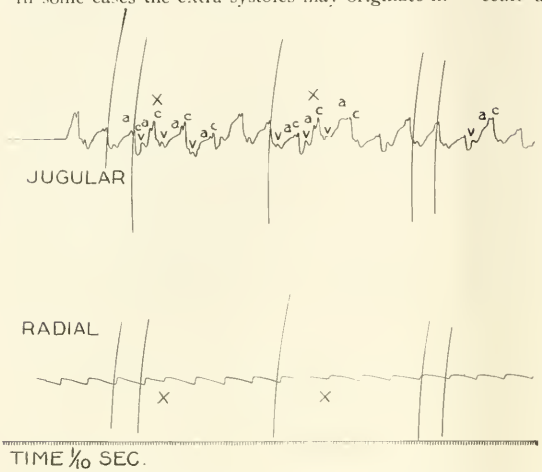

Fig. 3.—Extra-Systolic Arrhythmia of the Auricular Type—This polygram represents an extra-systole originating in an auricle. In the jugular tracings the extra-systoles are shown at X X. The a (auricular) waves represent the contractions of the right auricle. The extra-systoles are shown also in the radial tracing at X X. The compensatory pauses in the radial tracing are seen to be shorter than with ventricular extra-systoles.

The bigeminal pulse can be produced by extra-systoles. But it is not uncommon for several extra-systoles to appear in succession, as the result of abnormal stimulation, and with a certain regularity; the *trigeminal* and *quadrigeminal* pulses may be thus caused.

As a matter of fact, extra-systoles occur at all ages and under the most varying conditions, both in health and disease.

The coffee and tobacco heart and reflex conditions due to gastrointestinal disorders are common examples of extra-systolic arrhythmias. In high temperatures extra-systoles are held to indicate severe toxemia; in convalescence a weak heart; in pneumonia or rheumatic fever they suggest cardiac complications.

Extra-systoles occur more frequently when the heart is beating quickly, and yet the regular automatic action of the heart is not permanently disturbed by the ordinary extra-systoles proceeding from either auricles or ventricles. Practically, most cases of irregular pulse appear to be instances of extra-systoles.

As the well-defined extra-systole is followed by a long pause, it appears to afford a compensation to the heart for the extra work it has done, giving it an opportunity for rest. Marey has therefore called it the *compensatory pause*. Engelmann explains its production as follows: In consequence of the extra-systole, the ventricle is still in the refractory* stage when the next physiological stimulus reaches it; this stimulus therefore has no effect. Thus the normal systole that would follow the extra-systole is missed. But the normal systole that comes after the compensatory pause (post-compensatory systole) occurs at or about the moment at which it would have occurred had no extra-systole preceded it. Thus the extra-systole does not really disturb the general rhythm of the heart. And so, if two or more physiological beats are missed experimentally under an electric stimulus, the heart-beats still continue to be rhythmic when the artificial stimulus is supplanted by the normal.

The subjective symptoms of extra-systole are (1) the feel of the extra thud in the chest and neck, or (2) the impression that the heart actually stops during the compensatory pause; (3) patients often, too, become giddy for a moment. Some patients notice a quick fluttering in the chest when an extra-systole occurs. Then in the long pause "it feels" as if the heart had stopped. To intensify the extra-systole, let the patient run around the room, then take a deep breath and hold it. Occasionally patients are not conscious of the cardiac irregularity. But if one counts the pulse in such cases it is well to remember that if the irregular beats occur without eventually losing their natural rhythm, they are almost certainly instances of extra-systoles.

The most important function, however, of cardiac tissue is *contractility*. It can be influenced in various ways, as by poisons, and by the nerves. It may be disturbed independently of other functions, and can be induced positively as well as negatively, *i. e.* increased or diminished. It is not a common form of arrhythmia, however.

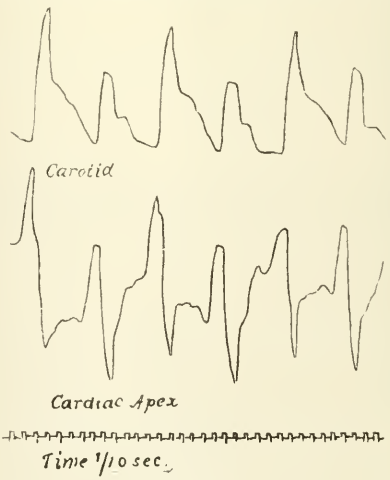

Fig. 4.—The Alternating Pulse—From a woman aged 33, with mitral stenosis, aortic regurgitation and failing compensation. Systolic blood pressure 220 mm. Hg.; diastolic 160 mm. Hg. By Stanton instrument with 12 cm. cuff. By courtesy of Dr. George Bachmann, Resident Physiologist of the Jefferson College Hospital, Philadelphia.

(3) Clinically, the "pulsus alternans" is an example of disturbed *contractility*. This alternating

*Marey discovered that the heart has a refractory stage or phase, when it cannot be excited, except by a very strong stimulus. This refractory phase begins just before the systole and continues for a short time after it.

pulse consists of the alternation of large and small beats. The astonishing regularity of its appearance should indicate to the physician that he is dealing with a case of alternating pulse rather than of extrasystole. Hurried movements around the room makes the alternation more evident. They differ from extra-systoles in that the pulsus alternans show a continuous alternation.

A variety of disturbed contractility has been described by MacKenzie under the name of *nodal arrhythmia* (Fig. 5) on the theory that the disturbance originates in the auriculo-ventricular node. This he proposes as a working hypothesis. To others it is known as the *permanently irregular pulse*, but inasmuch as this form of arrhythmia occasionally disappears, the latter term is inapplicable. Here the auricles and ventricles contract simultaneously (MacKenzie) or the ventricular precedes the auricular perhaps by only 1/10 of a second.

According to MacKenzie it is present in most cases of heart failure, and in a great many the immediate cardiac break-down is directly attributable

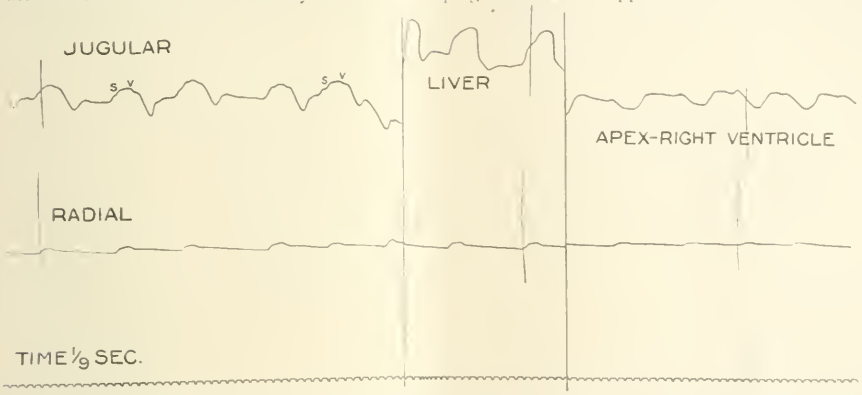

FIG. 5.—Absolutely Irregular (Nodal) Arrhythmia—This polygram was taken from a patient with a double mitral lesion, followed by a tricuspid regurgitation and auricular paralysis. In this case the absence of auricular waves in the jugular and apex tracings, the absolute irregularity in the radial and apex tracings, characterize this form of arrhythmia. The letter s indicates Bachmann's s wave, Hewlett's p wave, or MacKenzie's a wave.

to the inception by the heart of this abnormal rhythm.

The rhythm is invariably irregular. It may be slight, or pronounced, as in delirium cordis. Keith has found it chiefly among those who have cardiac sclerosis, by which he means rheumatic deposits in the heart. These hearts, according to him, show deposits of salts near the auriculo-ventricular bundle. These, he thinks, produces the early difficulty; the later is produced by secondary changes in these areas.

According to the law that the contraction starts at the most irritable part, this particular point is the one selected; or it may be due to distention of the auricle. Now as in these cases the ventricular systole is contemporaneous with or precedes the auricular by only, perhaps, 1/10 of a second, the normal order of events is reversed, so that there is a drain on the reserve force of the heart. And yet if the heart muscle is fairly sound, the organ may be able to cope with this difficulty successfully, for a while at least; but in proportion as the myocardium degenerates, or if the arrhymnia is complicated by the frequent pulse and dilatation, the outlook is bad.

MacKenzie from an experience of 600 cases distinguishes three classes.

1. Where the rate is not markedly increased.
2. Where the rate is greatly increased.
3. Where the nodal rhythm is transient and recurrent.

Where the rate is not markedly increased, patients may live for years, even up to the age of 70.

Where the rate is greatly increased, the patient usually has a sensation which he describes as something fluttering inside the left chest, but it is not palpitation. Also there is breathlessness, increasing up to dyspnea, edema of extremities, general dropsy, cyanosis and fullness of veins with pulsation. Acute dilatation of heart with pulsating liver are other signs. There may or may not be recovery. The young are apt to recover; the old less readily.

Where the condition is transient and the pulse beat is 200 or over, or where it is normal in rate or less, there may be recovery or the condition may become chronic.

MacKenzie finds that in the paroxysmal attacks patients may be relieved by a few deep breaths, slapping the chest, or applications of cold water to the chest, but he thinks that drugs in any case have little value and claims that digitalis has no effect. This is a rather pessimistic view, however.

In a case of MacKenzie's, one of mitral stenosis, which he thinks furnishes the best example of the permanently irregular arrhythmia, he found the tricuspid incompetent, inferior venæ cavæ much dilated, the sino-auricular node normal, but the auricular wall below it atrophied and fibrotic; tænia terminalis hypertrophied; His bundle stretched and Tawara's node flattened. Two-thirds of the left ventricle was fibrotic.

In *affections of conductivity* (5) the stimulus for contraction starts in the sinus, passes through the auricle, and then over the auriculo-ventricular bridge of primitive tissue to the ventricle. But this bridge may be so affected that the stimulus is delayed; it may not cross at all; or it may be blocked beyond the auriculo-ventricular node.

This constitutes the cause of the several varieties of "heart-block."* To recognize it clinically apart from the tracings, note the slow radial pulse, or a slow ventricular rate, while the veins in the neck pulsate more frequently, owing to the normal rate of the auricular contractions being retained.

*The name given by Gaskell in 1882 to this condition. *Journal of Physiology*, 1882, Vol. IV, p. 121

For example, if the pulse at the wrist is 34, each beat may correspond to 2, 3, or 4, auricular contractions. In health the conductivity as represented by the time occupied between auricular contractions and the carotid pulse (a-c) occupies 1/5 of a second; less, of course, however, in frequent action of the heart. But while this 1/5 of a second a-c interval may be considered normal, considerable lengthening of it may take place without much interference with the cardiac rhythm. But even in conductivity depressed to 2/5 of a second, the heart may beat regularly for years.

Depression of conductivity can be shown experimentally in the lower animals by passing a ligature between the auricle and ventricule (Gaskell) when the ventricle can be made to beat with the auricle; to respond to every second contraction, third, or fourth, etc.; or remain quiescent.

In complete heart block, the ventricle pursues one rhythm and the auricle another (see Fig. 6). There is, however, a very close relation between the permanently irregular pulse and heart block.

For nodal rhythm may be due to degeneration or irritation of the auriculo-ventricular node, though in a few cases it may be caused by a break between the sinus and the auriculo-ventricular node, on account of the atrophy of the auricle from long-continued distention. So that the causes of nodal rhythm and heart-block are closely allied. In fact, one may develop into the other. But pneumogastric stimulation may also cause heart-block.

The muscular bridge is sometimes crippled by syphilis, fibrosis, neoplasms, etc., but the cause may lie in changes in the base of the brain, and especially pressure on the nucleus of the pneumogastric.

Symptoms of heart-block are irregularity and slow ventricular rhythm. In some cases there is a sense of weakness, in others exertion brings on dyspnea. Sir W. T. Gairdner is said to have suffered from heart-block—but lived to 82. The syncopal attacks are due either to cerebral anemia induced by the slow actions or temporary stoppage of the ventricles. Most of them, in my experience, have been of an apoplectiform nature. A man will have a pulse of 70, and then an attack will lower it to 30, or even 20. According to MacKenzie the stimulus will once in a while go through, then the rate will be 70, perhaps then the stimulus failing, the blood will not reach the brain and the result will be a fainting attack. This would be a case of partial heart-block. Patients with this mild form of heart-block may live 10 to 20 years. When the patient is liable to syncopal attacks, his term of life is uncertain, and he is apt to die suddenly in an attack. One of my patients with partial heart-block has lived more than eight years, but he has had no syncopal attack during this time.

And yet we occasionally hear of cases where after repeated attacks of syncope and long continued slow pulse, the conducting power is restored, and the rate becomes normal. Such cases should encourage us. The cause may be in the pneumogastric, and 1/60 grain of a atropine may cause it to disappear.

Errors in conductivity are easily made out by polygrams, or they may be determined by the inharmonious action of the radial or apex and jugular.

Of this form of arrhythmia, due to loss of or defective conductivity, there are three varieties.

1. Partial heart-block, where there is incomplete dissociation, the impulse being occasionally carried through.

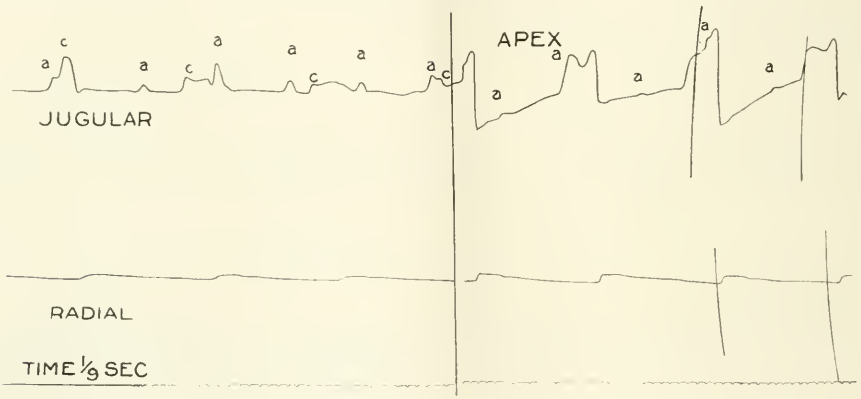

Fig. 6.—Adams-Stokes' Syndrome with Complete Auriculo-Ventricular Dissociation (Heart-Block)—This patient suffered from attacks of syncope and vertigo due to entire loss of auricular-ventricular conductivity. In the jugular tracing the waves marked a represent auricular contractions, and those marked c the carotid pulse. There are 64 auricular contractions per minute, and 38 ventricular. The auricular rhythm, as shown in the jugular and apex tracings, bears no relation to the ventricular rhythm, so that the case is one of complete heart-block.

2. The complete form, where the auricular contraction bears no relation to the ventricular contraction.

3. The Adams-Stokes syndrome, where dissociation is combined with syncopal attacks (Fig. 6).

I have refrained from discussing abnormalities of excitation and tonicity because, as already said, we possess as yet no clinical criteria for recognizing them. Over-excitability has, however, much to do with the production of extra-systoles, and can intensify nodal rhythm; and the lack of tonicity produces dilatation.

So far as treatment is concerned, we are taught by these recent studies that better methods of diagnosis lead up to better methods of treatment.

In the matter of (1) disturbed rhythmicity, in the first type discussed, we see that there are certain normal variations that do not merit treatment; that functional disturbances should be traced back to their cause, and the underlying conditions treated; while the disturbance may be brought about by over-dosing with digitalis or its congeners, where the line of treatment is apparent.

(2) Extra-systolic arrhythmias may also have a functional cause, as when due to reflexes from the gastrointestinal tract, as in indicanuria; also in the coffee and tobacco heart, when the therapeutic indications are plain. When due to high blood pressure plenty of out-door exercise is indicated (MacKenzie).

(3) In errors of contractility and in nodal rhythm the ataxic conditions being due to myocardial diseases, adherent pericardium, dosing by digitalis, asphyxia, etc., the therapeutic indications are for a very intelligent dosage with heart stimulants, or vasomotor drugs; carefully regulated diet, perhaps baths, exercises, etc.; while in loss of conductivity as well as in nodal rhythm, the possibility of syphilis must ever be kept in mind, and the importance of treatment by mercurials.

Patients with mild arrhythmias, whether young or old, should not be unnecessarily alarmed; young people especially; but older people should be forewarned. As a rule baths have a soothing effect on arrhythmia.

In conclusion, however, I must add that while the polygraph has enabled us to make more exact diagnoses, we should not altogether pin our faith on polygrams without careful study, remembering always that to be truthful representations of actual conditions, they must be taken by an experienced hand.

But polygrams are so necessary in the diagnosis of arrhythmias, that no well-equipped hospital should be without a good polygraphic instrument. Polygrams should be taken of every arrhythmic case, as far as practicable, certainly whenever there is a venous pulse. Up to the present time we are lacking in a good portable instrument. It is to be hoped that one will soon be devised.

THE CAUSE OF TREMBLES AND MILK-SICKNESS.*

By E. L. MOSELEY,

SANDUSKY, OHIO.

Trembles and milksickness are due to aluminum phosphate. In Ohio and Illinois animals get this substance by eating white snakeroot, in New Mexico by eating the rayless goldenrod.

The proof, briefly stated, is as follows: "Aluminum, although, like silica, everywhere present in the soil, is only in exceptional instances taken up by plants," Strasburger. We have found considerable quantities of aluminum phosphate in the leaves of white snakeroot, *Eupatorium ageratoides*, and the stems of the rayless goldenrod, *Isocoma heterophylla*. Aluminum phosphate placed in the usual food of rabbits from day to day produces the same effects as feeding either of these weeds. The effects of feeding white snakeroot to various animals are identical with the symptoms of "trembles." Not only is their behavior affected in the same way, but the macroscopic and microscopic alteration of the organs are the same. Aluminum was found in the milk each day after a cow began eating the white snakeroot and this milk produced trembles in cats and rabbits. Aluminum was found in the urine, kidneys, liver, and muscles of rabbits fed with white snakeroot and the meat of such rabbits, whether raw or cooked, produced trembles in cats.

In the northern states, wherever trembles prevails, the white snakeroot grows abundantly. We know of a number of cases of trembles following the eating of this weed by animals in the woods, and we believe that in every case of trembles investigation carefully made would show that they had eaten it. On the other hand, they may eat small amounts without serious effects. The weed grows in many places where trembles is unknown, but in these places better-tasting plants are so much more abundant that white snakeroot forms but an insignificant part of their food. Commonly in these places the white snakeroot shows no signs of browsing. Millions of animals in the northern states are pastured where white snakeroot does not grow. We do not know of a single case of trembles ever occurring among them.

The Bureau of Plant Industry of the U. S. Department of Agriculture failed to obtain such results in their experiments with white snakeroot because they used aqueous extracts and aluminum phosphate is not soluble in water, though readily soluble in dilute acid, like that of the stomach. The only experiment in which they actually fed the weed is described in two lines, in their bulletin of sixteen pages, "The Supposed Relationship of White Snakeroot to Milksickness or Trembles," as follows: "A lamb weighing about 25 kilos, when fed 58 grams of the fresh plant, showed merely some diarrheal symptoms." This quantity would probably not kill a full-grown rabbit, although a much smaller weight of dry leaves will do so.

Inasmuch as the value of our earlier experiments described in the *Ohio Naturalist* for February and March, 1906, has been questioned by the Bureau of Plant Industry, before giving an account of our later ones, I wish to present as evidence that aluminum is the cause of trembles and milksickness some statements whose correctness in no way depends upon our experiments upon animals. This evidence may be verified without the trouble of experimentation by any physician familiar with the disease or who will take the trouble to look up the symptoms described by Professors Edwin O. Jordan and N. M. Harris, of the University of Chicago, in their paper, "The Cause of Milksickness or Trembles," published in the *Journal of the American Medical Association*, May 23, 1908, and compare them with the general action of aluminum, as given in Cushny's "Pharmacology," third edition, page 701. The latter is based upon experiments by Paul Siem in Germany, described in a pamphlet entitled "Ueber die Wirkung des Aluminiums und des Berylliums auf den thierischen Organismus." In order to make the comparison more satisfactory, I quote in full what Cushny says on the subject: "Aluminum has a very remarkable general action when it obtains access to the blood. In Siem's experiments on animals the sodium-aluminum lactate or tartrate induced a very slow intoxication, mammals never dying from the effects sooner than one or two weeks after the intravenous injection of the salts. In frogs the symptoms were those of a descending paralysis of the central nervous system, the heart and the peripheral nerves and muscles being little affected. In mammals the first symptoms appeared only after three to five days [this was where the poison was injected daily in small doses] and consisted in constipation,

*Read before the Erie County (Ohio) Medical Society, March, 1909.

rapid loss of weight, weakness, torpor, and vomiting; marked abnormalities in movement and sensation were observed later, such as tremor, jerking movements, clonic convulsions, paresis of the hind legs, anesthesia of the mouth and throat, and lessened sensation all over the body. Before death, diarrhea often set in, and albuminuria was generally present. The mucous membrane of the stomach and bowel was found swollen and congested, the kidney and liver had often undergone fatty degeneration, and hemorrhages were found in the renal cortex. Aluminum was found in the urine.

"Like the other members of the heavy metal series, aluminum therefore acts on the bowel and kidney in general poisoning, while many of the symptoms point to a direct action on the brain. Dollken has recently confirmed Siem's results, and showed that the nerve cells and fibers of the cord and medulla undergo degeneration, particularly those of the lower cranial nerves."

Now, these effects of the injection of aluminum, remarkable as they are, are the same as the effects of milksickness and trembles. The "constipation, weakness, torpor and vomiting" are familiar to all who have seen persons or carnivorous animals affected with the disease. The "tremor, clonic convulsions, and paresis of the hind legs" are striking features of the "trembles" in animals. As to "loss of weight," Mr. Louis Quinn, who has lost more than a thousand dollars' worth of stock from trembles, says: "The hide of a cow that has been sick for two weeks with trembles will not weigh within forty per cent. of a normal cowhide." Concerning anesthesia, he says: "Salt placed on the nostrils of a cow calls forth no response." "Cattle in which trembles proves fatal live on an average hardly a week after they are first seen to be affected, but the time differs considerably; a few live about two weeks." Sheep live less than four days after the disease is first noticed. Siem's experiments were with cats, dogs, and rabbits.

For our knowledge of the pathological anatomy and histology in "trembles" we are indebted to the article by Jordan and Harris, referred to above. Not only did they find all the lesions which Cushny mentions on Siem's authority, but many others which are mentioned in Siem's pamphlet on the action of aluminum.

Feeding Eupatorium Ageratoides.—Our experiments have been made in the fall and winter, with plants that grew in the vicinity of Sandusky, Ohio, in 1905 and 1908, and in 1906 in the case of one rabbit. We found the weed effective each of these years. Much of our material was gathered after hard frosts. The greater prevalence of trembles in dry seasons is probably due to the animals being harder pressed for food. In the fall, however, after transpiration has been going on all summer, the leaves should contain more aluminum phosphate than earlier in the season, and this, together with the fact that the white snakeroot remains green after most plants have withered accounts for the greater prevalence of trembles late in the year.

Plants from seven woods representing a variety of soils, have been used in our experiments, all proving effective. In 1908, we fed quite a number of rabbits with white snakeroot for the express purpose of testing the relative strength of the plants growing in different soils. We had thought that plants from woods which were deemed quite safe as pasture might fail to produce serious effects, but our experiments did not accord with this supposition. Plants from woods where trembles have often originated seemed most effective, but the difference was not great and may have been due merely to individual differences in the rabbits that were fed.

Although season and locality make little difference, at least so far as shown by our experiments, the part of the plant used makes a great difference. A rabbit when fed with thirty grams of stems appeared not half so much affected as another of the same size after it had eaten about four grams of leaves. Another rabbit fed with fifty grams of stems, in the course of about six days, showed less effect than five grams of leaves produce in any rabbit. After a few days this rabbit was fed fifty grams more of stems with slight effect. We conclude that the leaves are more than ten times as effective as the stems. They contain more than ten times the quantity of aluminum phosphate.

Effect of Milk.—One of the most remarkable characteristics of "trembles" and milksickness is the readiness with which animals convey the malady to their offspring by the milk, the mother oftentimes showing but little effect. Before we had discovered the inertness of the stems we fed fifty grams of stems and leaves of Eupatorium in the course of four days to a rabbit with four unweened young, resulting in weakness, trembling, stupor, and dullness of eyes in all of them, the mother being affected first and quite as strongly as any of them. Respirations were greatly accelerated, at one time 175 and at another about 200 a minute in the mother.

A cow affected with tuberculosis was fed with leaves of Eupatorium gathered December 6, ten ounces a day from Monday to Thursday, and 20 ounces on Friday. She showed no effect except such as might easily have escaped notice. Monday she drank 28 lbs. of water, Tuesday, 40 lbs., Wednesday, 48 lbs., Thursday, 60 lbs., Friday, 43 lbs. and Saturday, 49 lbs. On Wednesday, a cow of about the same size, in the same barn, but not fed any Eupatorium, drank 30 lbs. The respirations were usually 26 to 28 per minute, but Friday, when double the usual amount of the weed was fed, 34. Possibly this was due to her having some exercise that day, although some hours before the respirations were counted. Her temperature ranged from 101.3° to 103.4°. On Thursday, she seemed nervous and we noticed quivering of the muscles along the jugular furrow. We looked for the same movement in other cows, but could not see it. Friday, we saw a twitching of a thigh muscle. Her eyes showed some effect, the sclerotic being congested. There was no constipation or diarrhea or loss of appetite. Besides the bran and middlings with which the Eupatorium leaves were mixed, she had plenty of clover hay.

Although this cow was given only 60 ounces of the weed altogether, and showed no serious effects herself, the milk had a decided effect on the animals to which it was given. The quantity of milk at first was 5 pints a day, rich in cream, but later less than 4 pints. Two cats and several rabbits were supplied with it. One of the cats had been the subject of previous experiments but had recovered. Within 12 hours the milk caused prominent trembling again. Another cat not previously experimented on, was kept with the first, but did not drink so much of the milk. It was not affected, or at least not strongly affected, so soon, but after two or three days the effect on the first cat diminished and on the second

increased so that when held up all four of her feet trembled rapidly. She showed stiffness of the hind legs when walking and inability to climb upon a horizontal board. Her eyes were reddened and there was some vomiting. Both the cats seemed stupid and tired.

Most of the rabbits to which milk was given were those which had recovered from the effects of previous experiments. The milk set them trembling again. The urine contained a large amount of albumin. One fresh rabbit, weighing 1,800 grams, was given milk drawn 3 days after the cow had eaten the last of the Eupatorium. Nearly a quart was consumed in about 3 days, causing a slight backward and forward motion of the body, quivering of the loins, trembling of the legs when the animal was held up by the ears, respirations somewhat accelerated, diminished activity, eyes not so wide open as normally, and 75 grams loss in weight. The urine contained granular casts and a little albumin, indicating nephritis. Two days after the milk had been consumed the animal showed improvement and gained day by day.

A small amount of butter was made from the milk and given to three rabbits, producing so far as it went the same effects as the milk.

Five samples of milk drawn on as many days after the cow began eating the Eupatorium were burned in platinum dishes and the ashes found to contain aluminum.

Effect of Meat.—Another characteristic of "trembles" is that the meat of animals which have died of it, whether "raw or boiled," will cause trembles in animals that eat it. The author of Bulletin No. 121, of the Bureau of Plant Industry, after quoting this from Graff, says, "but there is evidently some mistake, as he states on page 361, that 'I boiled a large quantity of the beef in pure water for several hours, and afterwards evaporated the liquid thus obtained to the consistence of cream. Although this extract contained a large quantity of gelatinous matter, with some of the other constituents of the flesh, yet, on being given in large quantities, no perceptible effect was produced.'" The mistake was on the part of the writer of the bulletin in concluding that if an aqueous extract of boiled meat could do no harm, neither could the boiled meat itself. We have steeped the leaves of white snakeroot in hot water for hours, but after passing the extract through filter paper could find no aluminum in it. The leached leaves, dried and fed to a rabbit, produced the same effect as leaves from which nothing had been extracted, but leaves treated with dilute hydrochloric acid and then washed and dried had no effect.

The young rabbits which were poisoned by their mother's milk did not die from that cause, but when they were recovering were accidentally killed by a dog several days after their mother had eaten the last of the white snakeroot. They were kept cold until the next day when two of them were cooked and fed to a large and vigorous tom cat, causing trembling of various parts, vomiting, dullness, and slight increase in respirations. A week after the cooked meat was fed he had recovered from the effects and was fed with the raw meat of a rabbit that had died after being fed Eupatorium, the same symptoms being reproduced but with greater intensity and no vomiting noticed. There was some constipation and the eyes were dull. He would not jump upon a box where his food was placed, as he had been accustomed to do, and when allowed to grasp a projecting board with his forefeet, he seemed unable to climb upon it or to do so more than once or twice.

In 1905 we produced trembles in several cats, and the death of one of them by feeding them the raw meat of rabbits which had died after eating Eupatorium, also trembles in cats and a dog by giving them meat from a lamb which had died of trembles after being fed this weed. (See *Ohio Naturalist*, March, 1906.) We attribute the smaller effect of the cooked meat used in the experiment not to the fact that it was cooked but that the animals from which it was taken had not received with their food enough aluminum phosphate to kill them.

Effect of White Snakeroot on Rabbits.—The symptoms described for the milk, together with thirst, are those which follow feeding the weed itself to rabbits, but if the feeding is continued they become more serious. In some rabbits the respirations continue more rapid than normal until the day of death, when they are slow. In other rabbits, after a few days of acceleration, they continue slow for many days. One recovered after its respirations had become as low as 32 a minute, although for three days in the earlier part of the experiment they were 92 to 102. A little exercise makes the animal pant longer than a normal rabbit, and even when at rest the breathing is irregular. The characteristic back and forth motion of the body, when the animal is at rest is not synchronous with the breathing. Exercise increases the trembling. After they have become strongly affected sensation is much reduced. They can be handled with little remonstrance. In some of them touching the hind leg, when the animal is held up, causes quivering. If the hind leg is pushed into a different position, the animal is likely to leave it in that position.

Progressive loss of weight has been so generally noticed in rabbits under the influence of Eupatorium that where the balance has failed to show it we have attributed the apparent exception to the retention of more material in the bladder and the alimentary canal, a condition shown not only by post mortem examination, but by bulging of the abdomen and diminution of the amount of feces and urine passed. The same explanation probably applies to cats when they have increased in weight. The appetite in rabbits continues good during the greater part of the experiment, but loss of flesh may be noticed by feeling of the back.

Effect of the Rayless Goldenrod on a Rabbit.—In December we received from Professor E. O. Wooton, of the New Mexico Agricultural College, about three ounces of stems with a few leaves of the Rayless goldenrod, *Isocoma heterophylla*. This is the plant which the ranchmen claim causes "trembles" among their cattle. We analyzed a sample of ash from the stems of this and one from the leaves of Eupatorium and a third from timothy hay at the same time, using the same method and reagents from the same bottles. In the timothy we found a trace of aluminum phosphate, too small to weigh, but perhaps one or two per cent. as much as in each of the others. From ten grams of Isocoma stems we obtained .007 gram of aluminum phosphate and from ten grams of Eupatorium leaves .0047 gram. Later we discovered that aluminum phosphate after being strongly heated is difficult to dissolve with hydrochloric acid, so instead of reducing the leaves to ashes we made an extract with dilute hydrochloric acid and destroyed the organic matter in this extract with potassium chlorate. In this way

we obtained much more aluminum phosphate than before from the Eupatorium leaves.

About forty grams of the Isocoma were fed in the course of eleven days to a vigorous rabbit weighing 5 lbs., 4 oz., in the same room where three rabbits were being fed with Eupatorium and two with aluminum phosphate. The effect was the same, but the supply of the weed was exhausted before death was produced. At times the trembling was more pronounced than at any time in any of the other rabbits, perhaps because the animal to start with was the largest and strongest among them. The respirations before and after the experiment were between 70 and 80 a minute, but during the experiment mostly between 80 and 104. He showed no thirst. His abdomen became enlarged and on the eighth day he weighed eleven ounces more than at the beginning of the experiment, no feces or urine having been observed for quite a while. The next day he had lost seven ounces and the following day twelve ounces more, so that he then weighed half a pound less than at the beginning of the experiment.

Effects of Feeding Aluminum Phosphate.—The phosphate used in our experiments was freshly prepared by adding a solution of disodic hydric phosphate to a solution of aluminum chloride and washing the precipitate on the filter paper. This was kept moist and given to rabbits in bread, middlings, oatmeal, or milk. The effects were so similar to those produced by feeding the leaves of *Eupatorium ageratoides* that it is difficult to be sure of any differences. The same trembling, torpor, loss of weight, and other effects already described for rabbits poisoned with Eupatorium were observed in those which received aluminum phosphate in place of Eupatorium. There seemed to be less thirst and more enlargement of the abdomen produced by constipation. Other salts in the Eupatorium doubtless increase the thirst and may prevent constipation.

Post mortem examinations showed no differences. The same parts were strongly injected, the same parts moderately injected; the same odor of acetone, the same condition of heart, liver, kidneys, bladder, and the rest. The urine contained albumin and granular casts. Microscopic examination showed the same tissues affected and in the same way, so that the description of the pathological histology of rabbits that died after eating Eupatorium applies also to those that died after eating food in which aluminum phosphate was placed. Aluminum was found in the liver and urine, the only parts examined for it. A cat fed with meat, without the viscera, of a small rabbit which had died after taking a little aluminum phosphate each day for twenty-three days, showed trembling, increased respiration, reddened eyes, and constipation.

Four rabbits of the same litter, eight weeks old, were fed in the same room, two with Eupatorium leaves, 2½ grams a day for the pair, the other two with aluminum phosphate, about .007 gram a day for the pair. All were well supplied with good food. On the thirteenth day of the experiment one of each pair died. The other one of the two fed the Eupatorium died two days earlier, and the other one taking aluminum phosphate twelve days later. This and other experiments indicate that the animal fed with Eupatorium leaves is more likely to die within a few days than one which receives a small amount of aluminum phosphate with its daily food. Other salts in the Eupatorium may tend to produce diarrhea and thus lessen the strength of the animal.

Aluminum chloride was tried on three rabbits and produced in two of them some of the effects of aluminum phosphate, but seemed considerably less potent than the same quantity when changed to a phosphate.

Some of the animals developed a taste for aluminum phosphate so that they would take first that part of the food in which it was placed. When the feeding was stopped and the animal given time to recover from its effects, it could endure more than an inexperienced rabbit. Those that had recovered from the effects of taking Eupatorium, or milk from the cow that had eaten it, were able to endure more aluminum phosphate than fresh rabbits. We think that, in whatever form it is given, the animal recovering from its effects can endure more of it the next time, whether given in the same or a different form. This might not be true after a long interval. Some of the young animals that survived the experiments made upon them were stunted in growth.

The quantity of aluminum phosphate in the milk drawn two days after the cow was first given any Eupatorium was found to be about .07 gram per liter. While our experiments in feeding the milk and the artificially prepared phosphate were not made in such a way as to admit of exact quantitative comparisons we are safe in saying that the quantity of aluminum phosphate required to produce the same effect as the milk is not a great deal more or less than the quantity which the milk contained. In one gram of leaves we found about .003 gram of aluminum phosphate and our experiments show that one gram of leaves is more effective than .002 gram, but less effective than .005 gram, of artificially prepared aluminum phosphate.

Other Metals in White Snakeroot.—Most of our analyses of the ashes of *Eupatorium ageratoides* were of weeds gathered November 1 in the eastern part of Sandusky County, Ohio, where the soil is calcareous and where trembles is more prevalent than in any other place we know of. They were dried like hay. Of the dry leaves the ash forms 7 or 8 per cent., of the stems, about 4 per cent. The quantity of potassium was not determined; calcium oxide, 1.8 per cent. of leaves, 0.9 per cent. of stems; magnesium oxide, 1 per cent. of leaves, 0.2 or 0.3 per cent. of stems; ferric oxide, less than 0.1 per cent. of the leaves. These with the aluminum were the only metals found in the hydrochloric-acid solution. Iron phosphate occurring in considerable quantity and the general action of iron when injected into the blood being similar to that of aluminum, some experiments were made in feeding iron phosphate prepared in the manner described for aluminum phosphate. A rabbit that had been taking .003 gram daily of the latter was given in addition .003 gram daily of the former and the symptoms already observed seemed to be increased, but experiments with fresh rabbits failed to show much, if any, effect of the iron. One taking daily .003 gram of each showed much less effect than another of the same litter, taking daily .006 gram of aluminum phosphate. A third taking daily .006 gram of iron phosphate remained very active and apparently well, although the breathing was rapid and a tremulous motion was noticed in the muscles of the jaw. The milk of the cow fed with Eupatorium contained about the usual amount of iron.

As magnesium compounds constitute something like a third of the ash, we thought at first that these might be responsible for the effects of the weed. Considerable time was spent in determining the quantity of magnesia in the milk of different

days, but it was found to be little, if any, above the amount in good milk. Rabbits fed with magnesium nitrate representing the quantity of magnesia occurring in poisonous doses of the weed showed no effect.

It is therefore improbable that any of the inorganic constituents of *Eupatorium ageratoides* other than aluminum are absorbed into the blood in sufficient quantity to produce any noticeable general action. Their presence, however, is not without significance. They give the weed an unpleasant taste, so that animals having good pasture will not eat much of it. They doubtless produce thirst and probably produce diarrhea in many animals. The percentage of magnesium compounds may be higher in weeds growing in the region where our samples were collected than in many other regions. The cattle there when affected with trembles have diarrhea in "eight cases out of ten." The sheep, however, are constipated. People having milksickness are constipated, but they have not eaten the weed itself. Cattle in New Mexico are said to be constipated as a rule. In the rayless goldenrod stems received from New Mexico we found about one-sixth as much magnesia as in the leaves of Eupatorium.

Pathological Anatomy.—The behavior of animals of different species naturally presents some points of difference under the influence of drugs as it does when they are normal, but in the effect of aluminum on the organs of dogs, cats, and rabbits, Siem found so much in common that one description would do for all. Our autopsies have been mainly with rabbits. In them death is preceded by irregular breathing and in some at least by kicking and struggling. The cat died very quietly. The rabbit dies with muscles contracted, head drawn back and neck shortened, legs straightened, the hind legs extended back, the fore legs out and a little forward. In a rabbit examined half an hour after death, an auricle was still beating.

On opening the cavities there is in some, at least, an odor of acetone. The peritoneal cavity in rabbits usually contains but little free liquid, but in one which was chloroformed after several days' feeding of Eupatorium we found about half an ounce of straw-colored liquid. In the lamb which died in four days after it began eating Eupatorium leaves, the peritoneal cavity contained several ounces of liquid. In a cat, which was fed the meat of rabbits that died from the effects of Eupatorium, December 14 to 19, but survived until January 2, the peritoneal cavity contained two ounces or more of a perfectly clear amber-colored liquid of a slightly acid reaction In rabbits, litmus paper pressed against the moist peritoneum turns blue. In some of the rabbits the pleural cavity contained a little liquid, but liquid in the pericardial cavity was more common and noticeable. It was light straw colored and alkaline.

The bladder is more or less distended, the stomach and cecum full of food, and sometimes the colon contains gas. The small intestine contains no food or contains it only in a small part of its length.

The following parts show injection: Meninges, heart muscle, diaphragm, small intestine (ileum less than duodenum), the cecum slightly, the stomach, and usually the bladder. The colon is scarcely, if at all, injected.

The right auricle and ventricle are distended with blood, the left auricle contains some blood but always less than the right; the left ventricle in some cases is empty, in others it contains some blood but always much less than the right.

The inside of the stomach does not usually show conspicuous lesions, but minute extravasations in some parts of the mucous membrane. The small intestine shows marked injection inside and outside. It contains considerable yellowish mucus.

The liver is dark colored and commonly somewhat enlarged, the weight ranging from less than 4 to more than 6 per cent. of the weight of the body. The gall-bladder is filled with bile.

The kidneys on section show congestion and in some of the animals there are minute hemorrhages in the cortex. Generally they are enlarged, averaging in small rabbits rather more than 1.3 per cent. of the body weight, while those of a small normal rabbit weighed .8 per cent. of the body weight.

In the lamb the kidneys weighed 50.3 grams, or about double the normal for an animal of its size. Microscopic examination showed congestion and granular changes in the cells.

In most of the rabbits the urine contained albumin and granular casts, but in some, both were absent. Jordan and Harris apparently did not have opportunity to make careful examination of the urine, but Dr. B. F. Ward, assistant state veterinarian of Illinois, wrote me that horses affected with trembles appeared to have nephritis.

Pathological Histology.—The organs of three rabbits that died from eating Eupatorium were put in formalin and sent to Dr. Walter H. Rieger, pathologist of the Charity Hospital, Cleveland, for microscopic examination. His report follows:

"Brain: The only pathological condition found in the cerebrum and cerebellum was a congestion of all the capillaries. In the brain substance there was no discernible change.

"Lungs: Acute passive congestion; few blood cells out in the air spaces.

"Heart: No change; muscle somewhat congested, otherwise negative.

"Stomach and Intestines: Acute passive congestion; no other change.

"Liver and Kidneys: I will describe these together, as they show similar changes. A marked congestion of all the blood-vessels and the condition of 'cloudy swelling' in both the liver and kidney cells; this means that the cells have undergone a slight granular degeneration. The nuclei in these cells do not take the stain as well as they should, owing to this condition within the cell. Hence, the liver and kidneys suffer more than any other organ."

After sending Dr. Rieger the organs reported on above and those of a rabbit that had been poisoned with artificially prepared aluminum phosphate, I asked him if I should send unlabeled the organs of the next animal that died and let him decide whether it had been poisoned by eating the weed or by the phosphate inserted in good food. He replied, "I think it would be a pretty difficult task, as from my examinations I can see no marked differences." The next animal died from the effects of artificially prepared phosphate and the organs were sent unlabeled. Dr. Rieger was unable to tell in which way it had been poisoned.

I am indebted to many persons for assistance in ascertaining the facts presented in this paper. The help of four of my former pupils has been highly appreciated; Dr. Walter H. Rieger, now pathologist of Charity Hospital, Cleveland, is entirely responsible for the pathological histology; Dr. Fred Schoepfle, of Sandusky, has examined the urine for

albumin and casts, and August Guenther, Ph.D., now professor of physiology in the University of Nebraska, and Dr. Henry Schoepfle, of Sandusky, as well as the two doctors first mentioned, have assisted in autopsies and in other ways. I am also indebted to a number of other physicians and veterinarians of Erie County, Ohio, and quite as much to a number of my pupils who are not yet doctors.

125 Vine Street.

X-RAY DIAGNOSIS.*

By HOMER E. SMITH, M.D.,

Norwich, N. Y.

It shall be my endeavor in this paper to place before you the exact status of present-day Roentgen diagnosis, to outline its possibilities and to define its limitations. It should be clearly understood in the beginning that Roentgenology is a specialty of medicine and as such demands that the operator shall be a clinician of the first rank; the mere possession of the apparatus no more makes him an expert than would a kit of tools make him a mechanic. Outside of a thorough knowledge of medicine, as a whole, he must possess an exact acquaintance with the structural relations of the human body, not only the anatomy of the text-books, but what may be termed "*x*-ray anatomy." It should never be forgotten that what we are viewing is not the thing itself but its shadow, and as the shadow, say of a coin, would be either a disc, an ellipse or a line, according as it was held in relation to the source of illumination, so also are differing pictures obtained of the same human structures when viewed from different angles. The Roentgenologist must be master also of that branch of electricity which concerns induction and the management of currents of exceeding high voltage. He must know something of the physics of matter in its radiant state. He must be expert in the handling of his photographic material, and last, but not least, when he has obtained a perfect plate he must know what the shadows upon it mean. The latter is by far the most difficult part of all this highly technical work and can be learned only by experience. Roentgenography is only twelve years old, but it has made great advances in the last few years, mainly due to improvements in apparatus, technique and to the better interpretations of the plate brought about by comparisons, microscopical, pathological and post-mortem. The man behind the gun counts for very much, but he should not go after the Royal Bengal tiger with a pop-gun. If one is to do efficient *x*-ray work he must deliver into his tube a voltage rarely in excess of 300,000, but it must carry as large an amperage as the tube will stand. This means that it will take from ten to twenty kilowatts in the primary of the induction coil to do the fastest and the best radiography.

There are technical reasons why long exposures produce misleading and blurred pictures, and in just those cases where the *x*-ray is most valuable speed is an absolute essential to correct diagnosis. For abdominal and thoracic work plates can have no longer an exposure than the time wherein the patient can hold his breath; therefore if the apparatus be inefficient and incidentally the operator (for the personal equation is an important factor in this work), the results can only be disappointing or misleading. Good chest plates can be taken in a second; moving pictures of the heart in action have been secured and this means, of course, that exposures must have been made in a small fraction of a second. Plates for *x*-ray work are exceedingly sensitive to ordinary light and are difficult to develop without stain or fogging, and as we are depending on shadows alone it is essential that no extraneous ones are introduced to cloud either the picture or our judgment of it. The total depravity of all inanimate things is most surely shown in the behavior of the *x*-ray tube. A good one is, like a virtuous woman, more to be valued than rubies. What a tube will do under apparently trivial variations of vacuum, inductance, interruptance and current is more than any man can predict, and the greatest skill is required to get and keep it in tune with the generator.

I have touched briefly upon the technical side of this work because many physicians think that all that is necessary to do efficient *x*-ray work is to get a small static machine, a single tube, connect them up and set them going. One might with as good a show of reason tackle a face presentation with no knowledge of obstetrics, armed only with a pair of dressing forceps. As in other highly technical divisions of science, there is the popular conception and the expert appreciation, so it is of Roentgenology. Even among the medical profession it is considered mainly as a diagnostic agent in disturbed relationships of the osseous framework chiefly because fractures and dislocations make such evident and contrasting radiographic pictures. It is thought of also as standing alone in its positive findings, needing no anamnesis nor any corroboration. Neither of these conceptions are true. Its possibilities cover any pathological condition which alters tissue densities, and its limitations make it subservient to the history of the case, make it often only corroborative and simply an aid to other diagnostic investigations. Let it be borne in mind that Roentgenography is simply a study in relative densities and that superposed structures project their shadows onto one plane. It is true that this obstacle may be largely overcome by stereoradioscopy, but it is the greatest bar to the ready interpretation of the plate. There is no substance which is so dense as to be absolutely opaque to the ray and none of such rarity as to be absolutely transparent. Between these extremes it may be seen that by proper manipulation of current, tube and plate great differences in structure may be brought out and slight differences in density made manifest. Fat, muscle, tendon and ligament all show, as well as the bony structures, on a good plate, but of course the greater the difference in density the greater is the contrast in the shadows.

Taking up in detail *x*-ray diagnoses, let us begin with the easier ones. Metallic foreign bodies are relatively so much denser than the tissues in which they are imbedded that their detection is the simplest matter possible. Their exact location may be determined to the fraction of an inch relative to the surface from which they must be approached. Their removal may be equally easy or so hedged about with difficulties as to render any attempt unadvisable. We have in the *x*-ray a probe which is exact, clean and painless and is sure to succeed even if the most careful search by other methods has proved a failure. In no part of the body is it more important to be sure of the presence or absence of a foreign body than in the eye. All suspected cases should be radiographed and if the foreign body be

*Read at a meeting of the Tioga County (N. Y.) Medical Society.

found an immediate attempt should be made to remove it before a firm exudate has formed around it. To wait until the inflammation subsides in the hope of determining its position by the ophthalmoscope consumes valuable time and menaces the safety not only of the injured eye but its fellow as well. It is possible that the foreign body has gone completely through the eye. The radiogram will tell you if this be the case and then no surgical intervention is necessary unless, of course, the eye has been hopelessly disorganized. It is an axiom in ophthalmology that a foreign body in the eye, sooner or later, gives rise to sympathetic inflammation in the other and that the foreign body or the eye containing it must be removed. The technique of localization is exceedingly simple and its findings absolutely accurate. Two pictures are taken from different angles with two known factors, the distance of the tube from the plate and the position of the indicator. Where the latter touches the skin is marked by a cross. By taking a tracing from the two negatives, substituting for the lines of light two fine cords, their upper ends occupying the place of the tube in its first and second position, their lower ends placed on the two shadows of the foreign body, it is evident that the cords must cross at the point where, relative to the indicator, the foreign body rests. All that remains is to measure from indicator to this crossing. We now know in what direction and how deep it lies. If we decide to go after it we cut down directly upon it without dissection and make our wound no larger and no deeper than through which the foreign body may be made to emerge.

Diseases of the bones always present alterations in their radiographic appearances. Taking the picture is easy. Its interpretation is often difficult, but there is always alteration of structure and consequently of density. When the periosteum is irritated or inflamed a good radiogram will present various phases of alteration which throw light not only on the kind of irritation, but the time which it has been active. Diseases of the bone substance show marked changes. Osteomyelitis gives a mottled appearance; carcinoma, areas of rarefaction. Sarcomas are of two kinds: the giant-celled showing erosion of bone and cartilage, the spindle-celled, fusiform dilatation of the shaft of the bone with less transition of light and shade. Tuberculosis shows breaking down of bone substance, separation of periosteum and loss of detail in the cancellous structure. In the diseases of the joints the diagnosis of "rheumatism" is often a cloak behind which much diagnostic incapacity hides itself. This term should be limited to the inflammatory type which is simply the arthritic expression of an acute systemic infection. Applied to the chronic varieties it is just about as accurate a diagnosis as would be "threatened with a fever."

Types of this great class of joint diseases can be readily differentiated and divided into separate clinical entities which, except for the one common factor of joint envolvement, they are. Briefly these may be divided into: (1) Villous Arthritis—This is due largely to strain or trauma and is a proliferation of the synovia or a protrusion into the joint of the periarticular fat. This is often monarticular and almost invariably in the knee joint. There are no constitutional symptoms. (2) Atrophic Arthritis—This is polyarticular, most usually of the wrist and hands, and there is swelling and pain. The individual is badly nourished and the disease progressive. The Röentgenogram shows erosion and loss of cartilage and bone and a diminution in it of the lime salts. (3) Hypertrophic Arthritis or Osteoarthritis—This occurs in well nourished individuals, is often monarticular and insidious in its onset. Here we have thickening of cartilage, overgrowth of bone and increase in the lime salts. (4) The Infectious Arthritides—These may follow gonnorrhea, scarlatina, typhoid fever, pneumonia, influenza, tonsillitis, erysipelas or dysentery. These arthritides show a fibrous hyperplasia around the joints but almost never atrophy or hypertrophy of the articular surfaces proper; (5) Gouty arthritis, this gives a characteristic Röentgen picture in which are shown the tophi and the early loss of tissue in the shaft of the bone; (6) Tuberculous arthritis, this is too often diagnosed as rheumatism. An *x*-ray picture will clear up the diagnosis at once, will show the erosion of the bone and cartilage and the periarticular infiltration. Many a case of so-called lumbago turns out to be an infectious or hypertrophic spondylitis. Fractures and dislocations are the A. B. C. of *x*-ray work, but I am going somewhat into detail because this part of the subject, perhaps may interest you most. To begin with, whenever possible, the *x*-ray should be used in every case of fracture. Some urge its use in complicated cases only, but the difficulty with this plan is that one can never tell whether a fracture is complicated or not until a radiogram is taken. I have seen cases where union seemed perfect and where no deformity or shortening followed, but where function was greatly impaired, owing to a loose splinter of bone in the muscles. The *x*-ray furnishes a more accurate and detailed picture of a fracture than can be obtained in any other way. In some cases the diagnosis of a fracture can be made only after an *x*-ray examination, while in others which simulate fracture it can be shown that none exists. In severe sprains where the parts are much swollen it may be difficult or impossible, without the ray, to determine whether or not a fracture is present. Cases are frequent of Pott's fracture diagnosed as strain, and I had a case where strain of the elbow-joint was diagnosed and the two competent men who made this diagnosis were surprised when the radiogram showed fracture longitudinally of the humerus between the condyles. There is a saying, "A bad sprain is worse than a broken bone." A new light is thrown on this adage by *x*-ray examination, as it often shows a fracture which had gone unrecognized by other methods.

In certain cases it is difficult to determine by ordinary means, whether there is a dislocation or to differentiate it from a fracture. Moreover, these two conditions may be coexistent, and if occurring close together the diagnostic difficulties are multiplied. These problems are easily solved by a Röentgenogram. Time will not permit me to take up particular fractures and dislocations, but in dismissing this phase of the subject I want to impress upon you its value in all cases and particularly in those obscure injuries occurring around and in the wrist joint, the sprains, fractures and chipping off of small fragments which lead to impairment or loss of function. This is a matter of vital importance to those who depend upon their hands as a means of livelihood. Lastly, in this connection, beware of the fractures which result from trivial causes like an arm, for instance, which snaps when throwing a stone; this is suspicious of disease, and not infrequently malignant disease of the bone.

Of the more difficult Röentgen diagnoses, biliary

calculi, perhaps, stands at the head. It requires that the apparatus shall be powerful and the technique faultless, but it can be done. Vesical, ureteral, and renal calculi present less pronounced difficulties. In general, the ease with which calculi may be recognized depend upon their size, location and chemical composition. They are the more readily detected in proportion to the amount of the inorganic salts which they contain. Pure uric-acid calculi are almost as readily permeable by the ray as are the surrounding tissues, and consequently may be seen only with difficulty. Fortunately, pure uric-acid concretions are very rare. Again, calculi can be more readily detected in young or thin subjects, as thickness is one of the obstructions offered to the ray. Notwithstanding all the difficulties they may be overcome by proper apparatus and technique, and the percentage of error, even in gallstone cases, is less than 3 per cent. So much stress has been laid upon the surgical side of Röentgen diagnosis that we are apt to forget that it has a medical side as well.

For the detection of any trouble in the thoracic cavity it exceeds in accuracy any other method, and in some cases it is indispensable. In the prebacillary stage of tuberculosis it offers a ready means of diagnosis when auscultation and percussion give only negative findings. In pleurisy, with or without effusion; in emphysema, hydrothorax, empyema, mediastinal tumors or enlarged glands charactertistic pictures are presented which can hardly be misinterpreted. Certain diseases of the heart which modify its size or position show clearly on the plate, and the differentiation may be surely made between hypertrophy, dilatation, and pericarditis with effusion. Abnormalities in the great blood-vessels, aneurysm, calcification, or tortuosity of the aorta give each its own picture.

Below the diaphragm .r-ray work until recently has been confined to the detection of hepatic, renal, and vesical calculi, but improved methods have made possible the determination of the area of the spleen, the upper border and size of the liver and the position of the left kidney. The form and position of the stomach, possibly growths within it, gastroptosis, enteroptosis, the progress of digestion, and the rate of peristalsis, all may be determined.

The skull itself has been radiographed; the size, position, and healthfulness of the sinuses offer no difficulties, and even tumors and hemorrhages inside the cranial cavity, have been made out and the diagnosis confirmed by operation. I have necessarily been exceedingly brief in this sketchy outline of the possibilities of .r-ray diagnosis, but it is a truthful and fairly accurate statement of the present-day status of what is to me the most wonderful and beautiful thing in medicine.

CEREBRAL HEMORRHAGE FOLLOWING ARTERIOSCLEROTIC GRANULAR NEPHRITIS MISTAKEN FOR CEREBRAL EMBOLISM.*

By BOND STOW, M.D.,
NEW YORK,
PATHOLOGIST TO THE METROPOLITAN HOSPITAL.

THE main purpose in presenting the clinical and autopsy findings of the following case is to demonstrate an error in diagnosis consecutive to a heart lesion of more frequent occurrence than is commonly supposed.

*Read before the Section on Medicine of the New York Academy of Medicine, March 16, 1909.

M. C., widow, 45, English, was admitted to the Metropolitan Hospital, New York City, October 23, 1908, and died therein January 24, 1909.

Family history was negative. Occupation, housework. Drank beer. Use of tobacco, drug habits and venereal history negative. Measles, parotitis, and pertussis in childhood. Health always excellent until two months ago when upon crossing the street she suddenly lost the use of the right arm and leg with complete unconsciousness. She was brought into the hospital in this condition and since then to the day of her death was confined to the bed.

Physical Examination.—Pupils reacted to light and accommodation. Expression was melancholic. No facial paralysis that could be detected. Tongue deviated slightly to the left. With the exception of a few coarse mucous râles at the bases of the lungs there were no abnormal signs in the thorax.

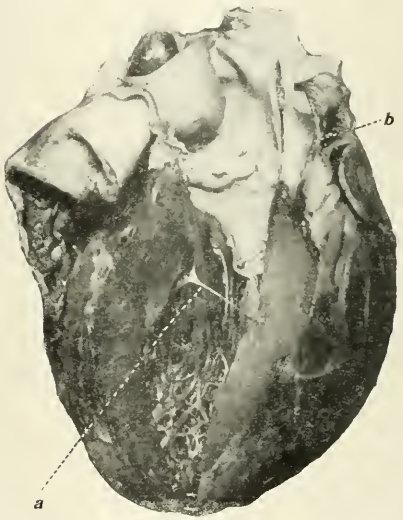

FIG. 1.—The heart, one-half natural size; *a*, An aberrant chorda tendinea, bisecting the left ventricle 5 cm. below the aortic valve; *b*, The normal aortic valve.

Heart.—Apex three fingers in breadth in the sixth interspace. Line of dullness to the right, extended slightly beyond the right sternal line, and to the left, from the third rib to the sixth interspace and two centimeters outside the midclavicular line. Auscultation at the aortic valve gave a loud, double murmur not unpleasant in timbre. This murmur was transmitted into the arteries of the neck. Accentuation of the second pulmonic sound. No thrill upon palpation over precardiac region. The free margin of the liver was felt at the lower border of the ribs. The spleen was not palpable. Paralysis of the right arm with paresis of the right leg. No sensory disturbances. No atrophies. The patellar reflexes were exaggerated, being greater on the right side. Ankle clonus on the right side. Babinsky negative. Very slight edema over the lower half of both tibias.

Bedside Notes.—Incontinence of urine. Constipation. Marked dyspnea and cardiac asthmatic attacks. Patient constantly craved for fresh air. Ap-

petite poor. Slept well up to December 24, when she became very wakeful and disturbed by the increasing asthmatic attacks. Gradually delirium set in with singultus, incoherent speech, and attempts to get out of bed. Constantly complained of pain over the precordial region.

Throughout the pulse was slow (64—68), regular, full, and nonintermittent. Temperature under 98° F. and once recorded as low as 96.4°. Respiration normal.

Uranalysis.—Pale yellow, alkaline, sp. gr. 1,010, large amount, slight traces of albumin, no sugar. Urea 0.011 gm. per c.c. No casts. Bladder epithelium, triple phosphates, calcium oxalate crystals, and large quantities of mucus were present.

Death due to convulsions, January 24, 1909.

Clinical Diagnosis.—Endocarditis of the aortic

FIG. . *A*, Outer surface of the right kidney, capsule removed; *B*, Cut surface of the left kidney (two-thirds natural size).

valve with embolism of the left middle cerebral artery.

Autopsy Record.—Body excessively pale and emaciated. Post-mortem rigor present. Hypostatic congestion of dependent portions of body. Finger tips and face cyanotic. Pupils evenly dilated 3 mm. Eyes slightly divergent. No marks on external surface of body. Slight edema over both tibias.

The circumference of the middle of the right leg was 24 cm.; left, 24½ cm.; right thigh, 31 cm.; left, 31 cm.; right forearm, 15 cm.; left, 18½ cm.; right arm over middle of the biceps, 18 cm.; left, 20 cm.

Abdominal cavity contained about 500 c.c. of a clear transudate. Abdominal organs in normal position. Diaphragm right side at the sixth rib; left, sixth interspace.

Pleuræ normal. Pleural cavities contained small quantity of a pale, clear transudate. Left lung showed passive congestion and chronic bronchitis in both lobes. At the base of the lower lobe was a small hemorrhagic infarct. Right lung showed same as left in middle and lower lobes.

Pericardium was normal. Slight amount of pale, clear transudates in pericardial sac. Heart weighed 625 gm. Endocardium was smooth, glistening, and transparent throughout. All valves were normal. Heart muscle was a light reddish brown color streaked with yellow. Left ventricle 3 cm., right 5 to 6 mm.; left auricle 1 to 4 mm., right 1 to 2 mm. Bisecting the left ventricle at its midplane (see Fig. 1) was an aberrant chorda tendinea 5 cm. below the aortic valve. Where the same was attached to the walls of the ventricle there did not appear to be any evidence of a present or past endocarditis. This chorda tendinea was 1 mm. in thickness and in every respect similar to the other normal chordæ tendineæ.

Liver weight 1,205 gm.; edges sharp, of tough leathery consistency and a dark yellowish brown color. Lobules definable. Spleen dark mahogany brown color. Trabeculæ increased.

The kidneys (see Fig. 2). Left, weight 80 gm. Dark mahogany brown color, very firm in consistency. Capsule thickened and firmly adherent. External surface coarsely granular and studded with miliary cysts. Cortex 2 to 3 mm. thick. Markings entirely effaced. Blood-vessels arteriosclerotic. Pelvis normal. Right kidney weighed 69 gm. and in all other respects was similar to the left. Adrenals normal.

Pancreas, stomach, and intestines normal. The entire vagina, both anterior and posterior walls, showed a chronic ulcerative vaginitis. The uterus and ovaries were normal. Bladder showed chronic cystitis.

Brain.—Dura mater and pia normal. The pial spaces over the frontal lobes were wider than usual and the frontal convolutions appeared slightly atrophic. The blood-vessels at the base of the brain composing the circle of Willis and their cortical branches showed advanced arteriosclerosis and atheroma; there were no abnormal anatomical distribution of the same.

Horizontal section through the central gray ganglion at their midplane in the right hemisphere showed recent hemorrhage in the putamen just bordering upon the external capsule, measuring about 2 cm. in length and 1 cm. in breadth. The anterior limb of the internal capsule was totally destroyed by encephalomalacia. At the knee of the internal capsule was a small recent hemorrhage about 3 mm. x 1 mm. The anterior nucleus of the optic thalamus showed a small hemorrhage about 4 mm. x 1 mm. and there was a small area of softening in the mesial nucleus.

In the left hemisphere at the same midplane of the central ganglion immediately opposite the knee of the internal capsule located in the globus pallidus was a recent hemorrhage averaging about 1 cm. in diameter. Likewise in the putamen another averaging 3 cm. x 1 cm. lying directly against the external capsule. At the lateral nucleus of the optic thalamus and pressing upon the posterior limb of the internal capsule was a recent hemorrhage about ½ cm. in diameter. Balance of the brain appeared normal.

Diagnosis.—Advanced arteriosclerotic nephritis; compensatory hypertrophy and fatty degeneration

of the heart with muscular insufficiency of the mitral valve; aberrant chorda tendinea bisecting the left ventricle; cyanotic induration of spleen and liver; chronic ulcerative vaginitis, chronic cystitis; chronic bronchitis with passive congestion and edema of the lungs; and cerebral hemorrhage and encephalomalacia due to advanced arteriosclerosis with obliterative endarteritis.

I desire to express my thanks to Mr. Brush, the official photographer of the Metropolitan Hospital, for the excellent photographs furnished in this case.

214 West Seventieth Street.

A NOTE ON THE BENEDICT METHOD OF QUANTITATIVE ESTIMATIONS OF SUGAR IN THE URINE.*

By I. R. PELS, M.D.,

BALTIMORE, MD.

Recognizing that a method for the quantitative estimations of glucose in the urine for office use is certainly to be desired, and that such a method should be (*a*) rapid, (*b*) easy of execution, and (*c*) approximately accurate, it was considered worth while calling attention to a procedure which fulfills these requirements, together with some critical remarks on its application. In an admirable paper S. R. Benedict[1] has called attention to a modification of the old Fehling method of both qualitative and quantitative estimation of sugar in the urine, and he has pointed out, in a convincing manner, the advantages of using sodium carbonate instead of sodium hydroxide in the alkaline solution.

This, however, was shown about the same time by Ivar Bang,[2] who used salts in making titrations for estimating the sugar content. The technique of this method need not be entered into here. Bang pointed out that the copper hydroxide in the presence of potassium sulphocyanate, when reduced by glucose, forms a white salt of cuprous sulphocyanate, which, however, is insoluble in an excess of cyanate solution. Benedict showed that by precipitating the white cuprous sulphocyanate the end reaction was sharp and absolute, being especially distinct because, toward the end of the titration the white precipitate makes an excellent contrast with the greenish solution. This will be referred to below.

Rudisch and Celler,[3] also recognizing the convenience of employing an excess of potassium sulphocyanate (in 50 per cent. concentration) to keep the cuprous sulphocyanate in solution, advocate a method of using the original Fehling solutions for titrating to a colorless solution. According to them the method requires one titration only, and is accurate within 0.25 per cent. This also will be discussed below

The method under consideration here is a combination of these two, the technique, however, being simplified. In offering a clinical method for estimating sugar quantities in the urine, to be done in the office, it is certainly sufficient and entirely satisfactory if the results of titration show (*a*) a limit of error of not more than one-half of one per cent. as compared with polariscopic readings, and (*b*) accuracy in the readings of titration to one-twentieth (.05) of a cubic centimeter. These conditions have been easily met in the method here offered. In the majority of titrations the variations from the polariscopic readings have been from 0.20 to 0.25 per cent., or easily within the limitations of the "individual equation."

Discussion of Methods.—The chief disadvantages of the methods most commonly used may be summed up briefly as follows:

1. The Pavy method[4] is unsatisfactory because of the loss of ammonia by boiling during the titration process, and the wide variations in any two given methods, due to reoxidation.

2. The Fermentation Method.—Einhorn or Lohnstein saccharimeters require twenty-four hours to decide results, require controls, and one of them necessitates the use of a thermostat. They are, besides, not uniform.

3. Roberts' method[5] of measuring specific gravity before and after fermentation, though on the whole very satisfactory, also requires twenty-four hours for the determination.

4. The Polariscope.—This is by far the simplest method, but the cost of such an apparatus is prohibitive for office work, and besides the presence of levorotatory substances, such as levulose, β-oxybutyric acid and other less important bodies may invalidate the readings.

5. Ivar Bang's Method.—This is too complicated and besides has the objection, as pointed out by Benedict, of the use of hydroxylamin; also necessitating the employment of three solutions.

6. Fehling's Method.—This requires three or more flasks; too much time is consumed, and especially so in deciding the exact point of the end reaction which, further, is often not definite.

7. Rudisch-Celler Modification of the Fehling Method.—This method has much to recommend it, but the chief objection which can be urged is that unless the reaction is carried out very rapidly there are evidences of reoxidation, thus making the readings inaccurate, and for this reason, in unskilled hands, no two titrations are the same. This reoxidation is readily seen by leaving the solutions which have been decolorized standing, when after a few minutes there appears a definite greenish tinge, which later becomes blue, eventually returning to the original deep blue color.

8. The only objection which can be made to the original Benedict method lies in the so-called "bumping" which occurs when the white salt of cuprous sulphocyanate is precipitated. To obviate this Benedict recommends that absorbent cotton be introduced and stirred about with a glass rod. It has been found, however, that this does not always act satisfactorily, and when some of the solution is lost through bumping the results of titration are obviously erroneous.

Author's Modification.—Apparatus:

One 10 c.c. burette graduated in 1/20 c.c. divisions.
Two 5 c.c. measuring pipettes.
Two Erlenmeyer flasks of 100 c.c. capacity each.
Graduate, Bunsen flame or alcohol lamp, etc.

(Benedict Solutions):

(*a*) Crystallized copper sulphate, 69.30 grams.
Distilled water ad 1,000 c.c.

(*b*) Crystallized Rochelle salt, 346 grams.
Pure anhydrous sodium carbonate, 200 grams.
Distilled water ad 1,000 c.c.

The urine is diluted with an equal amount of water, or dilutions of one to four or to eight may

*From the Clinical Laboratory of the Johns Hopkins Hospital and University.

be used.* Five c.c. of a mixture of equal amounts of copper and of alkaline solutions, *carefully measured,* are run into each flask and approximately 25 c.c. of a 35 per cent. solution of potassium sulphocyanate are added to each flask. Extra amounts of anhydrous sodium carbonate, as recommended by Benedict, are not absolutely essential.

The following uniform technique of titration has been found to be most desirable: The blue solution is brought to a brisk boil which is continued throughout the titration. As soon as boiling begins the sugar solution is added slowly, drop by drop, boiling continuously, until the blue solution turns a lighter color. The nozzle of the burette is now held out of the steam coming from the flask, which is then boiled for *one minute by the watch.* The sugar solution is now added in amounts of one to three drops at a time, and the boiling is continued briskly for *one minute* between additions. The end reaction, which is sharp, is evident when the solution becomes colorless, or takes on a faint golden tinge, this latter ensuring entire disappearance of any greenish color remaining.

The second flask can naturally be titrated more rapidly than the first. The average of two readings should be taken in estimating the quantity of the glucose present, and the estimations are made by considering that 20 c.c. of mixed copper and alkaline solutions are reduced by 0.073 grams of pure glucose.

The Advantages of the Method.—Besides possessing all the advantages of the Rudisch and of the Benedict methods, there is (1) no loss of copper solutions, through bumping. (2) Very little reoxidation, as compared with the Rudisch method, the flasks on standing twenty-four hours showing only a greenish tinge. Bang proved besides that reoxidation during the boiling process is of insignificant amount. (3) Titration readings differing by no more than 0.05 c.c.; certainly the smallest practical limit for a clinical method. (4) Reaction carried out in a flask in such a manner as to make it most simple and easy of manipulation.

Remarks.—The one objection to this method which, however, is applicable to others requiring the use of copper solutions for reduction lies in the fact that if boiling is prolonged too much such bodies as creatinin, creatin, uric acid, phosphates, glycuronic acid, etc. (as pointed out by H. MacLean[6]), if present in sufficient amounts, will effect partial reduction and so invalidate the readings. This is especially marked with the Benedict solutions, as shown by Benedict,[7] in which the reduction to hydroxide is more rapid because of lessened dehydrating properties of the carbonate as compared with the hydroxide. The discussion of this question, however, does not belong here. These reducing bodies do not effect the reaction before three to six minutes of boiling, and normal urines require two to three minutes boiling to effect any reduction.

As MacLean has shown, creatinin, if present in sufficiently large amounts, can mask the presence of a small amount of glucose.

As in most other methods, albumin if present should first be removed from the urine, and chloroform should be avoided as a preservative, carbolic acid being quite satisfactory in this connection.

I am much indebted, especially to Dr. T. R. Boggs, for valuable suggestions, and to Dr. R. S. Morris for courtesies extended in the completion of this work.

*This is merely arbitrary, the calculations thus being more easily made

Modern Ideas on Teaching of Therapeutics and Pharmacodynamics.—M. V. Tyrode, writing on this subject in the *Boston Medical and Surgical Journal* of April 1, 1909, divides the treatment of disease into four classes: (1) Physical, including surgery, hydrotherapeutics, massage, gymnastics, *x*-rays, Finsen rays, and radium; (2) physical, dealing with mental suggestion in the waking, hypnoidal, or hypnotic states; (3) the dietetic, including changes in the character of the diet, and (4) the chemical, or mechanical, which deals with drugs in the old sense of the word and with organ preparations, sera and antitoxins. The course in the latter division should include one in materia medica, chiefly laboratory work, and one in pharmacodynamics—taught by lectures, recitations, and conferences. Besides the practical therapeutics taught in the clinical courses in the various specialties, there should be a general course on therapeutics, taking up the subject from the point of view of diseases, reviewing and comparing different methods in the particular affections. Part of this work could be done didactically and part clinically in hospital wards. There should be electives and post-graduate courses in every department, although the teachers in the different branches might be attached to special divisions, yet there should be a special organization of the men teaching therapeutics in the different branches in order to secure thorough cooperation.

The Influence of Ovarian Secretion on the Mammary Glands.—L. Bouchacourt says that the correlation that exists between the mammary glands and the ovaries is a striking example of the relations between different organs in the body. After a study of these relations he gives these conclusions: It is probable that the mammary development at puberty takes place under the influence of an ovarian secretion. Many facts go to show that these glands secrete a substance unfavorable to the mammary function. These are the insufficiency of the ovaries accompanying hypertrophy of the breasts of pathological nature; the relative repose of the ovaries during pregnancy while the breasts are increasing in size; ovarian removal produces congestion; a natural menopause may produce the same symptoms; pregnancy during lactation has an unfavorable influence on lactation; ovarian castration during lactation increases and prolongs lactation; menstruation during lactation diminishes secretion. Practical results from these facts may be deduced: the nursing woman should be in a condition of sexual repose. Menstruation will indicate that lactation should cease. At the menstrual period the nursing woman should receive special supportive nutrition, and some nursings may be replaced by the bottle. A new pregnancy during lactation should be the signal for a gradual introduction of artificial feeding.—*Le Journal de Médecine de Paris.*

Aseptic Sloughing of Uterine Fibromyomata.—B. Auché and R. Brandes say that the name of true sloughing fibromata should be reserved for tumors that slough under the influence of microbian invasion. The authors have made careful microscopical examinations of five sloughing fibromata removed, to determine the type of degeneration which had taken place, and whether microbes were present. Sections were examined and cultures made from the tumors. They conclude that in the absence of any microbes phenomena of alteration become manifest in the interstitial tissues of fibromyomatous nodules. These result from circulatory changes. These lesions should be distinguished from those produced by microbian invasion. The authors believe that we may sufficiently distinguish these two types of slough by the presence or absence of septic sloughs.—*Journal de Médecine de Bordeaux.*

New York, May 15, 1909.

THE EFFICIENCY OF THE BODY AS A MACHINE.

At this period of the year, when the young men of the country are preparing themselves for athletic contests, when the account of track meets, Marathon races, and crew contests are filling the daily press, and when thousands are in regular systematic preparation for such contests, the subject of the results of training upon the human body and of the reason for the resulting increased ability to carry on its work is of interest. We all know that a trained athlete can work longer and more efficiently than a novice, but the question as to whether this is due to an increase in the size of his muscles or to an improvement of their power per gram weight is a matter still open to discussion.

In this connection a Bulletin recently published by the U. S. Department of Agriculture (Bulletin No. 208 of the office of experimental stations) setting forth the results of a long series of experiments carried on by Dr. Benedict and Mr. Carpenter is of no small interest. The work was done in Wesleyan University with the remarkable "respiration calorimeter," which has contributed so much in the hands of Atwater and Benedict to an increase in our knowledge of metabolism. The method consisted in placing different men in the calorimeter and measuring carefully the heat produced by them during a definite period of time. This was designated "heat produced during rest." Besides this, the subjects at other times, also in the calorimeter, rode for several hours on the bicycle ergometer, an apparatus built on the plan of a bicycle, with an electrical attachment which registered the exact amount of work done. The ergs of energy actually used to run the bicycle were then calculated as calories of heat and recorded as "heat equivalent of work done." At the same time the amount of heat produced by the subject while working was recorded by the respiration calorimeter. This was designated as "heat produced." The difference between the heat produced during one hour of the working period and that recorded during an hour of rest gives the amount of energy expended by the subject in driving the bicycle against resistance. The ratio therefore between the heat equivalent of the work done, as shown by the ergometer, and the difference between the resting and working heat production, or the energy expended, gives the efficiency of the muscular effort or the efficiency of man as a machine.

In their experiments the investigators studied men of various types—a trained college athlete, untrained students not athletic, and a professional bicyclist. The results of these experiments were surprisingly uniform. Though in a definite time the professional rider accomplished more work than the amateur athlete, and the latter more than the untrained student, each increase of work done was accomplished by a corresponding amount of energy expended and the efficiency coefficients of the different men were practically equal—for the athlete 21.5 per cent., for the untrained student from 19.7 to 21.2 per cent., and for the professional from 20.7 to 21.3 per cent.

From these statistics certain things are definitely shown. The human body is a machine of such a degree of efficiency that one-fifth of the energy expended by it can be utilized as work, and that this efficiency is constant in men of all types. The longest and most thorough training does not change this ratio. The professional athlete, if he is able to do more work than the novice, does it not because his muscles are of such a quality that he can get more work out of them for the same amount of energy, but because he is able to put more energy in the shape of tissue change into the action. It would seem then that training, besides preparing the heart to stand greater strain, acts to increase the subject's power of using up his tissues and by giving him more muscle tissue to use rather than by teaching him to conserve his energies. To adopt a metaphor from the mechanical world, the professional has a more powerful engine because he is able to use more fuel, not because he wastes less steam.

FLIES AND MILK CONTAMINATION.

The most striking feature of modern scientific research has been the conclusion generally reached that insects are largely responsible for the spread of destructive epidemic and of some endemic diseases. To the mosquito has been traced the rôle of disseminator of malaria and yellow fever. The rat flea is regarded by many authorities as responsible for the widespread propagation of plague, and sleeping sickness is conveyed to the human subject by means of a fly. This list, of course, does not exhaust the number of insect borne diseases, and indeed it is shrewdly suspected that members of the insect tribe have much to do with the spread of most tropical maladies.

Up to a comparatively recent time the common house fly was looked upon only as a nuisance and no one thought it to be a mischievous agent in the conveyance of certain diseases. But now war is being declared and waged against it, for the reason that it has been proven a prominent factor in the spread of more than one dangerous malady. That typhoid fever is not infrequently carried from place to place by the agency of flies has been demonstrated sufficiently clearly to allow it to be stated as a fact. That flies sowed the germs of typhoid fever broadcast during the Spanish-American war was abundantly proved. This view of the dangerous possi-

bilities of flies was confirmed during the Boer war to the satisfaction of those who made a study of the subject, and now few will be found to deny that typhoid fever is often spread far and wide by these innumerable and persistent pests.

Another fly borne affection of a deadly nature is epidemic diarrhea, and the evidence in support of the contention that flies are largely concerned in the dissemination of infantile diarrhea, especially in urban districts, is so convincing as to be practically irrefragable. But this is almost wholly, after all, a question of a pure milk supply, for it is by contaminating milk that flies play their part in spreading epidemic infantile diarrhea. There can be no doubt that if milk is effectually protected against flies diarrhea among young town children would be much less prevalent than it is now. Dr. J. T. C. Nash, writing in the *Lancet*, December 5, 1908, demonstrated by means of experiments undertaken by himself the close connection between flies and epidemic diarrhea. The results of his experiments with exposed and protected milk proved that a marked and rapid deterioration of milk exposed to flies took place, there being in the course of twenty-four hours approximately 40,000,000 more bacteria per cubic centimeter in the exposed milk, and ten times as many organisms capable of growing on agar at the body temperature. In round numbers, the exposed milk showed 700,000 bacteria per cubic centimeter capable of growing at the body temperature, against only 70,000 bacteria in the case of milk protected from flies.

In all large cities there are in the hot weather an immense number of flies. Furthermore, milk in the poor districts is never properly protected. The consequence is that flies contaminate the milk to a fearful extent. The greater the number of the flies the greater the milk pollution, and in fly ridden districts infantile diarrhea of an acute and virulent type is almost certain to prevail unless extreme care be taken to protect milk.

It would undoubtedly be a very difficult and perhaps an impossible task to keep flies down to such small numbers that they would be no source of danger to human life. But a well conducted war against flies could but result in a considerable diminution of their number, with a correspondingly satisfactory outcome so far as infantile diarrhea is concerned. In the meantime milk sellers and mothers can effect much by displaying great care in the protection of milk. Unfortunately many people are lamentably ignorant in regard to the bad results which are certain to follow carelessness in protecting the milk supply and need education both by example and by precept. Medical and lay journals should lend their aid in furthering this object.

A New Method of Estimating Blood-pressure.

Most modern instruments for measuring blood-pressure consist of a pneumatic cuff to compress a blood-vessel and a manometer to register the amount of pressure exerted. The time of taking the manometer reading is decided upon either by a certain amplitude of excursions of a pulse tracing if the graphic method is used, or more frequently by feeling for the return of the radial pulse after it has been obliterated by an excess of pressure in the cuff. In the *Münchener medizinische Wochenschrift* for April 6, 1909, Schrumf and Zabel describe their experience with a new method of determining the time of taking the manometric reading, a method proposed a few years ago by a Russian physician, Korotkoff. It consists in auscultating the brachial artery above the pneumatic cuff, while the pressure in the latter slowly sinks from a height that much exceeds the systolic pressure existing in the vessel. At a certain point a distinct sound may be heard over the vessels, which is followed by a number of other sounds, which finally disappear with a drop in the pressure inside the cuff. The pressure when the first sound is heard, as registered by the manometer, answers to the systolic pressure in the vessels; the diastolic pressure is measured by the reading taken when the last sound may still be perceived. The authors have compared this method with the others now in vogue and consider it quite superior to them. The graphic method involves the use of complicated and expensive apparatus that easily gets out of order; the palpation method does not seem to give the true blood-pressure as exactly as Korotkoff's method. It would seem easier too to designate the moment of measuring blood-pressure by the occurrence of the sound that by palpating the radial pulse, the figures obtained by different observers being much more in agreement when the former method was used; the first light pulse wave seemed to escape the observers much more frequently than the first sound heard over the artery. The authors recommend Korotkoff's method, therefore, as the one that leaves least room for subjective differences. The fact that it requires no other apparatus, in addition to a cuff and a manometer, than a stethoscope or a phonendoscope, with one of which every physician is provided, is, of course, a strong point in its favor, if the accuracy of its results is further corroborated.

Animal Tuberculosis.

The Bureau of Animal Industry, Department of Agriculture, calls attention to the increase of tuberculosis among live stock, as shown by the examination of animals at the slaughtering houses. The increased efficiency of inspection is, no doubt, the explanation for a part of this rise in the number of affected cases; but it is folly to accept this as the only explanation. Nearly 1 per cent. of cattle and over 2 per cent. of hogs have been found to be tuberculous when slaughtered, and in Washington about 17 per cent. of the dairy cattle reacted to tuberculin tests. It is estimated that throughout the country at least 10 per cent. of dairy cows have the disease. Considering the question entirely from a business standpoint, the Bureau points to the losses suffered by breeders who have tuberculous cows in their herds, and cites the loss in sales to Argentina, which country requires that all cattle imported shall be subjected to the tuberculin test upon arrival. As a consequence exporters in the United States have had the test made on cattle intended for shipment, and in some of the herds nearly 50 per cent. of the cattle have been found to be diseased, and have been refused. The large packing houses now prefer to buy their cattle subject to post-mortem examination, and the reason for this is found in the figures from abattoirs where Federal inspection is maintained.

During the last year ten billions of pounds of meat were inspected and forty-six millions were condemned, nearly three-fourths because of tuberculosis. Sooner or later, therefore, the economic loss will fall upon the producer of diseased cattle; and in the realization of this lies the best hope for stamping out the plague.

Meningitis in Pneumonia.

The occurrence of meningitis in pneumonia, manifested by clinical signs and symptoms of this complication, has been noted by most systematic writers on the subject. Thus Osler says in his "Practice of Medicine" that 8 per cent. of the fatal cases he had seen in a Montreal hospital had this complication. It was not always recognized during life, not being as a rule localized to the base of the brain. Recently it has been shown that pneumonia is very frequently accompanied by the presence of the pneumococcus in the general circulation, and this fact has led Liebermeister (*Münchener medizinische Wochenschrift,* April 13, 1909,) to suspect that involvement of the meninges is an even more frequent occurrence than is usually thought. He has accordingly made special examinations of the spinal cord in cases of death from pneumonia and records that changes characteristic of the inflammation of the meninges were found in one-third of all the bodies examined. Clinically, often no symptoms were observed leading to the suspicion of meningitis, and even at the autopsies the usual macroscopical examination of the spinal cord seldom showed any changes. Careful histological study, however, disclosed the existence of this serious complication. Liebermeister points out the fact that his investigations obviate in a large degree the necessity of falling back upon such a lame conclusion as the occurrence of "functional meningismus" in order to explain the frequent nervous symptoms of pneumonia; such symptoms often enough are due to real organic lesions produced by the pneumococci or their toxins in the central nervous system.

News of the Week.

Far Eastern Association of Tropical Medicine.—The first biennial meeting of this association will open at Manila, on Sunday afternoon, March 6, 1910, continuing throughout the week, and closing with a business session at Baguio, Benguet, the summer capital of the Philippines, on Monday, March 14, 1910. The committee on the program, appointed at the sixth annual meeting of the Philippine Islands Medical Association, has adopted the following outline for the sessions: March 6, Opening session; March 7, Protozoölogy, Helminthology; March 8, Cholera, Plague, and Leprosy; March 9, Surgery and Obstetrics; Diseases of Children; March 10, Fevers in the Tropics, including malaria, typhoid, etc.; March 11, Dysenteries, Beriberi; March 12, En Route to Baguio; At Baguio; March 13, Tuberculosis; March 14, Climate, Hygiene, and Sanitation; Business session. A suitable social program will be arranged also. In order that the committee on arrangements may as soon as possible receive information concerning the possible attendance and the material available for the program, it is requested that all those expecting to attend or to contribute papers communicate with Dr. E. R. Whitmore, Secretary-Treasurer of the Philippine Branch of the Far Eastern Association of Tropical Medicine, Manila, P. I. The meetings will be held under the presidency of Dr. Paul C. Freer of the Bureau of Science of Manila.

Conditions at the Canal Zone.—The Department of Sanitation reports that during the month of March, 1909, the death rate among the total number of employees was 8.76 per thousand, as compared to 37.44 for 1906, 40.23 for 1907, and 12.47 for 1908. Among the civil population of the Canal Zone, both employees and nonemployees, the rate for March, 1909, was 11.67, which again compares favorably with the rates for preceding years, which were 52.14 for 1906, 37.85 for 1907, and 17.29 for 1908. There are at present in the Canal Zone, 12,290 white employees, the total force being 43,825. The white employees from the United States number 5,179, and among these there was but one death during the month, making an annual rate of 2.31 per thousand. Including women and children there are 8,398 Americans on the isthmus connected with Canal Commission and with the Panama Railroad, and among these the deaths were only four, an annual death rate of 5.72, two of these deaths being from violence. During the month no death occurred from dysentery among the force, and the cases and deaths from malaria were decreased. There were no cases of yellow fever, smallpox, or plague. The sick rate was 20.60 per thousand, which is remarkably low. Dr. Gorgas calls attention to the low cost per capita of patients in the hospitals, $1.05. This figure includes every expense except that of building. As regards sanitation it is reported that conditions have been very satisfactory during the month for the destruction of mosquito life, as there has been very little rain. Nevertheless the larvæ are quite numerous in the streams which are contaminated with sewage at this time of year, and are also numerous in pools in the territory where the work of sanitation has not been done. The preventive measures taken to eradicate typhoid in the vicinity of the Gatun watershed have been effective, and no further cases have been reported. During the month 1,761 rats were killed, and a large number of baits poisoned with arsenic were eaten. The general draining of swamps and wet ground has been continued and conditions throughout the Zone are eminently satisfactory.

The Bull Memorial.—The committee appointed six weeks or so ago to consider plans for a fitting memorial to Dr. William T. Bull, is unanimously in favor of the creation of a large fund for conducting original research under the auspices of the College of Physicians and Surgeons. The secretary, Dr. John B. Walker, has issued appeals for contributions to this fund, which it is hoped may amount to $500,000. By intrusting this memorial fund to the College of Physicians and Surgeons, the necessity of equipping laboratories for the work will be obviated, and the entire income can be used for salaries and the direct cost of supplies. Contributions should be sent to Mr. George C. Clark, the Lincoln Trust Company, New York.

Dr. Hugh Angus Stewart has been appointed Adjunct Professor of Pathology at the College of Physicians and Surgeons, New York. Dr. Stewart is a graduate of the University of Edinburgh. He will take up his new duties in the fall.

Dr. David Lieberthal of Chicago has resigned

his position as Professor of Skin and Venereal Diseases in the Illinois Medical College.

Dr. Isaac A. Abt, having accepted the Professorship of Pediatrics in the Northwestern University Medical School, Chicago, with Dr. Frank X. Walls, has resigned his position as Associate Professor of Pediatrics in Rush Medical College. Dr. Carl Wagner, Chicago, has been appointed attending surgeon to the Columbia Hospital. Dr. William R. Parkes of Evanston, Ill., has been elected President of the Evanston Anti-Tuberculosis Association.

Jefferson Reunion.—Plans have been completed for the entertainment of the Alumni of the Jefferson Medical College at the next Commencement, June 7, which has been set aside as Alumni Day, and reunions of several classes will be held. At 3:30 P.M., Prof. W. W. Keen will hold a public clinic in the Jefferson Hospital amphitheater. At 7 P.M., the regular annual meeting of the Association will be called at the Bellevue-Stratford for the election of officers and transaction of business and this will be followed by the annual banquet at 8 o'clock. The subscription ($5) to the banquet should be forwarded at once to Dr. A. Heineberg, 1327 Pine street, Philadelphia.

The Oyster Trade.—The Board of Food and Drug Inspection of the Department of Agriculture will hold a hearing in Washington, on May 20, in order to obtain from dealers and others information as to the necessary regulations covering the growing, handling, and shipping of oysters. Particular emphasis is placed on the following points on which information is needed: the prevention of contamination of oyster beds; the practice of "floating" oysters in brackish water; the length of washing necessary before shipment; the method of shipment; and the sanitary precautions to be observed in reference to oyster houses.

Increase of Rabies.—Two interesting facts are noted in the Bulletin of the New York State Department of Health. One is the increase in cases of rabies in the State, the other the decrease in the deaths from typhoid fever. During 1908, the heads of 315 dogs were examined at the State Veterinary College, while during the first two and a half months of 1909, 177 were examined, a rate of 840 a year. During 1908, the death rate from typhoid fever was 16 per 100,000 population, the lowest ever recorded in the State. For the ten years preceding the average rate was 21.6.

Prison Doctors.—At the suggestion of Coroner Harburger, the jury in an inquest on the case of a man who died from a fractured skull in the Jefferson Market Court prison recently, included in its verdict a recommendation that surgeons be assigned by the proper authorities to each committing Magistrate's court and to each court prison, to examine every prisoner arraigned or committed.

Death Rate in New York.—During the week ending May 1, 1909, there were 1,521 deaths in New York City, a rate of 17.69 per thousand. This is an increase of twenty-one deaths over the corresponding week of last year, when the rate was 17.38. The increase occurred in the mortality from diphtheria, bronchitis, and tuberculosis. There was also an increase in the number of deaths in institutions and in tenements and among infants under one year of age. Whooping cough caused thirteen deaths during the week and influenza fourteen.

Commencement Exercises of Illinois Medical College were held April 30, when degrees were conferred on a class of thirty-one by Dr. J. F. Burkholder. Dr. William F. Rittenhouse delivered the Doctorate Address.

The Kansas Medical College.—Dr. W. E. McVey was, on April 24, elected Dean of the Medical Faculty of the Kansas Medical College, the medical department of Washburn University, to succeed Dr. W. S. Lindsay who has held the office for the past three years. Dr. McVey occupies the chair of Rhinology, Laryngology, and Diseases of the Chest in the medical faculty. At the commencement exercises of the school, held on April 28, the degree of M.D. was conferred upon seventeen graduates.

Cocaine Law in Pennsylvania.—The Governor of Pennsylvania has signed the bill passed by the last Legislature imposing a fine of $500 and two years' imprisonment for the sale or giving away of cocaine or any derivative or compound of cocaine except upon the prescription of a licensed physician, and prohibiting the possession of any such substance by others than physicians, druggists, dentists, and veterinarians, except as purchased on a physician's prescription.

Against Adulteration or Misbranding of Drugs.—Governor Stuart has signed a bill passed by the Pennsylvania Legislature at its recent session prohibiting the sale of adulterated or misbranded drugs. A drug is deemed adulterated if it differ in strength, quality, or purity from the standards laid down in the United States Pharmacopeia, the National Formulary, or the American Homeopathic Pharmacopeia.

State Insane Asylum Site.—A new site for the State Insane Asylum, for which an appropriation was made by the last Legislature, has been selected at Farmingdale, Long Island. It is understood that there will be no opposition to the location of the asylum in this district, as there was in the other places suggested.

Enlarging Flower Hospital.—Plans have been filed with the Building Department for the purposed addition to the Flower Hospital and Homeopathic Medical College, New York. The addition will be an annex to the present dispensary and will contain clinic rooms and a diet kitchen, as well as rooms for the professors of the college and the hospital physicians.

Home for Sick Babies.—The problem of obtaining facilities for the proper care of sick babies during the summer months has been partially solved in McKeesport, Pa., where a wealthy resident has placed his own home at the disposal of the Salvation Army during the coming summer to be used for housing the babies and their mothers. The house will accommodate twenty-five children at a time.

"Smiling Joe."—In July, 1905, there was admitted to the Sea Breeze Hospital a small boy, suffering from tuberculosis of the spine, whose picture, showing him strapped to a board, has gone from one end of the country to the other. With the caption "Smiling Joe" the appeal of this picture has been felt by all, and many a donation to the hospital has been due to it. On the 14th of April, nearly four years after his admission, Dr. Ely, the attending surgeon, recommended "Smiling Joe's" discharge, with the note that he was "cured, with a very slight deformity." The Association for Im-

proving the Condition of the Poor now has the quarter of a million dollars necessary for the erection of a hospital at Sea Breeze, for which the city has promised to donate the land.

The Litchfield County (Conn.) Medical Association at its one hundred and forty-fifth annual meeting, on April 27, elected the following officers: *President*, Dr. S. G. Howd of Winsted; *Vice-President*, Dr. G. H. Wright of New Milford; *Secretary*, Dr. F. H. Lee of Canaan; *Committee on Membership*, Drs. Goodwin, Page, and Swett; *State Councilor*, Dr. E. H. Welch of Winsted.

The Berkshire District (Mass.) Medical Society held its annual meeting at North Adams on April 29. The following officers were elected: *President*, Dr. Harry B. Holmes of Adams; *Vice-President*, Dr. Clifford S. Chapin of Great Barrington; *Secretary and Treasurer*, Dr. I. F. S. Dodd of Pittsfield.

The Middlesex North District (Mass.) Medical Society at its annual meeting, recently, elected the following officers for the ensuing year: *President*, Dr. C. A. Viles; *Vice-President*, Dr. O. P. Porter; *Secretary*, Dr. A. R. Gardner; *Treasurer*, Dr. T. B. Smith; *Librarian*, Dr. P. J. Meehan.

The Worcester North District (Mass.) Medical Society held its fifty-first annual meeting at Fitchburg on April 27. The following officers were elected: *President*, Dr. E. L. Fiske; *Vice-President*, Dr. W. N. Cowles; *Secretary*, Dr. Walter F. Sawyer; *Treasurer*, Dr. F. H. Thompson, Jr.

The East St. Louis (Mo.) Medical Society, at a meeting held on April 26, elected the following officers for the ensuing year: *President*, Dr. O. J. Culbertson; *Vice-President*, Dr. R. S. Stanton; *Secretary and Treasurer*, Dr. U. S. Short.

The Brockton (Mass.) Medical Society held its annual meeting on April 20, when the following officers were elected for the ensuing year: *President*, Dr. W. P. Safford; *Vice-President*, Dr. E. C. Frost; *Secretary*, Dr. R. A. Elliott; *Treasurer*, Dr. E. E. Goodwin; *Librarian*, Dr. D. E. Brown.

The Manitoba Medical Association will hold its annual meeting at Brandon, Man., on June 22 and 23. Among other important matters to be considered are the questions of interprovincial registration and of the registration of the vital statistics.

The Rhode Island Medical Society.—The date of the annual meeting of this society has been changed to Tuesday, June 1. The meeting will be held at Providence.

Central Illinois District Medical Society.—The following officers were elected at the annual meeting of this Society, held in Pana, April 27: *President*, Dr. D. W. Deal, Springfield; *Vice-Presidents*, Drs. Franklin A. Martin, Tower Hill, and J. William H. Sparling, Moweaqua; *Secretary*, Dr. Charles Burgess, Pana; *Treasurer*, Dr. John N. Nelms, Taylorville; *Censors*, Drs. Everett J. Brown, Decatur, John D. Polk, Litchfield, and Louis F. Brown, Hillsboro.

Illinois State Medical Society.—The fifty-ninth annual meeting of this Society will be held at Quincy, May 18, 19, and 20, under the Presidency of Dr. J. W. Pettit of Ottawa. An interesting social and scientific program has been arranged, and it is predicted that the attendance will be large.

Ohio State Medical Society.—The sixty-fourth annual meeting of this society was held in Cincinnati on May 5, 6, and 7, under the presidency of Dr. D. R. Silver of Sidney. The election of officers resulted as follows: *President*, Dr. W. H. Snyder of Toledo; *Vice-Presidents*, Drs. H. R. Geyer of Zanesville, A. D. Rudy of Lima, O. N. Wiseman of Zanesville, and C. A. Hough of Lebanon; *Secretary*, H. J. H. Upham of Columbus; *Treasurer*, James A. Duncan of Toledo. The next annual meeting will be held in Toledo.

Obituary Notes.—Dr. Burr L. Houghton of Brooklyn, N. Y., died suddenly of apoplexy at his home on May 1, aged 55 years. Dr. Houghton was graduated from the New York Homeopathic College in 1887.

Dr. James Warren Freeman, for thirty years a practitioner of Saginaw, Mich., died at his home, on May 3, aged 81 years. Dr. Freeman was graduated from the Albany Medical College, N. Y., in 1864.

Passed Assistant Surgeon James P. De Bruler, medical officer of the United States gunboat *Paducah*, died aboard that vessel at San Juan, Porto Rico, on May 7, aged 32 years.

Dr. W. B. Wall of Redlands, Cal., died on April 21, after a short illness, aged 79 years. Dr. Wall was graduated from the Jefferson Medical College, Philadelphia, in 1853.

Dr. Henry E. Pressly of Birmingham, Ala., died on April 22, at Due West, S. C., after a long illness. He was graduated from Bellevue Hospital Medical College in 1899, and practised in Birmingham until his health failed.

Dr. C. A. Landrum of De Funiak Springs, Fla., died at his home on April 23. He was graduated from Tulane University in 1876.

Dr. Manuel Amador, first president of the Republic of Panama, died at his home in that country, after a lingering illness, on May 2, aged 74 years. Dr. Amador, a Colombian by birth, settled in Panama in the early sixties and soon became the leading physician on the Isthmus. In 1869, against his inclination, he was elected president of the State of Panamá, but before he could take office a revolution drove his party from power. He resumed the practice of medicine and became chief physician of the Panama Railroad Company and the Pacific Mail Steamship Company. Much of the success of the movement which secured the independence of Panama in 1903, was attributed to Dr. Amador, and in 1904 he was elected president of the newly established republic.

Dr. Charles J. Sharrets of Bayside, Long Island, died at his home, on May 7, of a complication of diseases, at the age of 54 years. Dr. Sharrets was graduated from the College of Physicians and Surgeons, New York, in 1880, and had been for many years connected with the Metropolitan Life Insurance Company.

Dr. Samuel M. Plush died at Arcola, Pa., on May 4, at the age of 68 years. He was a veteran of the Civil War, an inventor, and a pioneer in the development of the Bell Telephone Company. He was a graduate of Ursinus College and of the medical department of the University of Pennsylvania in the class of 1876, and he was for many years expert electrician to the Western Union Telegraph Company.

Dr. William Howard Finn died at Philadelphia on May 5 at the age of 74 years. He was graduated from Bucknell College and in 1863 from the medical department of Harvard College. He served as a surgeon during the Civil War and was for a time in charge of a hospital ship.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INFANT MORTALITY WITHIN AND WITHOUT THE WORKHOUSES —SLEEPING SICKNESS—HENOCH'S PURPURA—CYSTIC CHANGE IN BRAIN—RESEARCH DEFENCE—OBITUARY.

LONDON, April 23, 1909.

THE Local Government Board has now issued a return concerning the infant mortality in workhouses and in it distinctly traverses the minority report of the Royal Poor Law Commission, which estimated the death rate in workhouses as two or three times greater than that of infants born outside. The new memorandum admits that it would be surprising if the children of the general population had not a better chance of life than the offspring of mothers who found a temporary refuge in Poor Law institutions, but to ascertain the precise difference would be extremely difficult. The statistics put forward in the minority report are pronounced of little value on account of the inadequacy of the materials and the conjectural elements which entered the calculations. The Local Government Board understands that few, if any, of the returns were furnished to the compilers of the minority report later than July or August, 1908, yet the statistics purport to give the life history for twelve months, *i.e.* up to December, 1908, of the infants born up to December, 1907. The Local Government Board's comment on this is that "though these statistics are thus open to question, in addition to the fact that they are admitted to be imperfect, the authors of the report have based upon them definite and sweeping assertions which would only be fully justifiable if they were supported by the most thorough enumeration of individual cases." The paper points out that the cause dominating the mortality of the workhouse-born infants is the type and character of the parents, and the evidence as to this is actually cited in the minority report itself, but its extent is omitted in considering the conclusions. In 1907 out of 2,653 births in metropolitan workhouses 60 per cent. were illegitimate, whereas out of 122,745 births outside only 3.75 per cent. were so. The inference is obvious and it is needless to labor the condition of the mothers and the prenatal influences. The death rate in 1907 was 42 per 1,000 in the first week, nearly double the rate in the general population, clearly due to prenatal and maternal conditions, quite independent of the wards, for in the second week of life the rate sank to 6.1 per cent. lower than the rate outside (6.4 per cent.). The instability of the workhouse population is pointed out by the Local Government Board as rendering some of the comparisons in the minority report with the general population quite valueless. Further, it is said that the comparisons between different workhouses are fallacious. "To take an extreme illustration, very different results might be expected in maternity wards where the mothers are healthy farmohuse servants, as compared with similar wards recruited from the slums, yet the importance of district mortality and morbidity, which is an essential factor of institutional statistics, has been disregarded" in the minority report. The signatories of the minority report say that they had not been able to obtain statistics of the comparative mortality of mothers in workhouses and hospitals or under domiciliary treatment. This, say the Local Government Board, calls for inquiry. If intended to suggest want of success in Poor Law institutions, there is no information to support such a suggestion. The Senior Medical Inspector of the board, who was on the Royal Commission, stated in evidence that in the maternity wards the Poor Law afforded an example of extraordinary success. Other evidence submitted to the commission certainly confirmed this. Further, the Local Government Board's memorandum shows that all the information available goes to prove the satisfactory condition of the wards and the nurseries.

Dr. Allan Kingborn, whose return from Africa I reported to you a fortnight ago, has already given a review of the expedition of himself and Mr Montgomery, sent out by the Liverpool Tropical School. Addressing the African Section of the Liverpool Chamber of Commerce on Monday, he said their twenty months' investigation extended over an enormous area. They found the *Glossina palpalis* was the transmitter of sleeping sickness, and that disease seemed to have begun in West Africa, but was carried elsewhere by the increased migration of the natives, especially by the extensive movements due to the foundation of the Congo State. In a very dry air the tsetse died quickly; it also needed shade. So when the river banks were cleared it disappeared. It could not flourish at an altitude above 4,000 feet and its presence was seasonal. In Rhodesia he thought isolation of cases would tend toward protecting the people, with the clearing of watering places, prohibiting fishing, and the use of canoes—measures that had been attempted with advantage. He would add international cooperation.

What is Henoch's purpura? The question suggests the inconvenience of such nomenclature which seems to be growing. No doubt there are instances in which a name has served a good purpose temporarily, but in most cases the sooner another term is agreed upon the better. The above question is raised anent a paper at the Royal Medical School by Dr. Porter Parkinson describing three cases of so-called Henoch's purpura. The first was a boy of eight with a purpuric rash over most of the body, pain and tenderness of abdomen in the epigastric and right iliac regions. The spleen could be felt. Albumin and a trace of blood and casts in the urine. Occasional vomiting. Two injections of horse serum were given without benefit, but the boy recovered and was discharged with the urine still albuminous. The second case was a boy of six with abdominal pain, but not tenderness, and vomiting, purpuric spots on the limbs. In hospital he was suddenly attacked with more pain and the left lumbar region was tender. Similar crises were repeated at intervals of two days. Blood was found in the stools, the face became puffy. In two months he began to improve. At first calcium chloride was given, later three injections of horse serum. Two groups of spots came out while he was taking calcium. The third case was also a boy of six under Dr. Botton's care, admitted with pain, bloody stools, measly nonpurpuric rash, and coryza. Next day vomiting, blood and mucus by rectum, abdomen distended, and on suspicion of intussusception the abdomen was opened, but only some flecks of lymph found in peritoneum and some evidence of peritonitis. Death next day. At the post mortem general peritonitis and on the small intestine about 13 extravasations the size of peas projecting from both inner and outer surfaces. A foot from the iliac valve was a larger hemorrhage. Near the splenic flexure diffuse hemorrhage, looking almost gangrenous. Dr Parkinson thought the diagnosis lay between measles and Henoch's purpura, the suspicion of intussusception not being verified. He favored purpura, though the absence of blood and albumin in the urine was unusual. He thought the case supported the view of Mr. Hugh Lett as stated in the "reports" of the Children's Society—that it is not wise to operate for intussusception in such cases unless a tumor is felt.

Mr. Hugh Lett thereupon spoke, remarking that the presence or absence of intussusception was a most important point. In one case which he had reported he operated on an intussusception which developed during the illness, but another intussusception occurred seventeen days later and the child died. He thought there should be no operation unless the characteristic sausage-shaped tumor could be felt. He had operated on 28 cases, but in every one he felt the tumor either from the abdomen or per rectum. In two of them he could not feel it without an anesthetic. In Henoch's purpura operation was a very serious proceeding, for hemorrhage from the wound had sometimes proved fatal. In a future case of undoubted intussusception with purpura he would try injection before operating.

Dr. Langmead said an extravasation of blood might simulate intussusception, and Dr. E. I. Spriggs said he had had such a case. Dr. E. Cautley said the term Henoch's purpura ought to be discontinued, for the disease was obviously purpura hæmorrhagica with abdominal symptoms, a view in which Dr Pernet also agreed, as do, I think, many others.

At the same meeting Dr. Edward Cautley showed the brain from a case of cerebral diplegic spasticity. The whole frontal and parietal regions had been converted into a bilateral cyst bounded mesially by a wall containing some cerebral tissue. As far as the history could be ascertained, the child had been healthy up to seven weeks of age, when an illness came on which seemed to have been meningitis or encephalitis. From the post mortem it looked as if the illness had been congenital, due to some developmental error in the prosencephalon. Dr. Langmead said that there

was a specimen in the museum of the Great Ormond St. Hospital which closely resembled this case and it showed some narrowing of the small cerebral blood-vessels.

Dr. G. Carpenter said he had neither seen nor read of such a case, but he had seen a locular cystic condition, which Dr. E. Jones reported as in his view due to syphilis. During life the child had been spastic, with head retraction and atrophic patches in its choroid.

The "Research Defense Society" started here promises to be successful, its object being to make known the good done to mankind through vivisection. At a meeting at the Royal Society of Medicine's house Mr. Stephen Paget gave a lecture to nurses to put them in a position to meet the prejudices sometimes manifested by patients. He referred to Harvey's work on the circulation and passed on to show how what we know of the processes of digestion and other functions was based on experimental investigation. A chart of the whole surface of the brain, indicating the province of the various parts, was now available, and it was possible to remove a tumor on the brain. He illustrated such a chart by a picture on the screen. Formerly, he continued, the use of certain glands was unknown. When surgery had so advanced as to make the removal of goiter possible it was soon found that excision of the gland was followed by a slowing down of life and the patient drifted into imbecility. So it was discovered that some cases of idiocy in children and long vitality in others were due to failure of the gland to supply its necessary secretions. That was the origin of myxedema and the successful treatment of this condition was brought about by Sir V. Horsley's experiments on monkeys and sheep (1884). In 1888 the grafting of glands from animals was tried with success, and then came the use of the gland's secretion, which brought the sufferer back from the myxedema, so that you could see, said the lecturer, in the pictures on the screen of the children in various stages, the soul, so to say, coming again into their faces. Passing on to germs, he told how Pasteur experiments on sheep had been the means of producing his first vaccine for anthrax, then how the discovery of tuberculin freed cows from tuberculosis, and similarly of how antitoxin protected horses from tetanus. The mortality of diphtheria had been reduced from 66 to 29 per cent. by its antitoxin. The latest triumph, perhaps, was the serum for cerebrospinal meningitis, reducing the mortality from 75 to 36 per cent. The cases of Malta fever, malaria, and yellow fever were also explained and illustrations thrown on the screen.

Mr. Simeon Snell, the leading ophthalmologist in the north of England, died on the 17th inst. at his home in Sheffield, where he was a J. P., surgeon to the Royal Infirmary, member of Council of the University, in which he had been professor of anatomy, consulting ophthalmic surgeon to various hospitals, and president of the literary, scientific, and medical societies. He qualified at the two London colleges in 1872-1873 and became F.R.C.S. Edin. in 1892. He made many contributions to his specialty during his long career, among them on miner's nystagmus, hygiene of the eye in childhood, reports for Government on dangers to eyes, accidents and diseases connected with occupations, etc. He also published an account of his method of cataract extractions without iridectomy, with an analysis of 300 operations. Mr. Snell was also a journalist. He founded and edited a Sheffield medical journal which was afterward called the *Quarterly Medical Journal*. Mr. Snell was president of the British Medical Association at the meeting held last summer in Sheffield.

Dr. Septimus Gibbon died on the 17th inst. in his eighty-fourth year. He was a Cambridge man (scholar of Clare) and took his B.A. in 1849 and M.B. in 1851, following also medical classes at St. Bartholomew's Hospital, where he afterward lectured on natural philosophy, having taken the M.R.C.P. in 1852. At Cambridge he had served as resident at Addenbrooke Hospital. Afterward he was physician to the British Hospital at Smyrna and for some time assistant physician to the London Hospital. Abandoning medical practice for the sanitary service, he became Medical Officer of Health for Holborn.

Dr. Henry Stilwell died on the 12th inst., aged seventy-three. He was for forty-five years medical superintendent of Moorcroft Lunatic Asylum, devoting most of his life to this work, and being regarded by all his brethren as an efficient organizer and acute yet careful alienist, whose opinion was of the greatest value in difficult cases.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

THE GERMAN MEDICAL PROFESSION AND SOCIAL MEDICINE—WORKINGMEN'S INSURANCE—THE FIGHT AGAINST TUBERCULOSIS—THE PREVENTION OF VENEREAL DISEASE—DEATH OF R. VON RENVERS.

BERLIN, April 24, 1909.

THE manner in which German physicians have endeavored to fulfill their social duties may be very well studied by consulting the report of the activity of the Seminar for Social Medicine, presented by Peyser at the meeting of the Berlin branch of the Union of German Physicians. It may be supposed that the State takes interest in the education of physicians, so far as social medicine is concerned; the truth is, however, that German universities are very weak in this respect. The Union of German Physicians has attempted to correct matters by forming a Social Science Seminar for the doctors and the medical students of Berlin. In the report for 1908 a series of lectures are mentioned, presented before the Seminar, which had for their subject the position of the physician as an expert in workingmen's insurance questions. The members of the seminar were acquainted with the usual proceedings that take place in the consideration of the claims of workingmen under the insurance laws. At the end of the year 1908 another series of lectures were held dealing with the activity of physicians in relation to workingmen's insurance. The course consisted of eight lectures, after which the students took part in the deliberations of the courts occupied with questions arising out of the insurance laws; the members of the seminar were afterward shown the practical duties of physicians in this connection, the manner of filling out certificates, etc. For the graduate physicians there was held another series of lectures dealing with the relations of the physician to the business of the commonwealth in which he works; the care of the poor and the various other branches of charity work were here considered. The Berlin organizations for fighting fire, for relieving emergency cases of sickness, and for transporting sick people were visited by the members of the seminar.

The insurance organizations of Berlin have developed a new system of fighting tuberculosis, which is at present used only experimentally, so that the results may be compared with those previously attained. The object in view is to save the healthy members of the workingmen's class from being infected by workingmen suffering from tuberculosis. As soon as the fact becomes known that a tuberculous patient lives in any dwelling, a special physician is sent to visit the house. He gives proper advice as to the selection of the rooms for the patient, sees that he is provided with a separate bed, without any expense on his side; the dwelling is kept clean and properly fumigated, if necessary, and occasionally additional rooms are hired, if the patient cannot be properly isolated in the existing conditions. The workingmen living in the same rooms are examined from time to time, and in case the disease develops in any of them immediate treatment is begun. There exists very thorough cooperation between the work of this organization and all other organizations occupied with fighting tuberculosis among the masses of the population. As a rule the patients are treated by their own physicians, but in case sanitarium treatment or the use of tuberculin is required the insurance organization supplies these.

The German Society for the Prevention of Venereal Disease has recently held its annual meeting, at which the work of the year was discussed by the members. A number of circulars have been issued by the society dealing with the question of preventing the spread of venereal disease, special circulars intended for women and for parents having been issued. These circulars are either distributed gratis or sold at a nominal price, and contain information in regard to the prophylaxis of venereal disease, written in a popular form so as to be intelligible to the lay public. A number of lectures have also been delivered before the students of the higher institutions of learning, this method of reaching the youth of the nation having proved quite successful. Dr. Gräser of the German Sailors' Hospital at Naples has been awarded a prize for a brochure dealing with the prevention of venereal disease and intended especially for distribution among seafaring people. Dr. Zinsser of Cologne lectured on the new regulations of the Prussian Government dealing with the question of prostitution. These regula-

tions permitted prostitutes to engage private physicians for the treatment of venereal disease, thus excusing them from obligatory stay in special hospitals established for the purpose. Apparently this permission has been but little availed of by the patients of this class, who preferred to stay in such hospitals instead of undergoing private ambulatory treatment. However, final judgment in reference to the working of the new regulations cannot yet be passed; though the experience with them has been unfavorable in Berlin, better success seemed to have been attained with ambulatory treatment in other cities, such as Essen.

On the 22d of March occurred the death of the Director of the Moabit Hospital, Dr. R. von Renvers. He probably had the most extensive medical practice in the city of Berlin, his imposing personal appearance, his confidence-inspiring manners, and his sure medical sense having made him extremely popular. He took part in a great many medical undertakings concerned with social and sanitary medicine, among them in the attempt to prevent the spread of tuberculosis by the methods described above. He was president of the Prussian Central Committee for Postgraduate Instruction and superintended also the activities of the governmental organizations occupied with similar work

THE EPILEPTIC VOICE.

To the Editor of the Medical Record:

Sir:—The London letter in your issue of May 8 reports that Dr. Alfred E. Russell considers epileptic fits to be analogous to fainting fits, and minor epilepsy to be due to the cardiovascular nervous mechanism, by which the loss of consciousness becomes more sudden. This is in opposition to the view that there is some organic brain lesion underlying all varieties of epilepsy.

The existence of the "epileptic voice" (Clark and Scripture, "The Epileptic Voice Sign, Medical Record, Oct. 31, 1908) indicates that there must be some anatomical lesion. This peculiar voice is invariably found in every case of epilepsy, recent or ancient, light or severe, with or without bromides. The patient is never conscious of it himself; it cannot be imitated successfully by a normal person. The trained ear can distinguish its negligent monotony at once from the strained monotony of the stutterer and from the tired monotony of the neurasthenic. It can never be confused with the flexible voice of the hysterical person, and can serve for differential diagnosis in such cases. The only close resemblance we have found is with the voice of early paralytic hemiplegia. For epilepsy, as well as for this last disease, we must assume some underlying structural defect of the brain.

E. W. Scripture, M.D.

Treatment of Obstruction of the Lacrymal Duct.—J. C. Berry says that in infants ordinary cases of dacrocystitis call for only nasal cleanliness, boric acid eye wash and slight pressure over the sac, while more persistent cases may call for nasal aspiration or possibly the passage of the lacrymal probe. Obstruction is sometimes due to membranous closure of the nasal end of the canal. Intranasal inspection is always prudent and at times necessary when probing the duct. The seton is a remedial measure of great promise in certain rebellious cases. In adults the ideal treatment is by gradual dilatation, avoiding violence to the membrane of the canal, but if this proves unsuccessful we must divide the structure and dilate rapidly and fully. Dilation beyond 2 mm. is rarely necessary. Forced dilation to 4 mm. exposes the eye to contamination and lessens the propulsion power of the sac. The leaden style can be employed to advantage between treatments, reducing the frequency of probing and favoring absorption of the hypertrophied tissue by continuous pressure. Acute cases of inflammation of the sac can be aborted if seen early, the treatment being to wash out the sac, inject argyrol, and follow with hot strips of lead and opium, observing general antiphlogistic measures. If phlegmon occurs, the passage of the probe should be delayed until swelling and induration subside.

Intermittent Hydronephrosis.—D. F. Jones reviews some of the recent literature on this subject and reports four personal cases. The following have been found to be the causes of this condition. Valve formation at the opening of the pelvis into the ureter, oblique insertion or high insertion of the ureter into the pelvis, stricture, twists or angulations of the ureter, flexure over abnormal vessels or pressure upon the ureter by abnormal vessels, pressure by the normal vessels of the kidney, tumors of the bladder or renal pelvis, stone in the pelvis, pressure by new growths or inflammatory masses along the course of the ureter, adhesions along the ureter, uterine prolapse, renal injuries, and scoliosis. Symptoms in a given case are pain, nausea, and vomiting, constant desire to pass water, and possibly a tumor. Increase in the amount of urine voided after an attack of pain is a fact of much significance. Cystoscopy may be of value in diagnosis. Operation which may relieve the condition are aspiration, fixation of a movable kidney, nephrotomy, nephrectomy. Modern surgery has had recourse to conservative plastic procedures, several of which are described in this well-written and finely illustrated paper.

New York Medical Journal, May 1, 1909.

The Toxic Secondaries of Chronic Tonsillar Disease. A. R. Elliott declares that many grave and fatal infections enter the body through the tonsils, such as endocarditis, rheumatism, scarlet fever, tuberculosis, etc., and in addition to these specific processes other less virulent and nonspecific organisms may become established there and poison the body with their toxins. When the latter once gain access to the circulation they exert certain catalytic and hemolytic, which, if the toxemia is long continued, may eventuate in organic degenerative changes or abnormal blood states. The most common secondary from chronic tonsillitis is anemia of the simple type. Many tonsils in these patients contain crypts plugged with all sorts of débris, which soon becomes cheesy and foul smelling. Another condition frequently associated with chronic tonsil disease is rheumatism. Absorption of septic toxins from the tonsils may so lower the vital resistance to infections that the individual becomes liable to certain minor infections, such as styes, furuncles, and acne. Also herpes and erythema have both been observed in connection with tonsil infections. Toxins in general exert a degenerative effect on body tissues and there is no doubt that Bright's disease, diabetes, arteriosclerosis, myocarditis, etc., are toxic secondaries produced by long-continued, low-grade toxemia. A chronic closed infection of the tonsil is just as noxious to the organism at large as similar processes elsewhere.

Treatment of Appendicitis.—Beverly Robinson says that it is very difficult to make a diagnosis between appendicitis and colitis. The best plan to follow is the following: (1) Rest in bed, and with rest in bed little or no voluntary movement while pains are acute, temperature elevated, and other general symptoms threatening or grave. (2) Ice bag, or, preferably, hot water bag, or poultices, or stupes with hot water and oil of turpentine and soap liniment; flannel covered, or not, with impermeable, *i.e.* oil silk, or rubber tissue. (3) Laxative enema with castor oil and oxgall, sometimes a little glycerine being added. Flaxseed tea should preferably be the menstrum of the enema. (4) A moderate amount of codeine every hour or two, by mouth, if pains seem to require it, from 1-20 to 1-10 or 1-5 grain. (5) In rare instances only are hypodermic injections of morphine to be given and then only for excessive pain not otherwise relieved. If to this treatment, whenever the stomach tolerates it, ten grains of salicin in cachets be added every two or four hours, we shall have a practical, rational, effective treatment of appendicitis. During acute stage only liquid food in small quantities and properly selected, should be permitted. Whenever an abscess is well defined it should be opened and drained. In this connection it should be remembered that very many perforated cases of appendicitis cause an abscess limited by protective false membrane, if not operated on too soon or ill advisedly. Of course, perforations will occasionally occur and then operation is immediately called for. But, says the author, up to date this diagnosis is never certain; only probable, and at most relatively infrequent.

Diagnosis and Differential Diagnosis of Appendicitis.—H. Fisher makes three varieties of the disease acute suppurative, acute catarrhal, and chronic catarrhal. With reference to palpation of the appendix he quotes certain authors who in a series of 800 normal individuals were able to palpate the organ in over 51 per cent. The author says that to obtain these results, the following conditions must be present: (1) The appendix must lie upon the apo-

neurosis of the psoas muscle and must run obliquely parallel to the same, otherwise it will in most cases be covered by the cecum. (2) The abdominal walls must not be so massive and rigid. (3) The psoas muscle must be relaxed by fixing the thigh. (4) The right index finger must be held transversely to the course of the psoas muscle, until one feels its sharp and rigid edge. By a slight to and fro movement the appendix will roll under the finger. Concerning the McBurney point the author quotes Lanz investigations on this point. The Lanz point is found by connecting the two superior anterior iliac spines by a line divided into exact thirds. The junction of the right with the middle third corresponds approximately to the base of the appendix. Lanz therefore concludes that: (1) The situation of the appendix—as far as its point of junction with the cecum is concerned—is much more constant than it was hitherto thought to be. (2) McBurney's point does not correspond to the situation of the appendix. (3) McBurney's point corresponds to the mesical side of the colon ascendens at a point five centimeters above the base of the appendix. (4) Lanz's point on the interspinal line is of greater importance to the determination of the vermiform appendix than McBurney's point. Notwithstanding Lanz's conclusions, the author believes that sensitiveness over McBurney's point is of great clinical significance. Diseased states to be considered in differential diagnosis are inflammatory lesions of the female genitalia, carcinoma of the colon, tuberculosis of the cecum, intestinal obstruction from various causes with beginning general peritonitis, inflammation of a Meckel's diverticulum, extrauterine pregnancy, typhoid fever, acute pancreatitis, lead colic, acute enterocolitis, etc.

Treatment of Acute Rheumatism at the Indianapolis City Hospital.—S. F. Earp thus describes the plan followed: The use of calomel is followed by a magnesium mixture (2 gallons of water containing 8 pounds Epsom salts, 3 pounds granulated sugar, 1½ pounds citric acid, 8 ounces aromatic sulphuric acid) until the bowels are freely opened, and they should then be kept open. The patient should take plenty of water. Thirty grains of sodium salicylate should be given each three hours until pain is relieved or there is unpleasant head symptoms. Then the dose is dropped to twenty grains, and when the joints can be used freely without pain or stiffness is continued fifteen grains four times a day for one week. When the patient considers himself well there are given ten grains three times a day for two weeks. Oil of wintergreen is applied to the joints twice a day, and they are dressed in cotton and oiled silk or rubber sheeting. If the patient has a subnormal pulse and lowered temperature, a moderate dose of strychnine is given every four hours. If the stomach seems rebellious to so much sodium salicylate, ice may be used in the mouth. Sodium chloride on the tongue and milk as a vehicle for the remedy. If the stomach cannot be controlled, the author has in several instances used sixty grains by the rectum. If the rectum is sensitive, and the fluid is not retained apply two inches above the sphincter muscle a two per cent. solution of cocaine.

Journal of the American Medical Association, May 1, 1909.

The Scope of Obstetrics.—B. C. Hirst says we have mastered the etiology and pathology of the puerperal infections to a great extent, as well as the physiology and pathology of conception and gestation. The point where we are weakest now is in the recognition and correction of the pathological consequences of the childbearing process. He thinks it practicable for the maternity hospital physician to look out for and remedy the injuries of the genital canal, malpositions of the uterus, pathological conditions of the broad ligaments, and appendages, lack of tonicity of the abdominal walls, and feeble support of the abdominal viscera, injuries of the coccyx, and impairment of function in the pelvic nerves, all of which are conditions that can be traced sometimes to childbirth. He thinks it would make a vast difference in the health of parturient women if this were done and a great amount of suffering would be saved, and that it would also save the specialty of gynecology from extinction, of which he thinks he sees present indications.

Phosphorus as Brain Food.—W. Koch has investigated the phosphorus content of the brain in health and disease and finds that even in conditions of extreme exhaustion, the brain is plentifully supplied, not only with phosphorus, but also with its special form of phosphorus, namely, lecithin. He concludes, therefore, that there is no evidence of any need to supply phosphorus to the brain in such conditions. The actual amount lost in the exhaustion of general paralysis can not, of course, be replaced on account of the inability of the central nervous system to regenerate. The phosphorus required for the growth of the brain is amply supplied by the phosphorus of our daily diet. If desired, the addition of phosphorus-rich foods, such as eggs, sweetbreads, liver, and some meats, can be made and meet further requirements, and will do far better in this way than dosing with drugs. The use of such foods, however, is limited by their richness and their tendency, on account of their fat contents, to disturb gastric digestion.

Tuberculous Joints.—H. J. Whitacre says that we must conclude that there is no one correct line of treatment for tuberculous joint disease, but that the method selected must depend on the nature and stage of the lesion, the age and social position of the patient, facilities for treatment, the individual experience of the physician in charge, and a combination of all available methods is sometimes called for. Rest, diet, favorable hygienic conditions, Bier's hyperemia, iodoform injections, vaccine therapy, and cutting operations all have their place and may all be used in various combinations. He details in full the technique used by him in tuberculosis of the joints, including thirteen cases in the knee, seven in the ankle, three in the elbow, one in the wrist, and one in the hip, twenty-five in all. His methods may be stated in a general way to consist in free opening of the joint. In the knee by transverse incision across the center of the patella, sawing through that bone and excising all tuberculous infected tissues in the synovial cavities and bone, going down to healthy tissues and filling any cavities left with iodoform mass after thorough cleansing with carbolic acid subsequently neutralized by alcohol. Decision as to the amount of bone involvement in these cases is a heavy responsibility and should not be made until a careful microscope study has insured its accuracy. The end of a bone must be seriously damaged before he would justify its removal. The preservation of a limb of normal length is considered by him a very important point. Drainage is used by him for six or seven days, the limb is put in a supporting splint which is removed in from three to five weeks. Bony union is slow and may not be complete for eight or twelve weeks after the operation. The after treatment is the same in case of the knee, ankle, joint, and wrist, though the details of the operation are, of course, modified by the needs of the case, and the passive exercise is begun a little earlier in the wrist, about three weeks after the operation. A complete analysis of the twenty-five cases is given. There were no fatalities, twelve patients are now completely cured, two have still a small sinus remaining with good function, one was lost sight of, there were three subsequent amputations, and in the remainder sufficient time has not elapsed to justify a final report.

The Philosophical Anatomy of the Tongue.—E. Souchon defines the aim of philosophical anatomy as the study of the reason of things, of the principles and general laws of anatomy, and the relation of cause and effect. It includes also, last but not least, the special features presented by organs and the endeavor to explain their reason, their why, and their wherefore. With this object in view, he takes up the tongue, remarking that this organ, the nose, and the skin are the only organs of special sense which perform other functions. It is the only organ except the heart which presents a base, a body, and an apex. It is the only organ which can be protruded out of the cavity which contains it. No other organ can assume such various shapes and is so movable. Other peculiarities are the differences of its papillæ in the anterior two-thirds and the posterior third. It is one of the organs which present a dual structure in accordance with its dual functions, motor and sensory. Its color varies more than that of any other organ. It is more solid than any other viscus, the only other muscular one being the heart, which is hollow rather than solid like the tongue. Its papillæ are really similar to those of other mucous membranes but larger and more specially developed. It is the only organ presenting the three kinds of nerves, i.e. a nerve of special sense; a nerve of ordinary sensation, the glossopharyngeal; and nerve of motion, the hypoglossal. There are other peculiarities, such as that the gustatory is the only nerve of special sense that is a hard nerve, the others, the olfactory, the optic, and the auditory, being remarkably soft nerves.

The Use of the X-Rays.—A. L. Gray reviews the history of the therapeutic use of the *x*-rays, showing

how it has been modified with our better knowledge of the agent and the conditions to which it can be applied. We have learned that the pathological conditions involving the epithelial structures can be influenced by the *x*-rays when sufficiently superficial to be reached by those which are active. Fibrous growths and lesions in which fibrous tissue involvement is largely present are very slightly affected unless the treatment is pushed to the point of actual burning or cautery. He believes that a satisfactory unit of quantity by which the *x* ray can be measured will soon be obtained. Every apparatus is a law to itself and there is no fixed rule that applies to all, but an operator can so study his instrument as to learn to a large extent its therapeutic capacities. From the facts now known he deduces the following conclusions: "First, malignant disease, while yet local, may be treated with the assurance of good results, provided the lesion is on the skin or very near the surface, and the age of the patient or condition of the general health is not such as to render the reparative powers too low. The treatment of deep-seated primary cancers should never be undertaken except in inoperable cases, or when the patient will not consent to surgical procedure. In these cases it is best to remove the diseased parts as radically as possible, and, if practicable, leave the wound open to be treated by the Roentgen method, and, if necessary, resort to a second plastic operation to close it. Second, such skin diseases as involve the epithelial and glandular structures are more or less amenable to treatment. Those involving the fibrous tissue of the corium respond with great difficulty, or not at all. Third, glandular enlargements, so long as they are due to gland-cell hyperplasia, will be greatly benefited by *x*-ray treatment; when the hyperplasia involves the connective tissue element very little result will ensue."

The Lancet, April 24, 1909.

Treatment of Bronchiectasis by the Continuous Inhalation of Oxygen (Stoker's Method).—W. P. Harringham describes his experience with this method in the case of a young man of twenty years. Oxygen was inhaled for six hours daily out of one of the bags devised by Stoker for this special purpose. The patient was kept under treatment for four months. The special features of the case were the large amount of fetid sputum and the general well being of the patient while taking the inhalations. The author says there is no more troublesome complaint to treat than this condition of bronchiectasis with offensive sputum. Oxygen inhalations are far more agreeable than are those of creosote which were tried in this case but without effect.

A Case of Anomalous Edema with Bright's Disease.—R. W. Walker reports the case of a woman of twenty-three years with a tumor in the right popliteal space and swelling of the leg below it. Eight years previously the right ankle began to swell and the swelling gradually spread up the leg. The enlargement behind the knee had begun five years before she was seen. In the meantime swelling had begun on the left side and gradually spread upward. During the eight years she had had good health except at times severe headaches. On examination the popliteal growth appeared like a pedunculated lipoma except that it pitted on firm pressure. No cause for it could be found. On admission to hospital there was no albumin in the urine, but on the third day later there was considerable together with hylaline and granular casts. The average daily output of urine was about twenty-six ounces. With rest in bed all the swellings would almost disappear and the popliteal enlargement as well but on resuming exercise all came back again. Finally she was put on a salt-free diet and it was noted that the swellings rapidly disappeared although she was exercising. On such a diet she continued free from the swelling although the urine contained albumin varying greatly from time to time in its amount. There was an entire absence of any cardiovascular changes throughout and the patient showed none of the anemia and cachexia so often seen in Bright's disease.

Epsom Salts as a Poison.—C. Fraser reports one case in which this familiar remedy gave unusual symptoms and adds notes of six other cases collected from literature. His own patient was a boy of three and a half years who during the absence of his mother had taken a heaped-up teaspoonful of Epsom salts thinking it was sugar. This dose was washed down with a glassful of milk. In a few minutes he was found retching and with mild griping pains in the abdomen. These symptoms continued for several hours when the boy presented a condition suggesting an acute irritant poison. Thirst was intense, scarcely any urine had been passed in twenty-four hours, and the bowels had not acted. The condition was later diagnosticated as acute peritonitis and laparotomy was deemed necessary and the child was removed to hospital. On opening the abdomen about a quart of blood-stained serum escaped but it was found sterile. The large bowel was found full of feces and gas and the small bowel contained greenish matter. The postoperative condition was critical for the first two days, but on the third day the bowels opened frequently, urine came more freely, and the general condition greatly improved. From that time on, recovery was uninterrupted. The author enumerates the symptom-complex which led to a diagnosis of peritonitis as against volvulus and intussusception. The prolonged constipation resulted doubtless from paralysis of the bowel. The author could find only six similar instances of poisoning following Epsom salts in the literature from 1841 to 1896.

Two Cases of Metrorrhagia at an Advanced Age, Not Due to Malignant Disease.—A. H. Lewis reports the cases, the first patient being a woman of 73 years with menopause at 53. Since then there had been no vaginal discharge till the spring of 1907 when there was an escape of blood lasting nine days, followed by a continuous stained discharge. On exploring the uterus a polyp was found and removed without incident. Microscopical examination showed a very adenomatous growth. Some of the glands were cystic and the stroma was infiltrated with inflammatory products, but it was decided that the tissue was benign. The second patient was a woman of 70 whose menopause came at 50. When first seen she had had a discharge for some eighteen months. Exploration revealed a polyp which the microscope showed similar to that of case 1. The author cautions against the acceptance of the diagnosis of benignancy in these cases unless it is confirmed by the microscope. Hemorrhage at this age generally means a malignant condition.

The Blood in Rickets.—L. Findlay presents his material in a largely tabulated form and we can quote only his conclusions. (1) In active and uncomplicated rickets anemia is not the rule and is to be regarded as exceptional and, when it occurs, due to adventitious causes. (2) On the contrary in rachitic children the amount of hemoglobin and the number of red cells in the author's cases were notably in excess of the normal average. (3) The red cells as a rule vary more in size than in normal individuals but otherwise there is no abnormality. (4) Nucleated red cells, polychromatophils, and myelocytes are of the rarest occurrence. (5) In rachitic subjects there is little characteristic change so far as the leucocytes are concerned. They may be normal, slightly increased or even diminished in number. The mononuclears more frequently than the polymorphs show an absolute increase in number per cubic millimeter.

British Medical Journal, April 17 and 24, 1909.

The Surgical Treatment of the Umbilical Cord.—This subject is considered by J. W. Ballantyne, who says that infection in the newborn through the umbilicus is more common than is realized, and he quotes one of the Berlin physicians, who says that 2 per cent. of infant mortality is referable to infection acquired as above stated. Under the author's supervision six different methods were tried on 16 infants. The plan which he claims alone fulfills the requirements of modern antisepsis was as follows: The cord was cut off flush with the skin of the umbilicus, and the skin surfaces were joined. With a scalpel a circular incision was made at the junction of the infant's skin with the sheath of the cord. The incision was gradually deepened till the vessels were approached; then by careful dissection the vessels were cleaned from the jelly of the cord and tied separately; next the cord was severed and finally the edges of the skin were freshened and united with silkworm gut or catgut. Ten minutes were required. No jaundice occurred in the four instances in which this plan was followed. Healing of the stumps was complete by the fourth day and the cicatrix retracted. The good results were evidently due to the removal of all the dead structures and the freshening of the cutaneous surfaces. No putrefaction whatever took place. The author anticipates and replies to certain objections which might be made against the method he commends.

Tetanus Occurring After Surgical Operations.—W. G. Richardson notes that in practically all such cases, blame has been laid on infected catgut used. But in one personal case, in which an elderly woman operated on for gallstones and who did well for a week, suddenly died from tetanus after two days' illness, the catgut was examined and pronounced sterile. By a logical process of reasoning the author gradually comes round to the thesis

that as all catgut used in surgery comes from the intestine of the sheep it may be that the disease from which patients suffer is not true tetanus after all. There is no evidence along the line of animal experimentation to show that tetanus can be communicated to animals from any catgut that has been used in operations. From following up the facts in connection with 21 cases the author has come to the following conclusions: There is a group of diseases among sheep, the symptoms of which are closely allied to tetanus, and the bacilli of which cannot be distinguished from those of tetanus. In these diseases the bacilli are normal inhabitants of the sheep's intestine, but at certain periods of the year they pass from the lumen of the bowel into the blood, where they become bacteriolized, and the liberated toxins give rise to the symptoms of the various diseases of the group. During these seasons the bacilli are found in the peritoneal cavity, but in no other part of the body. These diseases are endemic in certain portions of the British Islands, and it is in these portions and in these alone that all the 21 cases of supposed tetanus in the human subject occurred. More than 90 per cent. of the post-operative tetanus cases have followed operations involving the opening of the peritoneal cavity. He therefore suggests that the disease we call post-operative tetanus is not tetanus at all, but one of the sheep diseases, that it has no reference whatever to the catgut used, and that at the time of operation the patient is the host of the bacillus.

Loss of Hair in Exophthalmic Goiter.—H. G. Macleod reports one instance occurring in a girl of 28 years and presenting the usual features of the disease. In addition, there was marked alopecia at the back and top of the head. Later the forehead became affected, and finally the eyebrows and eyelashes commenced to fall off. No other cause than the exophthalmic goiter could be assigned for the alopecia.

Destruction of Sweat Glands by the Roentgen Rays.—A. H. Pirie has found that the application of the *x*-ray to areas over which the sweating is excessive destroys the sweat glands. Six seances are all that are required for the purpose, one each month, and the giving at each the maximum dose the skin will stand. The sweat glands are the glands most readily affected by the rays in the entire body, and are the most readily destroyed. By making efficient applications to the axillary region, not only are these glands destroyed, but the hairs also.

Ménière's Disease.—J. F. Horne refers to a paper by Syme on aural vertigo in the journal of April 10, and adds certain comments on symptoms observed in a personal attack and in cases under his own care. He says that most of the cases seen are the result of some congestive or inflammatory derangement of the auditory nerve, usually of the nerve terminals of the labyrinth. If due to this condition the watch on the affected mastoid will be heard very imperfectly or not at all. All cases of functional vertigo are not due to aural disease. Deafness is constant to a greater or less degree but is not an essential symptom. Treatment calls naturally for the removal of the cause. Quinine and salicylate of soda are avoided by the author, who considers strychnine the remedy par excellence alone or in conjunction with dilute hydrobromic acid with counterirritation behind the ear by a stimulating liniment or blister, followed later by galvanism. In one obstinate case relief was obtained from a seton worn behind the ear. Destruction of the labyrinth by radical operation should be reserved for the last resort.

How Much Fluid Does the Body Require?—Alex. Haig says that if a man leading an ordinary sedentary life not entailing visible perspiration, takes from fifty to sixty ounces of fluid per day, then a weight of 150 pounds apparently requires about fifty ounces of fluid, this amount being passed each day through the kidneys. The question he asks is, By how much may this be reduced before physiological difficulties are encountered? This amount, Haig thinks, is too large, and most people can do with less than 50 oz. daily. A greater quantity is more habit than necessity. Haig generally aims at 30 oz. This reduction is a great gain to a diseased or dilated heart. The total fluids in the body are reduced by several pints, and the weight falls a corresponding number of pounds. A dilated heart resembles a dilated bladder and is well known. The latter may lose all expulsive power. A heart thus enabled to get a more complete grasp on its contents saves a great expenditure of force in the course of twenty-four hours, while valves incompetent in the dilated condition may, even though diseased, become completely competent. Astonishing results have been noted by the author in patients on a dry diet. He goes on to specify certain diseased conditions in which a reduction of the fluid intake is beneficial. If the 30 ounces daily do not relieve thirst, fruit or extra water is permitted, but most patients can reduce to 30 ounces daily, or with fruit to a less amount for a time.

Note on the Pulsus Bigeminus.—E. E. Laslett presents some copies of pulse tracings showing a hitherto undescribed (he believes) form of jugular pulse associated with the pulsus bigeminus. His patient was a painter with uncompensated aortic disease. The tracings of the jugular and radial pulse when the pulsus bigeminus was present show the extra beats which were the cause of the bigaminal rhythm. The auricles contracted during the ventricular systole, and there was one large wave synchronous with the extra beat in the radial body. In such cases the increased size of the wave is due to the fact that the right auricle is unable to empty itself into the contracted ventricle, and therefore a larger quantity of blood is sent into the jugular veins. The unusual feature in this particular tracing lies in the fact that the combined wave commences distinctly beyond the middle line. That is, nearer to the postextra systolic auricular wave than to the preextra systolic. The author is unable to explain the peculiar rhythm. It is evident that the alternate auricular contractions failed to appear at the normal period, but whether the sinus rhythm remained regular or not it is impossible to say.

A Case of Heart Block with Fibrous Degeneration and Partial Obliteration of the Bundle of His.—B. Bramwell describes the case and appends copies of several pulse tracings. The patient was a man of 29, with a very slow pulse and a history of several febrile rheumatic attacks. Full account is given of his symptoms, which were of the typical character. Autopsy revealed a fibrous degeneration of the auriculoventricular bundle of His. A calcareous nodule was situated at the right end of the attachment of the anterior mitral flap, extending into the septum, invading and almost obliterating the bundle toward its auricular extremity. There was a general adherent pericarditis, with dilatation of all the cardiac cavities. The ventricles were hypertrophied. There was old endocarditis, with calcareous deposits in the aortic and mitral valves. In addition to the mitral changes above noted there was thickening of the tricuspid, with some dilatation of the orifice. The pulmonary cusps were slightly but uniformly thickened.

Münchener medizinische Wochenschrift, April 13, 1909.

Significance of Urobilin.—Hildebrandt concludes a lengthy article as follows: "Urobilin originates only from Bilirubin being produced by the action of reducing bacteria. This reduction takes place in the intestines and in rare cases in the bile passages, so that there are only enterogenous and cholangiogenous urobilinuria. If the liver is in a normal condition, urobilinuria may arise because of increased destruction of blood cells, which leads to a relative insufficiency of the liver. If blood destruction is not increased above normal, the presence of urobilin in the urine always signifies a disease of the liver parenchyma which has led to local obstruction to the formation and flow of bile; in such a case the insufficiency of the liver is absolute. Fever in itself does not cause an urobilinuria. If the gall-duct becomes completely obstructed, all urobilinuria disappears. In Laennec's liver cirrhosis the presence of urobilinuria shows that the disease begins in the parenchyma cells, the development of connective tissue being a secondary phenomenon. Hildebrandt calls attention to the importance of examining for urobilin in all urine analyses.

Deutsche medizinische Wochenschrift, April 8 *and* 22, 1909.

Retardation of Metabolism.—Staehelin says that retardation of various individual processes of metabolism as well as of the entire oxidation going on in the organism plays a much more important *rôle* in disease than is usually supposed. Even under normal circumstances the metabolism of one substance is very much retarded if another substance is fed which takes its place in the process. Thus carbohydrates and fats given together with proteid diminish the metabolism of the latter substance. This phenomenon is also present in pathological conditions such as diabetes, in which nitrogen products are but slowly excreted in the urine. The same thing takes place in certain cases of obesity. In gout the purin bodies are but slowly excreted, the nuclein metabolism being very much retarded in this disease, as well as in lead poisoning and in chronic alcoholism. The metabolism of carbohydrates is not only retarded in diabetes, but probably it is not as complete as in normal health. In cases in which the function of the thyroid gland is interfered with carbohydrate metabolism is likewise very much slower than normal. Any retarda-

tion in the metabolism of fat is very often coincident with severe somatic changes, because it leads to the diminution in the production of energy, that is necessary for carrying on the processes of life. This is exemplified in such a condition as cachexia strumipriva. Still more interesting is the fact that the organism possesses the power of accommodating its production of energy and its demand upon certain substances to the supply of such substance. Thus Chittenden's work has conclusively shown that this is the case with the proteids, which may be very much diminished in the food as compared with the customary quantities used. Many diabetics seem to adapt their production of energy to the amount of food supplied; this is shown by the fact that many such patients do not lose weight when their diet is very much limited by the exclusion of carbohydrates. The most interesting conclusion from all these facts is that retardation of metabolism is common to two conditions, namely, to the so-called diseases of metabolism on the one hand and to loss of glandular functions on the other. The study of the latter may therefore throw light upon such diseases. Practically retardation of purin metabolism in gout shows that purin free diet is a proper therapeutic procedure, while the capacity of diabetics to adapt themselves to low supply of food should teach us not to hesitate in diminishing their food whenever necessary in the therapy of diabetes.

Color Reaction in Syphilis.—Schürmann in a preliminary communication describes a color reaction which he has obtained with the sera of luetic patients. To 0.1 c.c. of serum he adds enough physiological saline solution to bring the quantity to 3 or 4 c.c., adds to this one drop of perhydrol, which serves as an oxidizer, and then mixes this fluid with 0.5 c.c. of the reagent. The latter contains 0.5 of phenol, 0.62 of 5 per cent. iron chloride solution and 34.5 c.c. of distilled water and is best prepared fresh for each examination. Normal blood serum shows a slight green ring at the junction of the two fluids, which disappears almost entirely on shaking. The mixture, too, remains clear and transparent. Syphilitic sera, on the other hand, show a dark brown color at the junction of the fluids, and on shaking the mixture appears very thick. The reaction occurs in from one to two minutes; any change in color or transparency occurring later is of no significance. Schürmann has corroborated the specificity of his test by performing parallel reactions according to Wassermann's method.

Specific Therapy and Wassermann's Reaction.—Purckhauer says that in general specific treatment of syphilis changes a positive Wassermann reaction into a negative one, but such results cannot be expected to take place in every individual case. Especially the positive reactions occurring in the tertiary stage of syphilis usually persist, although very thorough treatment has been carried out. Even if a negative reaction seemed to have followed specific treatment, the relation of the two is not necessarily a causal one, because changes in the reaction have been noted in the absence of treatment. It is, however, quite possible to use the Wassermann reaction as an index of treatment in early cases of syphilis; specific treatment must be persisted in in such cases, so as to keep the reaction negative, just as it has been before infection or in its early stages. There seems to be no question that early and thorough treatment can cure syphilitic infection absolutely; this is much more difficult, on the other hand, if the infection has been allowed to exist for some time with insufficient treatment or none at all. The persistence of a positive reaction should not always be looked upon as an indication for continuing specific treatment beyond reasonable time. There is no doubt that prolonged intermittent specific treatment is the proper procedure after a syphilitic infection. The introduction of Wassermann's reaction simply corroborated the truth of this conclusion long ago made from clinical observations. The rule should be to treat the infection as early as possible after the diagnosis, and to repeat the treatment at certain intervals, even though no symptoms of the disease are present. Purckhauer's conclusions are based upon the study of several thousand cases seen in Neisser's clinic at Breslau, complete statistical data being given in his paper.

Diagnosis and Treatment of Pancreatitis.—Dreesmann says that the diagnosis of pancreatitis would be made much more frequently if the possibility of the disease is always kept in mind. The disease is certainly not as rare as has been thought; chronic pancreatitis especially must frequently coexist with cholecystitis, enteritis, cholangitis, etc. The author has in one year observed six cases of acute and three of chronic pancreatitis, the diagnosis being made sure by operation in all the cases. The picture of acute pancreatitis is often very characteristic, beginning with colicky pains usually in an obese patient; intense central abdominal pain follows, accompanied by collapse and the vomiting of fluid containing bile. The temperature usually remains normal, while the pulse becomes frequent. These symptoms are followed by tympanites and by the development of ileus. Variations in all these symptoms are, of course, frequent. A tumor mass is but seldom palpable; if present it is felt in the epigastrium or in the region of the gall-bladder, if the head of the pancreas is affected. The blood picture does not help in the diagnosis. The examination of the feces is of importance, for steatorrhea speaks for pancreatic disease if icterus and enteritis may be excluded; a good corroborative finding consists in the presence of undigested meat fibers. The various tests for pancreatic disease cannot be at all considered as specific. Sugar appears but rarely in acute pancreatic disease. The presence of indican in the urine is of no significance, but calcium oxalate crystals and bile are very frequently present and are of some use in the diagnosis. The Cammidge reaction is a help in the diagnosis, but it is not at all as specific as has been claimed. Chronic pancreatitis does not produce such violent attacks of pain as the acute disease, yet often enough it is attended with paroxysms that are quite like those occurring with gallstones, the so-called recurrences after operations for gallstones are very often due to the development of chronic pancreatitis. Acute pancreatitis is usually a fatal disease, the free ferment of the gland being very destructive to the tissues of the peritoneal cavity. The indication, therefore, is to give an avenue of escape to the fluid containing the ferment, which, of course, is best done by operating and then draining the peritoneal cavity. The diagnosis at the operation is made on the presence of fat necrosis or even on the existence of a hemorrhagic exudate. Calcium chloride has been advised by many to be given before and after the operation to diminish the danger of post-operative hemorrhage. Of the 118 cases in the literature, 55 per cent. died; forty of the patients were treated by early operation and drainage, and of them only 20 per cent. succumbed. In chronic pancreatitis dietetic and medicinal treatment must be tried first. If this proves useless, surgical interference must be advised, and, as a rule, the operations upon the bile passages are the most beneficial. The pancreas itself may be decapsulated. On the whole, in both acute and chronic pancreatitis surgery offers much more hope for the patient than conservative treatment.

The Mechanism of Gastric Secretion.—Bickel says that the parenchymatous cells of the stomach are stimulated to activity by substances which circulate in the blood and which are of various origin. This function of the stomach is under control of the extragastric nervous system, impulses from which regulate the secretion by stimulating it or inhibiting it. This explanation of gastric secretion was corroborated by the author in experimenting with pouches isolated from the stomachs of dogs, these pouches being connected with the body only by several blood-vessels. Such nerveless stomachs secreted gastric juice after subcutaneous injections of foodstuffs or after food was introduced into the main stomach cavity. The substances which stimulated the nerveless stomach to secretion must have been contained in the foodstuffs or produced in them after their digestion in the large organ. These facts applied to clinical phenomena compel us to assume that there are two kinds of disturbances of gastric secretion, a gastrogeneous and a neurogenous one. Disturbances of neurogeneous origin may produce a hypersecretion or a hyposecretion of gastric juice, depending upon what set of nerve fibers, stimulating or inhibitory, have been excited by the cause of the disturbance. Experimentally, Bickel has produced hypersecretion by cutting all extragastric nerves in a dog. These facts show the *modus operandi* in the development of gastric disturbances, depending mostly upon general condition of the body or of the nervous system. They suggest too that psychic suggestive therapy has a very important place in the treatment of functional diseases of the stomach. On the other hand, the experimental evidence obtained with the nerveless stomach shows that dietetic treatment is the mainstay in handling gastric disturbances depending upon local changes.

Book Reviews.

Hoppe-Seyler's Handbuch der Physiologisch-und Pathologisch-Chemischen Analyse fur Aerzte und Studierende. Bearbeitet von Dr. H. Thierfelder, a. o. Professor und Vorsteher der chemischen Abteilung des physiologischen Instituts der Universität Berlin. Achte Auflage. Mit 19 Textfiguren und 1 Spectraltafel. Berlin: August Hirschwald, 1909.

Though over fifty years have elapsed since the first appearance of "Hoppe-Seyler," it is still a text-book of the utmost value, and every laboratory worker will welcome the eighth edition. The revision has been carried out by Professor Thierfelder, and its completeness is shown by the fact that the volume has swollen to quite an inordinate size, being over two hundred pages larger than the last edition, published in 1902. The editor has found it necessary to call to his assistance a number of other workers in the field of biological chemistry, who have taken up the revision of those portions of the book whose context has been the subject of their special studies. The subject matter has been brought down to the latter part of 1908, and it is interesting to note that a good many analytical methods recently published in this country have been included. The book still remains without a serious rival as the best laboratory guide to the analytical methods of biological chemistry.

Medical Reports of the Central London Throat and Ear Hospital. Vol. I. Pp. 134. London: Adlard & Son, 1909.

This book opens what bids fair to be a most valuable series of hospital reports. We note as of special suggestiveness, the papers by Dr. Dundas Grant on "The Retention of the Matrix in Operations for Cholesteatoma of the Middle Ear," Dr. Dan McKenzie on "Adenoids, Deformities of the Palate and Artificial Infant Feeding" and Dr. B. Kingsford on "A Review of Twenty Thousand Administrations of Anesthetics for Operation on the Throat and Nose."

Larynxtuberculose und Graviditaet von Dr. R. Sokolowsky, Koenigsberg. Halle: Carl Marhold, 1908.

This pamphlet presents the relations of pregnancy and laryngeal tuberculosis along the usual lines, and closes with a comprehensive bibliography. The general conclusion is that the prognosis of the laryngeal condition on the occurrence of pregnancy is most unfavorable except in case of laryngeal tuberculomata and when the first laryngeal manifestations come on during the latest weeks of pregnancy. In general the occurrence of pregnancy under the conditions of laryngeal tuberculosis calls for artificial emptying of the uterus.

Maladies des Organes Génito-Urinaires de l'Homme et de la Femme. Par R. Le Fur, Ancien Interne des Hôpitaux de Paris; et A. Siredey, Médecin de l'Hôpital Saint-Antoine. Avec 68 figures intercalées dans le texte. Paris: J. B. Baillière et Fils, 1907.

This is the twenty-second volume of Brouardel and Gilbert's System of Practice and Therapeutics; and it is the first time that we have seen the genitourinary disorders of both male and female treated in the same volume. The first part deals with urethritis in the male, in the female, and also in children. Prostatitis is next considered; then cystitis and other bladder disturbances, incontinence of urine, and urinary infection and intoxication. Orchitis and epididymitis are then discussed; and this section concludes that part of the volume which treats of the disorders of the male. The gynecological part has sections on menstruation, uterine congestion, infections, inflammations, tuberculosis, cancer, fibroids, and pelvic hematocele. It will be noticed that venereal diseases are not included in this volume.

The Body at Work. A Treatise on the Principles of Physiology. By Alex Hill, M.A., M.D., F.R.C.S., some time Master of Downing College, Cambridge. With 46 illustrations. London: Edward Arnold, 1908.

This book is not intended for either the physician or medical student, but for the ordinary educated layman who has not had preliminary training in biology, chemistry, and physics. The author describes the phenomena of life, and the principal conclusions which have been drawn as to their interdependence and as to their causes. Although the book is not put forth as an introduction to the systematic study of physiology, nor yet as an aid in the preparation for professional examinations; yet, we think that a medical student at the end of his first or second year would benefit greatly by a perusal of this admirably written volume. The author's style is particularly lucid and entertaining; while his recognized authority as a physiologist leaves nothing to be desired on the score of scientific accuracy. The author's statements are clean cut and dogmatic, expressed in forcible and spirited language; and the result is a definite and permanent impression on the reader's mind. The book is well printed, in large type, on thick unglazed paper of light weight, and contains sixteen chapters, as follows: Prolegomena; the basis of life; the unit of structure; the fluids of the body; internal secretions; digestion; respiration; the circulation; muscle; the nervous system; smell and taste; vision; hearing; skin-sensations; voice and speech. The only criticism that we have to make, is to express a doubt if the lay reader will understand all the terms employed, *e.g.*, Trichlorlactamide, benzoic alcohol, megacaryocytes, hemophilia, catechin, proteoses.

Tuberculosis of the Nose and Throat, by Lorenzo B. Lockard, M.D., Laryngologist to the Jewish Consumptives' Relief Society Sanatorium, etc. St. Louis: C. V. Mosby Medical Book and Publishing Co., 1909.

The work of Dr. Lockard reveals a vast amount of careful study and is a compendium of the present status of the tuberculosis question as involving the nose and throat. In these days of numerous special journals the text-book is rather a follower than a leader, yet it is a matter of great convenience, particularly to the special worker, to have all pertinent material sifted and collected as the author has done in this book. The illustrations, sixty-four of which are colored, are of unusual merit and not overcolored as is so often the case in representations of lesions on mucous membranes. The author says that complicating lesions of the throat occur in at least one-third of all persons with recognizable foci in the lungs. Autopsies on persons dying of consumption prove that nearly 50 per cent. have tuberculous lesions in the larynx. Experience demonstrates that the majority of such lesions are preventable, that of the lesions already existing one-half can be brought to the stage of arrest, and that in those too far advanced to be arrested, the more distressing symptoms can in the majority of instances be held in partial subjection. The author makes a plea for systematic examination of the larynx in every case of tuberculosis and a surrender of the all-too-common belief that laryngeal lesions are better left alone and that treatment of them will do more harm than good. It will be seen that he takes a hopeful view of the question and his book should be read carefully by all phthisiotherapists.

Les Autoplasties. Lèvres, Joues, Oreilles, Tronc, Membres. Par Ch. Nélaton, Agrégé à la Faculté de Médecine, Chirurgien de l'Hôpital Boucicaut; et L. Omeredanne, ancien Prosecteur de la Faculté, Chirurgien des Hôpitaux. Avec 291 figures dans le texte. Paris: G. Steinheil, Editeur, 1907.

This volume forms one of the valuable series of monographs now being published under the general editorship of Berger and Hartmann. It includes most of the autoplastic operations at present practiced (rhinoplasty is omitted) and is well and copiously illustrated. Cheiloplasty takes up more than half of the work; the other chapters are brief, but sufficient. At the end of the volume there is an unusually full and complete table of contents.

Primary Studies for Nurses. A Text-book for first-year Pupil Nurses. Containing Courses of Studies in Anatomy, Physiology, Hygiene, Bacteriology, Therapeutics and Materia Medica, Dietetics, and Invalid Cookery. By Charlotte A. Aikens, formerly Superintendent of Columbia Hospital, Pittsburg, and of the Iowa Methodist Hospital, Des Moines; late Director of Sibley Memorial Hospital, Washington, D. C.; Author of "Hospital Housekeeping" and "Hospital Training School Methods and the Head Nurse." Illustrated. Philadelphia and London: W. B. Saunders Company, 1909.

In this book the author brings together, in concise form, lessons on those subjects which the nurse needs as a groundwork for the more practical part of her professional education. At the same time the non-essentials are eliminated, with the result that the volume is of reasonable size and its contents are easy of assimilation. The book is well arranged, and should prove popular with first-year nurses, who will find here all they require on the subjects mentioned on the title page. Nurses in general are much more likely to derive benefit from the perusal of a volume such as this one, than they are from a more or less cursory and desultory dip into large and learned works for which they have neither the time nor the necessary preliminary education.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. March 1, 1909. Philadelphia and New York: Lea and Febiger.

With this number, Progressive Medicine enters its eleventh year. The surgery of the head, neck, and throax, is presented by C. H. Frazier, and occupies about one hundred pages. R. H. Preble contributes the article on infectious diseases, including acute rheumatism, influenza, and croupous pneumonia. Diseases of Children is by F. M. Crandall; Rhinology and Laryngology, by D. B. Kyle, and Otology, by A. B. Duel. For the busy physician, Progressive Medicine is the ideal year-book; for it gives in readable form, the gist of all that is of value in the previous year's literature. What is of no value has been carefully weeded out, by competent hands, before the process of "boiling down" is commenced.

Text-Book of Gynecological Diagnosis. By Dr. Georg Winter, O.O. Professor and Director of the Kgl. Universitäts-Frauenklinik in Königsberg, Prussia. With the collaboration of Dr. Carl Ruge of Berlin, edited by John G. Clark, M.D., Professor of Gynecology, University of Pennsylvania. After the third revised German edition. Illustrated by four full-page plates and three hundred and forty-six text illustrations in black and colors. Philadelphia and London: J. B. Lippincott Company, 1909.

In this volume we have the foremost German work on gynecological diagnosis, admirably translated, and edited (with necessary emendations) by a well-known American gynecologist. The result is that this is the most complete work on gynecological diagnosis yet published. The book is divided into three parts, the first devoted to general diagnosis, the second to special diagnosis, and the third to analytical diagnosis. In the first part will be found sections on: External examination, internal examination, combined examination, rectal examination, examination of the genitalia through the bladder, method of using specula, the uterine sound, microscopic diagnosis, cystoscopy, bacteriological diagnosis, and radiography. Part two contains over five hundred pages, and forms the main part of the work. In this part will be found a thorough exposition of every possibility in gynecological diagnosis. In spite of the large amount of material, the arrangement is so orderly that the reader is never bewildered, and the wealth of detail never becomes burdensome. The third part contains only about fifty pages, in which are discussed: The causes of hemorrhage, of amenorrhea, of dysmenorrhea, and of sterility, and analytical diagnosis of abdominal tumors. This part, though brief, is valuable, and with the exception of the last section might be studied before the part dealing with special diagnosis. The book is very readable, and in this respect is unlike many translations. We have detected very few slips; the most important is probably the statement, on page 65, that the gonococcus is Gram positive; elsewhere on the same page it is (correctly) said to be decolorized by Gram's stain. The terms "craurosis" and "vaginism" are unusual, and "cagimismus" is also found in the text; but these are mere specks on a magnificent piece of work.

Hemorrhage and Transfusion. An Experimental and Clinical Research. By George W. Crile, A.M., M.D., Professor of Clinical Surgery, Western Reserve Medical College; Visiting Surgeon to the Private Ward Service of Lakeside Hospital, Cleveland, Ohio. New York and London: D. Appleton & Company, 1909.

This work, by one who has contributed so much of the utmost importance to experimental surgery, is not a text book in the ordinary sense, but is a report of a long series of experimental studies on the phenomena of hemorrhage in man and animals with a full account of the experimental findings and a running discussion from the literature of the subject illuminated by the writer's own conclusions. A special section is devoted to the treatment of hemorrhage and the effect of drugs, especially saline infusion. An interesting comparison is drawn between the effects of acute hemorrhage and shock on the composition of the blood, and the sequelæ of cerebral anemia due to rapid hemorrhage. The second part of the book takes up the question of transfusion, beginning with an historical introduction and followed by the protocols of numerous animal experiments, the author being careful to state that anesthesia was used in all cases in which pain was inflicted. Numerous charts illustrate the changes in blood pressure after various surgical procedures. The effect of transfusion on the urinary constituents in animals is also taken up. Another chapter deals with the remarkable regressions noted in animal tumors after transfusion with normal blood, the work having been done with the cooperation of Dr. S. P. Beebe of Cornell University Medical College. The remainder of the book is given up to reports of clinical cases in which transfusion has been done on human beings. The writer has not hesitated to insert the unfavorable as well as the favorable results which have been obtained by transfusion, and tells of some of the ill-effects which have resulted from transfusion in persons suffering from pernicious anemia and leukemia, and the inefficiency of the transfer of blood in human beings for the cure of carcinoma. Many remarkably successful cases are reported where transfusion was done, either for postoperative hemorrhage, or for continuous loss of blood from gastric or intestinal ulcerations. The work is a very valuable one and incidentally is a most admirable testimonial to the value of experimental work on animals in the advance of our surgical knowledge.

Frühdiagnose und Tuberkulose-Immunität unter Berücksichtigung der neuesten Forschungen: Konjunktival—und Kutan-Reaktion, Opsonie, etc., speziell der Therapie und Prognose der Tuberkulose. Ein Lehrbuch für Ärzte und Studierende. Von Dr. A. Wolff-Eisner, Berlin, Arzt f. innere Krankheiten u. Bakteriologe des stadt, allgemeinen Krankenhauses Friedrichshain-Berlin. Mit einem Vorwort von Geh. Med.-Rat Prof. Dr. H. Senator und Geh. Med.-Rat Prof. Dr. A. Wassermann. Mit 7 farbigen lith. Tafeln, 1 schwarzen Tafel, 14 Kurventafeln, zahlreichen Abbildungen und Kurven im Text. Zweite vermehrte Auflage. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1909.

The appearance within a year of a second edition of Wolff-Eisner's book on the diagnosis of tuberculosis by means of the tuberculin reactions is an evidence of the extraordinary interest of the practitioner of medicine in any procedure which promises a rapid and accurate diagnosis of this disease. The large amount of work which has been done with conjunctival and skin reactions induced by tuberculin is shown by the bibliographic summary of nearly six hundred papers, all of which have appeared within two years. The author considers, first, the method of early diagnosis of tuberculosis, physical examinations, the staining of sputum, and the diagnostic value of the opsonic index; and then turns to the field which he has made peculiarly his own, that of the reactions produced by the local applications of tuberculin. The third part is devoted to an attempted theoretical explanation of these reactions, and the fourth to a consideration of the value of these tests in prognosis and in hygiene. The volume contains a very complete review of all that is known on the diagnosis of tuberculosis, and while somewhat diffuse is the best résumé which we have on the subject. The colored illustrations are quite satisfactory and any one who desires complete information on the subject must consult this book.

Manual of Diseases of the Ear, Including Those of the Nose and Throat in Relation to the Ear. By Thomas Barr, M.D., and J. Stoddart Barr, M.B. Fourth Edition, revised and enlarged. Glasgow: James Maclehose & Sons, 1909.

The authors of this volume are respectively lecturer and assistant lecturer on otology in Glasgow University, and their opinions and methods may therefore be taken as representative of the subject of ear disease as seen through British eyes. There is much that is commendable in this volume, but the method of presentation is not one to encourage industry in the reader. This seems to be due to a too great interweaving of closely related ideas. No subject is fully discussed and finished in any particular section of the book, but bobs up unexpectedly here and there, thus giving a disjointed effect to the whole. Facial nerve paralysis, for instance, is touched upon in thirteen different places, and the labyrinth can be studied only by consulting some forty references in the index. However, the illustrations, 215 in number, are for the most part well done, and help one to a satisfactory understanding of the text. The three colored plates representing various pathological conditions of the drum membrane scarcely give the exact coloring, although they are correct in other details. Formulæ for use in treating nose, throat, and ear are generously supplied in an appendix. The chapters on treatment of the intracranial and vascular complications of purulent middle-ear disease, while good in the main, are scarcely exhaustive enough when we reflect how closely this branch of otology is being studied by aural surgeons.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held March 16, 1909.

DR. F. P. SOLLEY IN THE CHAIR.

A Case of Raynaud's Disease.—Dr. G. A. FRIEDMAN presented a woman, 23 years old, a Russian. Raynaud's disease had never appeared in another member of her family. She had had the ordinary diseases of childhood and had malarial fever five years ago. She denied syphilis. Her hands and feet were involved, and there was anesthesia of one portion of the face. She first noticed that the fingers of the right hand became white and deadlike; the motion was normal but the sensation was lost. The skin soon became blanched. On very warm days during the summer she did not perspire as other people did, and she did not change her underwear as often. The physical examination showed that the skin of the hands, feet, and face was dry and tense. There was a lack of elasticity of the skin, and it was impossible to raise it from the extremities. The skin was also icy cold. The temperature sense was lost, and the tactile sense perverted. The heart's action was normal. No thickening of the arteries could be noted. There was no sugar nor albumin in the urine, but there was an excess of urates. The radiograph showed a certain amount of absorption of the bones of the phalanges. The patient belonged to a neurotic family. She was not a neurasthenic. She had been in perfect health until eighteen years of age, when she had an attack of malaria, taking large doses of quinine. After that attack she developed her present condition. The condition of her four extremities was better during the summer months. The pain sense was lost, not only in the affected parts, but over the whole skin. The small arteries of the fundus oculi showed marked contraction. There was a slight anemia. There were no dyspeptic symptoms, but she did not enjoy her food. A striking feature was the lack of free hydrochloric acid in the stomach contents. Anidrosis was present. In the literature on Raynaud's disease, malaria was spoken of as one of the causes. In this case there was a spasm of the arterioles not only in the extremities, but in the vessels of the fundus oculi as well. Dr. Friedman briefly reviewed the literature of Raynaud's disease.

Dr. ARNOLD STURMDORF said that his interest in Raynaud's disease was purely a surgical one, and dated back eighteen years, when a patient was seen by Dr. Freeman and brought to Dr. Sturmdorf for the purpose of having the fingers amputated. Raynaud's disease was a generic term which presented many clinical pictures. When one studied the literature of the subject with care he must come to the conclusion that the pictures presented could not be the result of one and the same process. There was a slight circulatory disturbance and complete tissue destruction. When one studied the reports of cases he would find all sorts of conditions to deal with, especially in the dermatological field—scleroderma, leprosy, certain organic lesions involving the spinal cord, such as syringomyelia, and diseases of the blood-vessels; in fact, every part of the body might be involved. According to Raynaud's theory, this disease was the result of some irritative lesion, probably in the cord or brain, producing spasm of the blood vessels. The question now arose, What caused the irritation? What deprived the parts of nutrition? He thought that possibly an explanation might be found in a study of the effects of the juices from the ductless glands, especially the suprarenals.

Dr. B. ONUF said he had seen two cases in which he had been struck by a certain etiological factor; rheumatism occurred in both. This discovery led him to investigate this factor as a cause of Raynaud's disease, and he made a tabulation of the cases in which was considered the family history, the previous history, and the results of actual examination. His investigation was conducted with the point in view of establishing a relation of this disease to vascular innervation in general: also, the influence of syphilis, tuberculosis, and other diseases. Dr. Onuf gave the results of forty-three cases taken from the literature and of five of his own cases. With regard to the family history he found that in all cases the importance of the rheumatic element as a cause was confirmed. In four out of his own five cases the patients had had acute articular rheumatism, gout, or arthritis. In the fifth case there was a history of myalgia, and he was not certain whether this was rheumatic or not. The histories of the cases in the literature were very meager. The cases occurred more often in the neurotic families, and family heredity played a rôle. Very interesting points were brought out regarding the previous history; in twenty out of the forty-eight cases, or about 40 per cent., there were disturbances of the vascular innervation. This showed that vascular innervation and Raynaud's disease bore a close relationship one with the other. There was a history of rheumatism in ten out of the forty-eight cases, or about 20 per cent. There appeared a predominance of the cases of hysteria. Most important of all the exciting causes, it seemed to him, was the influence of cold or low temperatures, not acting locally, but generally; this exposure showed a reflex rather than a direct action. The next frequent cause appeared in the neurotic cases. Again, depressing factors were particularly important in producing these attacks. With regard to the frequency with which the parts were involved, the fingers and toes were mostly affected; then the forearms, legs, thighs, etc. Raynaud's disease, with asphyxia, gave a graver prognosis than the gangrenous form. Females were more often affected than males; among the forty-eight cases there were thirty females and fourteen males. Dr. Onuf then described some of the general characteristics of the disease.

A Case of Abscess (Pneumococcus) of the Lung.—Dr. R. H. HALSEY presented a man, 30 years old. Last June he complained of cough, and he expectorated an excessive amount of very foul sputum. Because of this he was unable to work, and was brought to the hospital. He had been perfectly well until one year before, in June, 1907, when he was relieved of an obstruction in the nose, a turbinate operation being performed. He took a general anesthetic. He left the hospital the day after the operation and was very miserable for some time. Two weeks after he developed a cough which had continued until the present time: with this cough was the very foul sputum. In January the amount of sputum expectorated was from 600 cc. to 650 c.c. in twenty-four hours. He had had different treatments, had gained ten pounds in weight, and was practically well, so far as his general condition was concerned. In January, in order to show the condition on the right side, namely, an abscess just below the third rib, and to guide the surgeon, an attempt was made to *x*-ray the chest and get a radiograph. This failed, and a second attempt was made. Two days after this last attempt the amount of sputum expectorated dropped from 650 cc. to less than 100 cc. It was thought that possibly this was the effect of the *x*-ray treatment, and several treatments had since been given. The sputum expectorated since was not so great. The pneumococcus, and not the tubercle bacillus, was found. The Calmette, von Pirquet, and the Morro tests all proved negative, thus ruling out any tuberculous infection.

A Case of Cerebral Hemorrhage Following Arteriosclerotic Granular Nephritis Mistaken for Cerebral Embolism; Microscopical and Gross Specimens Shown.—Dr. BOND STOW reported this case and presented the specimens. (See page 846.)

Dr. Theodore C. Janeway reported the case of a man with tuberculosis of the lungs, cirrhosis of the liver, normal kidneys, small heart, and a low blood pressure, who was suddenly seized with unilateral convulsions, hemiplegia and death within twenty-four hours. In this case one would have felt justified in stating that this was the result of a thrombus. At autopsy there was found a hemorrhage in the occipital lobe and in the posterior horn of the lateral ventricle.

Demonstration of a Practical Hospital Polygraph.—Dr. T. B. Barringer gave a demonstration of this instrument, which he had used in Bellevue Hospital with success.

Edema of the Lungs; a Suggestion for Treatment Based Upon Experiment.—Dr. Haven Emerson said that he had found in a course of experimental tests upon rabbits and cats that edema of the lungs, caused by acute cardiac failure resulting from the extreme peripheral vascular constriction in adrenalin poisoning, could be successfully treated by the use of artificial respiration. The physics of this procedure had much to recommend it as an effective means of assisting an obstructed pulmonary circulation. Ample respiratory movements materially assisted in the passage of blood from the right to the left heart, and as edema was often due simply to a failure of the right heart, artificial respiratory movements might be expected to serve as an effective adjuvant treatment to the usual stimulation with drugs. Only such cases were likely to be helped by such a procedure as were of acute occurrence, or had taken place as a result of some brief and removable increase in the burden of the circulation.

Edema of the Lungs Treated by Artificial Respiration.—Dr. T. B. Barringer, Jr., reported a case of edema of the lungs treated by artificial respiration. The patient was a woman, 47 years old, who had had for a number of years a well compensated mitral stenosis, arising from a rheumatic endocarditis. Early one morning an attack of cardiac insufficiency came on, accompanied by a rapid, irregular pulse, dyspnea, cyanosis, and marked pulmonary edema. Hypodermic stimulation was given and artificial respiration was carried out. During the employment of the artificial respiration the patient coughed up large mouthfuls of frothy, blood stained sputa, and at the end of an hour the pulse had slowed, and the signs of pulmonary edema had markedly decreased. In forty-eight hours the patient had entirely recovered.

Dr. Walter Mendelson said, in discussing Dr. Emerson's paper, that before entering into the question of the rational treatment of edema it might be well to first consider the causation of dyspnea and hence of edema. Normal respiration was interfered with as soon as the velocity of the blood current was slowed, or the normal pulmonary blood pressure altered. When the right ventricle was weakened a slowing of the current resulted in low blood pressure, and consequent dysponea and edema. Clinically, however, the most frequent heart condition leading to edema was an incompetent left ventricle with a hypertrophied right ventricle. In this case the blood was dammed back in the lungs by the ventricular incompetence, with a necessary slowing of the current and with a high blood pressure against which even the hypertrophied right ventricle contended in vain. Another very important element in the causation of dyspnea and edema was the turgescence of the pulmonary capillaries, with consequent rigidity of the lung, which occurred in pulmonary congestion, and upon which von Basch had laid so much stress. Here the lumen of each air vesicle was seriously encroached upon by the turgidly dilated capillaries. In considering the probable effect of artificial respiration upon these conditions one should sharply differentiate in his mind between the positive pressure respiration of the laboratory and the negative pressure respiration (Sylvester's method) which one was obliged to use clinically. It was easy to see how the pressure exerted by the bellows on the pulmonary pressure (laboratory) method would compress and empty the turgidly congested pulmonary vessels, thus accelerating the current and reducing the blood pressure to normal. Very different, however, might the condition be with the negative pressure (Sylvester's method). Here, when the bellows were raised and a negative pressure was obtained in the chest, the blood—and that, too, from both sides of the heart—as well as air was aspirated into the chest, and *a priori* the result obtained would depend on whether the mitral valve was competent or not. If it was competent, then the compression of the chest which followed the raising of the arms must tend by positive pressure to drive the blood in the natural direction of its current and by so much as it accelerates it to overcome the dyspnea or edema. Possibly another explanation might be advanced as to the effects of artificial respiration upon edema, namely, that the muscular exertion, by diverting blood from the lungs to the muscles, relieved the work of the heart, on the well known principle of Schott. In this way its effects might be ranged with those of cupping, mustard foot baths, and the use of vasodilators, etc.

Dr. N. R. Norton called to mind a case he saw years ago, where the resort to Dr. Emerson's method, for another purpose than the relief of edema of the lungs, appeared to have been productive of good. In 1896, at the Presbyterian Hospital, a woman was brought in suffering from acute carbolic acid poisoning; she was in collapse, and had edema of the glottis and lungs and central depression of respiration. Sylvester's method was used, as well as inhalations of nitrite of amyl. Because of the edema of the glottis, artificial respiration was employed, and inside of ten minute the cyanosis disappeared and the pulse came up to about 90. The use of the soluble sulphates by mouth, together with artificial respiration, was followed by the recovery of the patient.

Dr. S. J. Meltzer said he was inclined to believe that artificial respiration in pulmonary edema might be of value. Pulmonary edema had two factors which might prove dangerous. The greater danger was from the presence of fluid in the bronchi of the lungs, and this had the same effect upon the individual as the water in cases of drowning. In such cases artificial respiration was of value. The second danger was in the constant production of the edema, and how could one explain why artificial respiration was of value here? Dr. Meltzer said he thought he was the first one to observe and describe the production of edema by the use of adrenalin. He had had a great number of animals, rabbits, and not cats and dogs. Many of these rabbits with pulmonary edema he tried to save by artificial respiration, but he could not save one of them; the only ones that were saved were those who were not treated by artificial respiration. He did not believe that one was justified in coming to the conclusion that this method would help in all cases. In Dr. Emerson's paper mention was made of the production of edema by the use of adrenalin, and it was a fact that many consultants in this city advised the giving of adrenalin in pulmonary edema. In a discussion in Washington a few years ago he said he was surprised to hear a man say that patients with pulmonary edema, when given adrenalin, got well. They got well in spite of the adrenalin. Dr. Meltzer advised against the use of adrenalin in cases of pulmonary edema.

Stated Meeting, Held April 20, 1909

Dr. F. P. Solley in the Chair.

Specimen of a Large Mass of Tartar Containing Many Teeth.—Dr. C. N. B. Camac presented this peculiar specimen. The patient was a woman, 60 years old, who had

a tumor mass of the lower jaw, extending from the last molar to the canine tooth, about three inches. It was painless, moved readily, and was attached by a small pedicle. A number of physicians and surgeons had examined it and pronounced it to be a sarcoma. She at first refused operation, and was kept under observation for a time. The tumor did not grow larger. She finally consented to operation. When she was about to be moved to the operating room the house physician took hold of the mass and pulled it off. No bleeding followed this procedure. An examination of this mass showed it to be a collection of tartar containing many teeth. The chief interest in this case rested in the mistaken diagnosis. The absence of pain, the absence of bleeding after removal, and the absence of glandular enlargement were indications against the tumor being malignant.

Specimens of Mucous Cast.—Dr. Camac presented a very long mucous cast which was passed by a patient with a mucous colitis, complicated by carcinoma of the liver. He also presented another specimen which was passed by a patient suffering from a mucous colitis. The form of the cast was somewhat like that of a cast from the respiratory tract; it was knotted. This emphasizel the necessity of giving colonic irrigations when there were vomiting and attacks of indigestion. A point of interest in this case was the presence of chronic cardiac disease. The patient had a mitral stenosis and she had fearful experiences with her attacks of pain and vomiting. There was a certain amount of periodicity in these attacks; they usually occurred about 2 A.M. Many diagnoses had been made, among them being angina pectoris and gastric ulcer. Since she had received colonic irrigation she had been free from these attacks for three years.

The Clinical Index of the Thorax Associated with Pulmonary Tuberculosis.—Dr. Walter L. Niles read this paper. He said that until very recently almost all the textbooks on medicine and physical diagnosis had described the thorax associated with pulmonary tuberculosis as flat, a curious survival of a medical fallacy which had apparently persisted simply because no one had measured any considerable number of such patients. Most of the chests did appear flat, it was true, but taking measurements on a few would show that in most cases the flattening was not real and the appearance was an illusion. Hutchinson reported in 1897 his findings in 20 tuberculous chests, and was convinced that the average tuberculous chest was not abnormally flat, but was, on the contrary, abnormally round. Measurements of the diameters of the chest were made on an imaginary horizontal plane passing through the junction of the fourth costal cartilages with the sternum. Dividing the anteroposterior diameter by the transverse diameter gave the ratio which the former bore to the latter, and was called the "clinical index" of the chest. Hutchinson's first series of 20 cases of pulmonary tuberculosis, representing all stages of the disease, gave an average index of 78. He subsequently reported 350 cases collected by him from various observers which showed an average index of 79.7. Dr. Niles's report was based upon a study of 1022 measurements made on tuberculous patients in the Bellevue Hospital and the Cornell University dispensaries. The subjects examined belonged to several races, and included both sexes and all ages from 8 to 84 years, in all stages of the disease. The average clinical index of all the cases was 75.98. In order to remove all possibility of error through the inclusion of normal infantile chests, he had excluded all under 20 years of age, leaving 929 patients; these gave an average index of 76. Sex was practically no factor in modifying the indices of tuberculous chests. Separating his cases into stages of the disease, he found that, though the average indices of the second and third stages were slightly higher than that of the first stage cases, the difference was so slight that it might be disregarded. Classifying the cases by decades of life, it was shown that the higher indices after the fourth decade were probably accounted for by the emphysema which normally developed with advancing years. What was the cause of the abnormal relations of the diameters of the chest which existed in three-fourths of the individuals who later developed pulmonary tuberculosis? Hutchinson's conclusion that it was due to an arrest of development seemed to be well founded. It was a fair conclusion that the typical tuberculous chest was one which had been arrested in its development at or about puberty. High indexed chests were frequently associated with various forms of so-called degeneracy, which were really conditions of maldevelopment. If high indexed chests predisposed to pulmonary tuberculosis, as had been claimed, it was possible to lessen this predisposition by exercises which tended to produce an increase in the transverse diameter, such as climbing, swinging by the arms, and movements laterally from the body. It also created the presumption that it might not be best to prescribe for patients with pulmonary tuberculosis exercises which tended to develop deep chests. The following conclusions were offered: (1) The typical tuberculosis chest was more nearly round than the normal chest. (2) The increased index preceded the development of tubercle infection in the lungs. It was due to an arrest of development at or about puberty and predisposed to pulmonary tuberculosis. (3) Abnormally high indexed chests in children should be corrected by proper exercises.

Dr. Woods Hutchinson said that it was curious to see to what extent Dr. Niles's findings had disproved the former beliefs regarding the measurements of the tuberculous chests, and he was gratified that the results had substantiated his own. The only basis for the claim that tuberculous chests were flat was to be found in a statement and cut published in a textbook forty-five years ago; no measurements nor any proofs of the correctness of the assertion were offered. Until quite recently this false statement was accepted, but when measurements were taken the incorrectness of the statement was made apparent. In his first series of 20 cases of tuberculous chests he said he had the expectation of finding them "superhuman" chests, or flatter than normal, but in that series, and in the examinations subsequently made, he found that these chests were round, and not flat, and they were due to an arrest in development. Chest measurements by various observers on both sides of the Atlantic to the number of some 750 had now been obtained, but Dr. Niles's contribution was far the longest series and a most valuable addition to the science of medicine. The tuberculous chests, while originally somewhat high, gradually tended to become higher and higher through the action of the muscles of respiration. The deep, or well developed, or roomy chest noted in the racehorse or in quadrupedal life did not belong to the human being. In the newborn infant there was the roomy chest like the chest of a prizefighter, the round, expanded chest. It was the quadrupedal chest which was normal in the infant. It was shown that 20 per cent. of the cases were below the normal index and 18 per cent. were under 68. In the inmates of hospitals, asylums and almshouses the index was likely to be higher than in the well to do—about 72 or 73; this was about the same as was found among soldiers. In city gymnasia the index dropped to about 69. At Harvard and Yale colleges it was 68.6. The further "humanization" of the chest occurred as one went higher in human society. One of the greatest things of value in connection with the index was in connection with developing children; when a child's index was above what it should be, he should be regarded as below par and there should be begun vigorous treatment in the open air and abundant feeding. The many procedures which aimed at throwing out the chest were unnecessary and often injurious, for the healthy chest was flat; the tuberculous chest should be kept at rest.

Dr. C. N. B. Camac made a strong plea for more earnest attention to clinical detail in diagnosis, such as was shown in Dr. Niles's paper.

Dr. S. A. Knopf thought that too little stress was laid upon the value of breathing exercises in pulmonary tuberculosis. In the quiescent stage, when there was a great deal of mucus, he knew of no measure productive of better results than deep breathing; as the air entered the lungs it caused a detachment of this mucus, causing a more frequent expectoration. In the early stages of the disease any exercise taken that did not tire the patient, including the breathing exercise, was advantageous. As a prophylactic measure in badly developed children, he favored breathing exercises. Children who were obliged to sit still in school were much benefited by these exercises when they went out doors.

The Influence of Glycosuria and Diabetes in New York City Between 1902 and 1907, with a Report of Two Cases of Essential Pentosuria.—Dr. T. B. Barringer read this paper. He said that there were sixteen among 71,729 applicants for insurance in a certain company in which pentose was found. Subsequently he visited eleven of these and secured twenty-four-hour specimens of urine. Nine specimens were negative, the subjects having originally been affected with alimentary pentosuria. The insurance company's examinations had been made chiefly during the summer months, and had also shown an absence of pentose on the succeeding day, when a second analysis was made. The greater consumption of fruit containing pentose during the summer months explained the origin of these cases. Two of the men showed pentosuria on repeated examinations. The first was a dentist, thirty-seven years old, in excellent health. He generally showed about 0.5 per cent. of a reducing substance, estimated as dextrose, in the twenty-four hour urine, which was identified as a pentose, by means of Bial's test, the spectroscopic reaction, and the melting point of the osazon between 150° and 155° C. The second man was a clerk, seventeen years old, in good health, and he showed constantly about 0.3 per cent. of pentose. Dr. Barringer was unable to carry out any metabolism experiments on these cases or to investigate the members of their families. In summarizing he said that (1) the incidence of diabetes in New York City reached the surprising figure of 1,895 cases per 100,000 population. (2) A large proportion of the cases of transient glycosuria were harmless and did not cause death. (3) Diabetes generally began as a slight intermittently appearing glycosuria, which gradually became more and more marked, until finally it was constantly present.

Dr. Hart said that cases of pentosuria were exceedingly rare, and that he had seen but one case. The condition was not a dangerous one, and the chief interest was concerned with the diagnosis and in the possible rejection of such patients by life insurance companies.

Dr. Henry S. Stark asked how soon the diagnosis of diabetes could be made; of course, the sooner the better. In the early detection of diabetes, the hereditary tendency should always be considered. This was an important and valuable aid, and he wished to lay much emphasis upon it. Ten years ago Dr. Stark pointed out the necessity of having the urine of every individual over thirty-five years old examined, and this should be done as a routine matter, the same as one consulted the dentist. Personally, he was of the opinion that in 90 per cent. of the cases of diabetes the disease started as an alimentary or transitory glycosuria; this continued and might run into a permanent condition. With regard to pentosuria, seven years ago in a paper on "The Treatment of Diabetes" he asked what was its clinical significance. Reasoning by analogy, pentosuria must exist, and it was surprising that it had not been discovered before. He also had read a paper on "paradiabetes," an anomalous type of diabetes, which was the counterpart of paratyphoid; in this glucose was never discovered in the urine. In other words, in paradiabetes there were the subjective symptoms of diabetes, but there was found no glucose in the urine.

Dr. Barringer called attention to a paper written some time ago in which he followed twenty cases of transitory glycosuria; at the end of five years he found that one-half of them had escaped the disease. No sweeping deductions could be made, but he found that there were two types of glycosuria, the harmless and the diabetic. A large proportion of the cases of glycosuria did not develop diabetes. A great difficulty was encountered in attempting to determine which was the harmless and which the diabetic type. Any man with less than 1 per cent. of sugar in his urine should be given the glucose test, which should be repeated month after month until no reaction appeared; with each monthly appearance of glucose in the urine after this test, however, there should be a greater suspicion of the disease, true diabetes, being present.

SECTION ON SURGERY.

Stated Meeting, Held April 2, 1909.

Dr. John F. Erdmann, Chairman Pro Tem.

Large Gastric Ulcer, Hour-Glass Stomach, Adherent Pancreas Closing Extensive Defect in Posterior Wall; Gastroplasty.—Dr. W. S. Schley presented this patient, a woman twenty-nine years old, who was admitted to the hospital February 8 and was discharged March 18 of this year. Six months prior to admission she lost her appetite, had indigestion, and was run down from overwork. Soon she was unable to retain solid food and vomited regularly after meals. She had pain in the epigastrium and hypochondrium after eating, and she belched up much gas. At no time was there blood in the vomitus. She was in the Newport Hospital from September 14 to November. Since coming to New York the pain had continued and had been very severe at times. The bowels were constipated, the stools dark in color. For several weeks prior to her entrance to the hospital there had been no vomiting. The pains were worse at night and shooting to the left shoulder and hip, and were accompanied with some fever. The pain was worse when she stood or lay on the left side. When admitted she had thin and shrunken abdominal walls, with moderate epigastric tenderness, but marked tenderness over the left upper rectus with reflex spasm. There was no palpable mass. The gastric analyses showed diminished hydrochloric acid and diminished digestive power. At operation the anterior wall of the stomach was found adherent to the abdominal wall under the left rectus muscle by a dense old cicatrix an inch and a half in diameter. This was separated with the knife. The stomach showed a marked hour-glass contraction at this point. On releasing the stomach from the abdominal wall, an opening was found, two and a half inches in diameter, extending into the lesser curvature and gastrohepatic omentum, and through this the stomach interior could be easily explored, and extending from its margin down the posterior wall and nearly to the greater curvature was noted the continuation of the ulcer. The pancreas was found to be adherent to and closing in the greater ulcer area on the posterior wall of the stomach, as the abdominal wall had done in front. The cicatrizing ulcer area attached to the abdominal wall in front and the pancreas behind drew the two together, displacing the latter. The patient's condition and the adhesions and anatomical derangements seemed to indicate a gastroplastic closure with a gastroenterostomy if the closure by this scheme did not sufficiently enlarge the opening between the two stomach sections. The edges of the ulcer were excised and the opening closed at right

angles to the long axis at the upper end, and suturing over the lesser curvature it was necessary to include the investment of the pancreas and some pancreatic tissue in each stitch, as the stomach walls were closely adherent to the pancreas from this point downward, and a separation of the stomach from the pancreas would only have meant a still further enlargement of the already large defect. After the closure in this manner, it was found that three fingers could be invaginated through the opening. Her condition seemed to contraindicate any more prolonged work, and the abdominal wall was closed, leaving a very small cigarette drain to the upper end of the stomach. She made an uninterrupted recovery. The ulcer evidently started near the lesser curvature and extended down the anterior and posterior walls, becoming adherent before perforation.

Cysto-Meningo-Myelocele.—Dr. A. A. Berg presented this patient, nine months old, who was admitted to Mt. Sinai Hospital last December with a tumor in the upper part of the sacral region, the size of a small orange. The skin over it was normal. The tumor was not fixed. The center of the tumor was more thickened than was the periphery, and there was fluctuation. The legs were not paralyzed. There were no congenital deformities. Because of the increase in the size of the tumor, interference was called for. He cut down upon it with the idea of at least removing it and, if the child's condition permitted, to do a radical operation for the relief of the spina bifida. A large cystic tumor was exposed, filled with a clear, translucent fluid. The walls were much thickened, and at the margin of the sac were found some terminal filaments of nerve trunks. Inside of this sac was found a second tumor, cystic in nature, the size of a small crab-apple, the walls of which were formed by nerve trunks. It contained translucent material, which was evacuated. The child's condition became bad and, therefore, the external wound was rapidly closed after removing the redundant tissue. At present there was considerable thickening present. The defect in the spinal canal was about the size of a fifty-cent piece and was easily palpated. A radical operation could not be done.

Perforated Diverticulum of the Cecum.—Dr. A. A. Berg presented a man who had been at the Mt. Sinai Hospital under Dr. Brill's care during January. He was well up to one week before his admission, never having had any abdominal pain previous to that time. His bowels moved regularly. He first had pain in the right iliac region and a moderate temperature, and he vomited once or twice after taking medicine. It was believed that he had a subacute form of appendicitis. Upon opening the abdomen the omentum was found to be surrounded by moderately firm adhesions, and there was a tumor in the right iliac fossa, soft, but not impressing one as being of carcinomatous nature. The appendix was free and the ascending colon normal. In the external lateral wall of the cecum was found a perforation, the size of a lead pencil; through this opening was seen a dark mass, which was believed to be a neoplasm, at the ileocecal junction. An exsection of the intestine was made at this junction, and an anastomosis was established between the ileum and transverse colon. Whether this was a congenital diverticulum or not was difficult to say. This was a rare instance of a diverticulum in the cecum.

Dr. Clarence A. McWilliams said that this case showed that one should be most careful in making a diagnosis, and he recalled the case of a man who presented symptoms of an acute appendicitis, with a temperature of 103°, and with a mass in the appendical region. He cut down upon it and found that this mass consisted of a thickened cecum; the walls were about one-half an inch thick and there appeared to be a neoplasm. An excision was done, and the man died. The microscopical examination showed that this mass was simply an inflammation of the cecum, and the appendix was found to be normal. In the cecum were found four or five ulcerations. This was a case of acute typhlitis. In the future, in cases of this character, Dr. McWilliams said he would have sections examined before doing anything. An acute diverticulitis was a very puzzling affection, especially when in the lower part of the intestine.

Mesenteric Thrombosis with Gangrene of the Intestine.—Dr. A. A. Berg presented an Italian, who was brought to the hospital with the history that, five days prior, he had suffered with intense abdominal pain. He denied any venereal history, and he was not addicted to the alcohol habit, and did not use much tobacco. There was no etiological factor in the patient's history or in his physical condition at the time of admission to explain the conditions that were found. His chief complaint was the abdominal pain. His bowels had not moved in three days, and he had a slight elevation of temperature. No blood had appeared in his stools and he had not vomited. The abdomen was moderately distended and fairly rigid. Although he gave the impression of being a sick man, a diagnosis of acute abdominal disease was not clearly made out. The appendicular region was particularly tender. The blood count was low. The polymorphonuclears were practically normal. Attempts to move the bowels were unsuccessful. A diagnosis of intestinal obstruction from an unknown cause was made, and an exploratory incision was decided upon. The abdomen was found to be filled with a bloody serum. A purplish colored intestine was noted which corresponded to the terminal end of the ileum. The mesentery of the ileum was found to contain soft, firm glands. Thrombi were found in the veins. There was no pulsation in the vessels corresponding to the infected area. The superior mesenteric artery pulsated. An exsection of the intestine was performed, an anastomosis established, and an uninterrupted convalescence ensued.

Combined Tuberculosis and Carcinoma of the Stomach.—Dr. H. M. Lyle presented a man, forty years old, a porter. One brother and one sister died of pulmonary tuberculosis. He had lues sixteen years ago. He had a mild cough, with some expectoration. About five months ago he began to complain of a dull pain in the region of the stomach and a moderate amount of gaseous distention, which had continued to increase. About four months ago he began to vomit, and this had persisted. Vomiting always took place from three to four hours after eating. The vomitus was large in amount, consisting of stomach contents and undigested food. Constipation was marked and he lost flesh and strength. On admission he was found to be much emaciated, weighing about one hundred pounds. There was possibly an old tuberculous lesion at the right apex of the lung. A hard, firm mass, about the size of a walnut, was found in the epigastric region to the right of the median line. It moved with respiration. The lower border of the stomach was two fingers' breadth below the umbilicus. A partial gastrectomy with gastro-jejunostomy according to the plan of Billroth's second operation was performed. The parts removed included a portion of the duodenum, the pylorus, and a portion of the stomach, with corresponding glands. An uneventful recovery followed. He was now in good condition and at work. The pathologist reported the specimen to be a diffuse carcinoma of the stomach and tuberculosis of its mucosa.

Extensive Third-Rail Burn of the Back.—Dr. J. J. Moorhead presented a laborer who was working in a manhole repairing the "channel rail" of one of the surface roads, the current of about 250 volts being turned on. In some manner he fell against this charged rail, so that his back contacted at about the lower scapular level, his feet being grounded on concrete. He remained in that position several minutes, and when released was found

to have a third degree burn that practically escharred his back from the midscapular to the lower lumbar region, and it was said that the burn reached far enough to expose the underlying viscera. He suffered profoundly from shock and was unconscious, and his recovery was protracted; and even at this date, six years later, there was an unhealed area about 3 x 4 inches in the central portion of the scar. Some months later, when Dr. Moorhead saw him, he had a butterfly-shaped scar in the involved area, in the lower portion of which was a lumbar hernia. The scar had contracted enough at first almost to draw the wings of the scapulæ together, and spinal flexion was impossible; but by continued self-bending and manipulation of his back he so far recovered as to be able to resume some manual labor. He at no time developed a traumatic neurosis. An interesting point was that he had never had any skin grafting done.

Dr. George A. Peck of New Rochelle presented a man who had received 11,000 volts while working on the New Haven Railroad. He was made insensible. He presented a severe burn on his index finger and the space between it and the middle finger. These slight injuries from high voltage he considered very remarkable.

Phagedenic Ulceration of the Abdominal Wall.—Dr. H. A. Haubold showed, for Dr. Luckett, a patient who had an ulceration which involved an area of ten and a half by six and a half inches which was the result of what was now seen very rarely, hospital gangrene. This was cauterized, and healed without any grafting being done.

Spina Bifida Occulta.—Dr. Walter M. Brickner reported two cases in young women, both operative. In both the symptoms were limited to the left lower extremity. The first patient was a Swede, aged nineteen, who since her twelfth year had suffered from ulceration and bone necrosis, successively involving all the toes of the left foot. Recently there developed perforating ulcers of the sole and necrosis of corresponding metatarsal bones. Examination showed a congenital lipoma symmetrically situated over the lumbar spine and dissociated sensory paralysis (left side) corresponding to the fourth and fifth lumbar, and first, second, and third sacral cord segments. A diagnosis of spina bifida occulta was corroborated by skiagraph, which showed absence of the left lamina of the fourth lumbar arch. (A lesion at that level would involve the posterior nerve roots corresponding numerically to the cord segments mentioned.) The speaker operated in July, 1908. The lipoma was found unencapsulated, finely lobulated, and almost free from fibrous tissue—characteristics of congenital lipomata. Issuing from an opening to the left of the fourth lumbar spinous process was found a meningocele adherent to the surrounding fat and containing a bundle of nerve roots, sharply angulated near the apex of the sac. These were reduced into the spinal canal, the sac was ablated, the dural opening was sutured, and the hiatus was closed by fascia. Since the operation tactile sensibility had been completely restored, and the thermal and pain sense had improved; but the trophic ulcers, which had slowly healed, had recurred, and bone necrosis continued. There were never any motor, vesical, or rectal symptoms.

The second patient was a German, aged twenty-six, who had suffered since her nineteenth year with attacks of pain in the left leg and foot, followed by the spontaneous appearance of ulcers in the calf, heel, or sole, which suppurated and healed slowly. There had been ulceration and bone necrosis of all the toes of the left foot except the first, requiring their successive amputation. No motor, bladder, or rectal symptoms. Over the upper end of the sacrum was a slight, irregular, apparently fatty prominence, at the left extremity of which was a small collection of fine, short hairs. Both the prominence and the hairs would escape all but a close scrutiny. There was on the left side dissociated sensory paralysis corresponding to the fifth lumbar and first to fifth sacral cord segments. The *x*-ray showed a large hiatus at the site of the first sacral arch, most marked on the left side, and asymmetry of the fifth lumbar arch, which arch was complete, however. At operation, September, 1908, by Dr. Elsberg, the fat was found of the same characteristics as in the first case, but much less abundant. A triangle of the lumbar fascia over the upper end of the sacrum was circumcised and lifted up with a mass of connective and fibrous tissue beneath and adherent to it. This tissue was seen to lead down and be attached to the slightly bulging, pulsating dura mater, seen through the large hiatus in the bone. No opening was seen in the dura. It was incised, and the nerve roots within were found floating free. The dural incision was sutured, and the opening closed over by muscle. Since the operation there had been slight improvement in the sensory paralysis, but the patient still had attacks of pain in the extremity; there were now two superficial ulcers on the calf and a superficial plantar ulcer; and from time to time since the operation she had had partial incontinence of urine and feces. Charts and photographs of both cases, showing the lesions at various stages, the dissociated anesthesia, *x*-ray tracings, and steps of the operations, were projected on a screen, and reduced stereoscopic skiagraphs of the spine were exhibited.

Virchow, who coined the term spina bifida occulta, was credited with the first report of a case in 1875, but the speaker had found records of two earlier cases. He had accumulated reports of in all about eighty-five cases, not including doubtful or spurious cases or cases of spina bifida anterior—which, properly, were also "occult." Of the eighty-five cases, some were in fetuses, some in children, most in adolescents and young adults, a very few in older persons. About a dozen were operated upon, and these, with the postmortem studies of other cases, furnished the anatomical pictures of the spinal conditions. Heredity played no rôle and coincident congenital deformities were rarely found. A few cases presented no symptoms, but many of these were in children and not unlikely developed symptoms in adolescence. The common symptoms were: incontinence of urine or feces, or both, and, in the lower extremities, atrophies, palsies, clubfeet, joint weakness, disturbed reflexes, anesthesia, trophic ulcers (feet, legs, buttocks). The lesion being almost always in the median line, both lower extremities were ordinarily involved, and Brickner's cases were unusual in the laterality of the lesion and the symptoms. The development of the symptoms during adolescence was generally attributed to the unequal growth of the bones and of the spinal cord, causing traction at the site of the lesion. This would not, in itself, account for all the symptoms. In two cases perforating ulcers appeared at the age of two. The ulcers and dissociation of the sensory paralysis (the latter a point to which little attention had been given in the reported cases) spoke for a lesion in the cord itself. There was reason to believe that the cord lesion was, sometimes at least, congenital; although it was not unlikely that it might become aggravated secondarily during adolescence. The speaker believed also, from observation of his cases, that callus, which surrounded the ulcers, was not dependent upon pressure, but was itself a trophic disturbance. So, too, was the bone necrosis. These perforating ulcers were very obstinate and in several cases had called for amputation. The spina bifida was usually located in the lumbar, lumbosacral, or sacral regions, in a few cases in the dorsal spine. The local signs were one or more of the following: Scoliosis or other spinal deformity in many cases; a depression, usually covered by wrinkled or scarred skin, in which the bone cleft might be felt; radiating, thin scar tissue, usually adherent, frequently vascularized, sometimes marked by an angioma, through

this the cleft was often felt; a congenital lipoma; distinct hair-growth, either alone or in combination with one or more of the above (least often with lipoma). This hypertrichosis was found in most of the cases. There were various theories of its genesis and significance. It might not appear, and often did not develop prominence until puberty. It might be long enough to constitute a veritable "tail." The museum freak who exhibited as "the woman with the horse's mane" had an extensive bifidity of the dorsal spine. Recklinghausen suggested that hypertrichosis was probably significant of a concealed spina bifida. Many cases of lumbosacral hypertrichosis had been reported, before and since the advent of Roentgenography, in which no mention of a spina bifida occulta was made; but in the absence of skiagraphs in all these cases, Recklinghausen's suggestion was not diminished in value. However, Ornstein, who reported the first case of lumbosacral hypertrichosis, collected 30 cases; Geyl saw it in a father, son, and grandson; Butler saw it in three children of one mother; Pendleton reported an identical observation; and Parry reported two sisters with lumbosacral hair growth. The atavistic theory is no longer adhered to, but, even recently, Bruggia regarded hypertrichosis, lumbosacral or elsewhere, when not part of an evident fetal deformity, as a stigma of degeneracy; but in the case he illustrates in his book he recorded no examination of the spine. The spinal lesions, like the external manifestations, were various. The cases operated upon or autopsied indicate that there was a cleft in the vertebral arches, of various length and breadth, and that this was accompanied by one of the following conditions: (1) The cleft might give passage to a distinct meningocele. (In the lumbar region the sac was apt to contain the posterior roots of the cauda equina.) (2) The cleft was closed by a tough membrane, adherent to the overlying skin or nonencapsuled fate and connective tissue. (3) The membrane was perforated by a dense band, attached to the subcutaneous tissues without, and compressing the cord structures within. (4) Lipomatous tissue within the canal was concealed by this membrane. (5) The cleft disclosed the bulging dura mater. (6) An exostosis within the canal compromised the cord tissues. (7) A myofibrolipoma extended through the cleft into the canal, distorting and compressing the cord and its nerve roots. In two cases with the last condition the cauda equina and other nerve roots showed marked degeneration, and there was degeneration in various tracts of the cord itself. In another case the central canal was dilated. Symptomatically, spina bifida occulta and spina bifida were one. Diagnostically, they were to be separated. Anatomically, they also differed, but here, too, they presented some features in common: tumor tissue sometimes accompanied evident spina bifida; hypertrichosis occasionally did; a meningocele was sometimes partially, but not entirely, concealed by a congenital lipoma; and, lastly, there were reasons for believing that a spina bifida sometimes shrank and left only scar tissue or other index to a spina bifida occulta. The results of operation had been: In no case death. In one or two cases no improvement. In most cases cure or improvement of incontinence, locomotion, anesthesia. In no case had trophic ulcers been relieved, again indicating their origin in a lesion within the cord. From these few cases Brickner believed that operation was indicated in spina bifida occulta, even and especially in children with no symptoms. (Not every congenital lipoma over the spine concealed a spina bifida, however. In a child recently operated upon at Mt. Sinai Hospital nothing abnormal was found beneath the lipoma.) Though a cord lesion (gliosis or other) probably existed in many cases, it did not produce all the symptoms; and, too, early operation might obviate degenerative cord changes. It was suggested by the reader that it might be wise to always sufficiently explore the canal to expose any exostosis or concealed tumor tissue. When it produced symptoms, as it usually did, spina bifida occulta was a most distressing condition; and the only hope of relief lay in its early treatment. In many of the cases, as in both shown by the reader, symptoms had existed for years before their cause was recognized. In his brief survey of the clinical features of spina bifida occulta, Brickner chiefly attempted to renew attention to the existence of this type of deformity, and he urged a careful scrutiny of the back, and an *x*-ray picture in all cases in which there was incontinence of urine or feces, or in the lower extremities, motor, sensory or trophic disturbances, the cause of which was not otherwise evident.

Injury by Electricity.—Dr. J. J. MOORHEAD read this paper. He said that, in view of the widespread and increasing use of electricity, it was not surprising that electrical trauma was on the increase. Authoritative information as to the physical effects of electricity was very scanty, especially in the American literature. After defining some of the more common technical terms, he said that, for all practical purposes, it was enough to remember that the volt was the unit to express pressure, intensity, and electromotive force, and that the ampere denoted strength and current quality. An electrical conductor could conduct three sorts of current, viz., continuous, interrupted, and alternating. The contact might be of four kinds, viz., positive, partial, brushing, and arcing. The intensity might be low (reaching 100 volts), medium (400 to 600 volts), or high (1,000 volts and over). The duration of contact might be short (from 1 to 3 seconds), medium (from 5 to 8 seconds), and long (from 8 seconds upward). The average electrical pressure in electrical lighting was from 100 to 225 volts, direct, usually about 110 volts; in overhead and underground trolley systems from 250 to 275 volts; in overhead long haul railway systems, 11,000 volts. In the third-rail systems, like the local subway, the voltage was 550. The highest voltage transmitted by wire in this country was at Grand Rapids, Michigan, 100,000 volts. A voltage from 200 to 500 was usually not dangerous to life. In the electrocution of criminals from 1,300 to 2,000 volts were used, the average being 1,700 of the alternating type. The physical effects were mainly determined by the amount and duration of the current, the site, type, and area of contact, and the individual. In a general way, they were three in number—death, burns, and disturbances of the nervous systems. Death from electricity was usually sudden, and was best represented by the execution of criminals, lightning stroke and unexpected contact with highly charged materials, the body completing and short circuiting two conductors. Under such circumstances there might or might not be decided external evidences of what had occurred. At post-mortem such cases were surprisingly free from gross microscopical changes, and the most careful search of all the tissues had as yet failed to give any adequately uniform cause of death. The findings were not unlike those noted after drowning and suffocation. Observers appeared to have two main theories to account for death under such circumstances; one being that the heart muscle was paralyzed by a tetanic spasm analogous to that observable in skeletal muscles under high voltage; the other theory was that there was a definite cellular destruction, especially of the vital centers. Burns by electricity differed from those due to extremes of temperature only in origin, and might be of the usual first, second, and third degrees. Electrical burns were apparently less painful and produced less systemic shock than certain other burns. In the absence of direct destructive or inflammatory damage to the nerve fibers and the subsequent development of a more or less localized neuritis, the nervous effects were almost invariably those of the hystero-neurasthenic type, it being rare in his experience to find either neurosis separately as a sequence of electrical or other

form of trauma. Where direct damage to nerve tissue was absent or minor, the subsequent development of neurasthenia and hysterical symptoms was generally psychic in origin or dependent upon auto or hystero-suggestion, and the signs then presented were usually disproportionate to the actual physical damage sustained. Occasionally cases were recorded in which blindness and deafness and other special sense defects had been attributed to electrical contact or flashes, but all instances of this sort fell into the class of so-called "fright neuroses." Treatment presented no special problems and was directed toward the relief of shock, burns or neuroses. In conclusion he said there was no special form of physical effect inherent to electricity, inasmuch as every symptom could be paralleled in other forms of trauma; likewise, there was nothing pathognomonic in "electric shock."

Dr. John Woodman said he had never seen permanent disease of the nervous system resulting from electric shock, either of low or high tension. The burns healed kindly.

Tuberculosis of the Kidney.—Dr. Benjamin S. Barringer presented these specimens.

Case I.—This patient was twenty-seven years old and had had bladder disturbances four months previous to the time when seen. She had noticed cloudy urine for only a week. The cystoscopic examination showed the right ureteral orifice surrounded by red granulations, with a few submucous hemorrhages; this was non-contracting, and there were no ulcerations. The bladder was otherwise normal. This case was found to be one of unilateral kidney tuberculosis, in which nephrectomy was performed and in which apparently there was a complete involution of the tuberculous process, so far as the urinary organs were concerned. Two months after the nephrectomy the cystoscopic examination showed that the granulations around the right ureteral orifice had entirely disappeared, and normal mucous membrane closed the right ureter mouth. The kidney was almost entirely destroyed, and the kidney with the ureter was removed.

Case II.—This patient had a bladder capacity of 150 c.c. The urine was cloudy and contained pus and tubercle bacilli. The cystoscopic examination revealed the right ureter retracted to the right and much thickened; its orifice was small, irregular and surrounded by an area of pink granulations with a few tubercles. The left ureter and the rest of the bladder appeared normal. The right kidney was almost completely destroyed by the tuberculous process. Four weeks after the nephrectomy the patient was convalescing. The cystoscopic picture was one that could not be mistaken for anything but an old tuberculous process, with extensive kidney destruction.

Case III.—This patient was a man, thirty-five years old, married, and who had had gonorrhea four years ago. One and a half months later he was unable to urinate, and had to be catheterized. Since then he had had bladder irritation, weakness of the back, lost flesh, had night sweats, and frequent urination. The cystoscopic examination revealed moderate congestion and a cystitis at the base of the bladder. The right ureteral orifice was open, rigid, and was surrounded by slight congestion, with a small ulceration at one angle. The left ureteral orifice was slightly congested, contracting regularly every ten to twelve seconds, with urine issuing. The urine was cloudy, and contained pus cells and tubercle bacilli. One year later the patient returned with a left tuberculous epididymitis. An examination of the nephrectomized kidney showed complete destruction of kidney tissue, with large cavity formation. The patient died on the second day after the operation from heart failure. In this case the cystoscopic picture gave no index of the extent of kidney involvement. The cystoscopic picture of the diseased ureter was but rarely seen with conditions other than renal tuberculosis.

Philadelphia Neurological Society

At a stated meeting held April 23, Dr. A. A. Eshner reported "A Case of Undiagnosticated Brain Abscess," and he exhibited the specimen. The patient had been a woman thirty-five years old, who gave a history of ear disease and complained of severe headache, together with nausea, vomiting, sleeplessness, pain in the back and legs, chills, fever, and sweating. There was, however, no paralysis, no discharge from the ear, no local tenderness, and the reflexes were normal. The Widal test yielded a negative reaction and the urine contained albumin and tube casts. The white blood cells numbered 10,000 in the cu. mm. The case was at first looked on as one of typhoid fever, and later as one of uremia. Death occurred somewhat abruptly, and postmortem examination disclosed an abscess in the temporal lobe of the left cerebral hemisphere, with caries of the adjacent temporal bone and suppuration in the internal ear. Dr. Alfred Gordon reported "A Case of Focal Epilepsy Due to Varicose Cerebral Veins; Operation; Recovery," and he demonstrated the patient. The case occurred in a man, 26 years old, who had been having at rather frequent intervals epileptiform attacks in part of Jacksonian character since the age of four. The attacks began in the left leg and invaded other portions of the body. Sometimes they were attended with loss of consciousness and at other times they were not. An osteoplastic flap was turned back, the dura incised and varicose veins disclosed on exposure of the upper portion of the motor area. The enlarged veins were ligated and excised. No convulsion had occurred in the more than two months that had elapsed since the operation, although palsy of the left upper extremity followed, with ataxia in this member and loss of stereognostic sense. Gradual improvement in the paralysis was taking place. Dr. George E. Price exhibited for Dr. Francis X. Dercum a girl, about 11 years old, who two years earlier, after exposure to cold, was seized with paralysis in both lower extremities, loss of control of the sphincters, lessened, followed by exaggerated, reflexes. Under rest, good feeding, massage, and graduated exercises, a considerable measure of improvement had taken place, so that the patient was able to walk and run quite well. Dr. S. D. Ingham reported "A Case of Cerebrospinal Syphilis with Internal Hydrocephalus, Causing Symptoms of Cerebellar Tumor." A striking symptom was the staggering gait, with a tendency to fall backward. After death a gumma was found obstructing the foramen of Magendie and the aqueduct of Sylvius, causing dilatation of the lateral ventricle. Dr. John H. W. Rhein reported "A Case of Spastic Paraplegia (Little's Disease?) without Demonstrable Lesions of the Pyramidal Tracts," and he demonstrated the microscopic sections. The patient had been a man, 64 years old, who had had spastic paralysis in the lower extremities since infancy. No lesion was found after death. He attributed the spasticity to the loss of inhibitory impulses normally conveyed from the cerebral cortex by reason of the fineness in size or smallness in number of the fibers from the motor area. Drs. Charles K. Mills and William G. Spiller presented a communication entitled "Symptoms of Disseminated Sclerosis produced by Arterial Sclerosis." The patient was an elderly woman who presented coarse intention tremor of the hands and shaking of the head, with scanning speech, but without nystagmus or exaggeration of reflexes. After death no sclerosis of the cerebrospinal system was found, but only the lesions of arteriosclerosis. Dr. Alfred Gordon presented a communication entitled "Histological Changes in the Spinal Cord in Pernicious Anemia, with Report of a Case of Diffuse Degeneration." He reported a case in which, following copious hemorrage from the nose, symptoms of pernicious anemia developed, and after death diffuse degeneration of the spinal cord was found

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE NEUROGENIC AND MYOGENIC THEORIES AND THE MODERN CLASSIFICATION AND INTERPRETATION OF CARDIAC ARRHYTHMIAS.

By S. J. MELTZER, M.D., LL.D.,

NEW YORK.

Introduction.—Irregularities of the heart-beat occur in all sorts of pathological conditions, and have to be dealt with quite frequently in all shades of medical practice. The proper understanding of these irregularities is therefore undoubtedly of importance to every practitioner. Within the last ten years a great change has taken place in the interpretation of these phenomena; students of this subject designate this change a veritable revolution. Keen investigators and leading clinicians throughout the world are now paying a great deal of attention to the study of the cardiac arrhythmias, and the literature on that subject has already assumed large proportions.

How much of this knowledge has reached the minds of the large mass of general practitioners? There are some reasons for the suspicion that in this country as yet not even the upper stratum has been deeply penetrated by the new light. I shall give at least one reason for this suspicion. It is now agreed by all active investigators of the nature of cardiac arrhythmias that extra systoles are responsible for a good many of the irregularities of the heart. Professor Friedrich Müller, of Munich, said two years ago in his Harvey lecture in this city, that more than half of the arrhythmias are due to extra systoles. Now, what is an extra systole? You may turn to many large books on diagnosis and see whether you will find that term in the index. However, I hasten to add that there are quite a number of notable exceptions. Indeed, it will give me great pleasure to point out later some of the important original investigations contributed by bright men of this country to the solution of the problems under discussion.

Your President, in honoring me with the invitation to present a paper before this Society, added that it should deal with a practical problem. In selecting the present subject for discussion in my paper before you, I have complied with the last-mentioned requirement; the problem of irregularity of the heart is, as as I have pointed out before, certainly of great practical importance. However, the very demand for a practical problem prompts me to point out to you before entering upon the details of our theme, the general lessons we may learn in this regard from the progress made in the clinical studies of our subject. The progress made in this field within the last ten years is incomparably greater than the one made in many of the foregoing decades, although there was throughout those decades no lack of great clinicians nor of intense studies of our subject. The success attained in recent years was won by the close application to clinical medicine of facts established by animal physiology. These physiological facts were discovered, however, not in an attempt to find something which has a direct bearing upon human medicine, but in an endeavor from a purely scientific point of view to establish the nature of the origin of the heart beat; in fact, a good many of the physiological facts were brought to light by the struggle for supremacy between the neurogenic and myogenic theories of the origin of the heart beat. Furthermore, most of these studies were not made upon higher animals, standing near the human species, but upon the hearts of lower animals, such as the frog and tortoise.

The progress in medicine was made by men, some of whom never had any experience with animal experimentation, but all of whom absorbed all the details of the facts and theories of the physiology of the heart and with great acumen and truly scientific methods applied them in the studies of the pathological phenomena of the human heart. Among the many important results thus achieved stands out the most satisfactory fact that many of the laws learned from the heart of the frog were found to hold good to their full extent for the human heart. From these experiences the following lessons may be learned. In the first place, we see here a striking instance in which experiences gathered from studies upon lower animals have great, and may have even full value in their application to the knowledge of the processes of human life. The sciences of medicine have to contend with the objections frequently made in certain medical quarters that that which was learned in animal experimentation cannot be applied to human beings, and even some of our modern pathologists speak with contempt of frog physiology. These opinions rest upon an unfamiliarity with the real facts in physiology and medicine.

We learn further that studies which were made with no other purpose than to learn the truth proved to be of great importance in their practical application. A study of any subject with the single purpose of learning the truth about it will reveal more of its intricacies and may be finally of greater practical value, than studies biased by the extraneous motive of their immediate practical application. The apparently abstruse phenomenon of the refractory period of the heart muscle proved to be a boon in the interpretation of some of the irregularities of the heart beat.

Finally we learn that the secret of the clinicians who succeeded in contributing so much to our knowledge of the nature of cardiac arrhythmias consists in their mastery of the details of the theories and facts underlying the newer contribution to the physiology of the heart. The mastery of the theoretical and scientific branches of medicine is a

great practical asset for the investigator as well as for the practitioner of medicine.

I shall now turn to our subject. As I have already indicated, the progress recently made in the knowledge of cardiac arrhythmias was based upon the application of the physiological facts derived from animal experimentation. These again were brought to light to a great extent in the struggle between the neurogenic and myogenic theories of the origin of the heart beat. I shall try at first to present to you in a brief and elementary way the chain of facts and theories which led up to the present phase of our knowledge about human cardiac arrhythmias. In so doing, I shall have to tell you something about the birth, growth, and struggles of the neurogenic and myogenic theories. If it will seem to some of you that I am lingering too long in telling the tales of the battles of theories, I would remind you of my view which I stated before, that theoretical knowledge is a practical asset. It is my aim to convert those of you who may be of another mind.

The Neurogenic and Myogenic Theories.—The neurogenic is the older of the two theories. Neurogenic means the supposition that the heart beats are originated in some part of the nervous system. The heart is a muscle and its function is simply that of contraction. For centuries it was assumed that the rhythmic contractions of the heart were carried on by impulses sent to that muscle from some part of the central nervous system in the same manner as the skeletal muscles are prompted to their sporadic contraction by impulses received through the motor nerves from the brain. This assumption was easily disproved by Haller, the celebrated physiologist of the eighteenth century, by the following experiment: the heart continues to beat for some time after its complete removal from the animal body; the cause of the rhythmic beats must therefore be located in the heart itself. However, the investigations of the nineteenth century gradually brought to light new facts which permitted the resuscitation of the neurogenic theory to new life in a new form. At the beginning of that century, Bichat, who divided the functions of life into animal and vegetative systems, assigned to the sympathetic nervous system the control of the vegetative life. About the middle of the thirties, Ehrenberg discovered the ganglion cells in the brain, which soon gave rise to the assumption that nerve cells are capable of spontaneous activity, that is, of what is now generally termed automatism. The study of reflexes began about the end of that decade, and the study of such functions as respiration and deglutition which are carried on by a complexity of reflexes, led to an assumption that they are managed by centers located in the medulla oblongata, that is, by groups of nerve cells possessing the power of automatically generating coordinate impulses adequate to the corresponding functions. Finally, in 1843, Remak discovered the presence of groups of nerve cells in the sinus of the frog's heart. Here was now the following chain of premises. Peripheral nerve ganglia belong to the sympathetic nervous system, which controls the vegetative functions. The heart belongs to the vegetative system. Nerve ganglia possess the power of automatism. The heart contains such ganglia. On the basis of these premises, Volkmann, in 1844, formulated the theory that the nerve cells of the heart are generating automatically the impulses which cause the rhythmical contractions of the heart, the heart ganglia being in a certain way comparable to the nerve cells of the respiratory center which causes the rhythmical contraction of the respiratory muscles. The new neurogenic theory agreed with the old theory that the heart beats originate in the brain, with the difference that it assumed that the heart carries its brain in its own tissue.

As I have indicated before, the bulk of the experiments on the origin of the heart beat were made on the heart of the frog. There are various potent reasons for it. In the first place the heart of the coldblooded animals is a more convenient object of study, inasumch as it shows a greater independence from the rest of the body, than, for instance, a mammalian heart. The heart of the frog can be removed from the body and kept alive and beating for hours and days under only moderate precautions. Then the various parts of the heart of the frog are more differentiated than the heart of animals. It consists practically of five sections: The mouths of the large veins, the sinus, the auricles, the ventricle and the aortic bulbus. Each of the chambers contracts as a whole, and these contractions follow one another in a peristaltic manner in the above-given order, beginning with the veins and terminating with the bulbus. Finally, the relatively slow propogation of the peristaltic wave makes the frog heart a convenient object for comparatively simple experiments.

One of these simple experiments became a fundamental factor in the discussion of the nature of the origin and conduction of the heart impulse. I refer to the experiment of Stannius. Stannius has not done much work in physiology; but this one simple experiment made his name famous. After all, even some of the fundamental experiments of our time are experiments of Stannius in disguise. For instance, the interesting and instructive experiment of Erlanger, that is, the exposing of the bundle of His to the compression of a vise, is in its inception a modification of the celebrated experiment. The experiment of Stannius consists in putting a tight ligature around some part of the auricle. The result is striking: all above the ligature continues beating in an undisturbed way, and all below the ligature stands still. This simple experiment was the starting point for a good deal of work and discussion. Many celebrated physiologists tried their hand at it, and it caused satisfaction as well as anxiety in the neurogenic camp. At a glance it would seem that it proves the neurogenic theory most beautifully. The rhythmic contractions of the heart are caused by impulses sent out from the nerve cells which Remak discovered in the sinus; a ligature, therefore, which cuts off the impulses from getting to parts under it will cause the stoppage of these parts. Bidder, however, found later that there are some groups of nerve cells also in the groove between the auricle and the ventricle. The question arose, then, what function do these ganglia have and why do they fail to cause the rhythmic beating of the ventricle after the application of the ligature?

I shall, of course, not attempt to try your patience by burdening you with a multitude of facts and arguments, which came to light in the further development of the neurogenic theory or the various modifications which the theory had to undergo from time to time. I shall only say in a general way that the neurogenic theory insists that the heart muscle, like any other muscle, is neither able to generate impulses nor to conduct them. The impulses are generated automatically in nerve cells and are con-

ducted, perhaps through several relay stations, by nerve fibers which finally convey the impulses to the heart muscle in the manner of motor nerves. There are some newer supporters of the theory, who no longer insist upon the exclusive importance of the nerve cell; they simply insist upon the general assumption that the automatic generation of impulses and their conduction is carried on by the nervous tissues and not by the muscle fibers, of whatever form they may be.

During the long domain of the neurogenic theory, very many important, well-settled facts were brought to light, bearing upon the nervous mechanism of the cardiac activity. I shall only mention the discovery of the two kinds of nerves by means of which the heart is connected with the central nervous system: the vagus nerves, stimulation of which inhibits the heart beats, and the accelerator nerves, stimulation of which accelerates and strengthens the heart beats. By means of these nerves the heart is in close continuous telegraphic communication with all parts of the animal body. I may say that even the interesting facts which are now used by the myogenists as their most available methods of study, like the refractory period, the compensatory pause, the all or none law, etc., were all discovered by the adherents of the neurogenic school. I shall add further that during the reign of the neurogenic theory, peripheral nerve ganglia were found in abundance in other organs which are endowed with involuntary movements. The intestines with their involuntary peristaltic movements present such an instance. It is a noteworthy fact which may be mentioned here that through the recent work of Bayliss and Starling and of Magnus it seems quite safely established that the peristaltic movements of the intestines originate indeed in the plexus of Auerbach and not in the unstriated muscle fibers of the intestinal wall.

The neurogenic theory dominated the teachings of physiology for a good many decades. Until very recently it was the theory which text-books, large and small, printed in large type; the professor told it to his students and the clinical writers and teachers found that it explained beautifully all the facts which they gather at the bedside.

We are now confronted with a radical change. The myogenic theory which only recently forged its way to the front won the battle, so it seems, in a short, sharp fight, and it must be admitted by friend and foe that it is already doing excellent work. The credit belongs essentially to two brilliant investigators, Engelmann and Gaskell. It is of psychological interest to note that Engelmann began his scientific career by studying the ciliary movements. Here he was confronted with coordinate rhythmical movements in which nerve elements had no share. At the end of the sixties he studied the peristaltic movements of the ureters. He could find no nerve cells in the walls of these tubes, and he therefore made the muscle fibers responsible for the safe conduction of the peristalic wave. Next he studied intestinal peristalsis and was inclined to ascribe the coordination of these movements to an inherent property of the muscle fibers of the intestinal wall. In these writings he already manifested his positive leaning toward the assumption of a myogenic origin of the cardiac movements. His effective experimental work on the physiology of the heart, however, was done only in the nineties of the past century. The work was so thorough, painstaking, and precise that it made Engelmann the flag bearer of the myogenists. It must be stated, however, that Engelmann's investigations were greatly facilitated by the excellent work of Gaskell, done about a decade before. This brilliant physiologist began work as a pupil of Michael Foster in the neurogenic school. Employing a new method of investigation, the so-called suspension method, and coming across the heart of the tortoise, in which the nerve fibers connecting the sinus with the ventricle run separate from the auricular muscle fibers, Gaskell became converted to the view that automatism and conduction are carried on by the muscle fibers. He soon brought together a number of facts in support of this view and laid the essential foundation of the myogenic theory as it is conceived to-day.

Turning now to the experimental facts which brought about the change in favor of the myogenic theory, we have to distinguish between the localization of the automatic generation and the conduction of the rhythmic impulses. Against the assumption that the generation of the impulses occurs automatically in ganglion cells, the following two objections were brought forward. In the first place, some parts of the heart, like the apex and the aortic bulbus, contain no ganglion cells, nevertheless they can be made to beat rhythmically under certain conditions after they are cut off from the rest of the heart. Also bits of the superior vena cava of the frog which contain no nerve cells continue to beat rhythmically after their isolation from the rest of the vein. Here then are rhythmic contractions of parts which have nothing else but muscle fibers. The second point was brought out by His, Jr., and by His and Romberg, and is a striking fact indeed. It rests upon observations which were made on embryos. In various animals pulsations of the heart appear in the embryo long before there are any ganglia in the tissues of the heart. According to His, the elder, the peripheral sympathetic ganglia do not develop within the corresponding tissues, but wander into it from the cerebrospinal or sympathetic system. In the chick the pulsations of the heart are noticeable in an embryo only 36 hours old, while the ganglia do not reach the heart before the sixth day. It is therefore evident that in the first days of embryonic life the heart rhythm cannot originate in the nerve cells.

That the conduction of the impulses from the sinus to the ventricle is being carried by muscle and not by the nerve fibers, was demonstrated first by Gaskell on the tortoise. As stated before, the nerves in this animal's heart run in a separate, easily accessible trunk. Gaskell found that by cutting the nerves the rhythm of the heart was not disturbed, but cutting away all the muscular connections between sinus and ventricle, while leaving the nerves intact, the ventricle stopped at first and then started off beating with a rhythm different from the one of the sinus. A similar experiment was performed by F. B. Hoffmann on the frog, where the nerves run in two thin bundles in the auricular septum and are hard to reach. These experiments show that in these coldblooded animals the impulse is conducted from the sinus to the ventricle through the muscle fibers, and not through nerves.

There was a question to answer why, if the conduction is carried on by muscle fibers, there is a delay in the progress of the contraction wave in passing from the auricle to the ventricle. The neurogenists explained this retardation by the delay which the impulse suffers while passing through nerve cells. Gaskell has shown that this delay was

due to the narrowness of the muscle bridge connecting the auricle with the ventricle. He has shown that if the bridge was still more narrowed by moderately cutting or compressing the connecting muscles, the delay was still greater, and by further cutting or compressing the connecting tissue one or the other of the impulses would not reach the ventricle at all, so that the beats of the ventricle in relation to those of the auricle would be of a rhythm of one to two or three and so on, until the ventricle would be entirely dissociated from the auricle.

However, the myogenists had still one question to overcome. The theory was applicable to the hearts of coldblooded animals, because there were muscle fibers which connected the ventricle with the auricle. For the mammalian heart, however, the contemporary anatomists were teaching that there were no muscular connections between auricles and ventricles. Now, if the nervous element cannot conduct the impulse, and muscle fibers are not present, how does the impulse reach the ventricle? In this emergency two publications appeared nearly simultaneously by Kent and His, describing a bundle of muscle fibers entering from the right auricle into the septum and branching out into both ventricles. That was in 1893. That bridge of muscle fibers is now known as the bundle of His. Of Kent we shall speak later a little more.

In 1895, a very brief communication appeared from His in which he stated that when the bundle was cut in living mammals, the ventricles were beating in a tempo different from that of the auricles. Very little attention was paid at that time to these remarkable anatomical and physiological data. About ten years later, however, the medical world was stirred up by various occurrences, and henceforth we find a number of investigators busying themselves intensely with anatomical and physiological studies of the nature and significance of the bridge connecting the auricles and ventricles in mammals. These studies mark a definite progress in our knowledge of the subject. Of the anatomical data which came to light we shall bring out in the first place the following point. According to the statements of Kent the fibers of the atrioventricular bridge differ perceptibly in structure from the other muscle fibers of the heart and are embryonic in character. His, however, stated expressly that on these points he completely disagreed with Kent. Of recent workers, Retzer as well as Braeunig agreed with His that the fibers of the bundle of His show no structural differences from those of the other muscle fibers of the heart. Tawara, however, who has done the most thorough and exhaustive work on the anatomy and histology of the atrioventricular bundle, on the contrary, agrees with Kent that there is a definite structural difference, and that these fibers are indeed to a degree embryonic in character. According to Tawara, some of these fibers are identical with the long-known fibers of Purkinje, which are thus present not only in the sheep's heart, where Purkinje observed them, but also in the heart of man and of other mammals. Furthermore, in the auricular section of the bundle, Tawara distinguishes from the rest of the fibers a complicated, net-like mass, which is now known as Tawara's Knoten, or the atrioventricular node. It plays already a distinct rôle in medicine. An additional interesting and important anatomical fact is the recent finding by Keith and Flack in human hearts of a small net-like mass of tissue similar in character to Tawara's Knoten at the junction of the superior vena cava and the auricle. Myogenists are inclined to look upon this node of Keith as the seat where the first impulses are automatically originated. The findings of Keith were very recently confirmed by Koch from Aschoff's laboratory where Tawara's work also was done. The original simple bundle of His appears now in the form of a quite complicated system, and, surely, the last word is not yet said on that subject.

One word more about the nerves. According to Retzer, the bundle of His contains no nerve fibers, a statement which brought joy to the myogenic camp. However, Tawara as well as Keith and Flack are emphatic in their statements that their nodes contain nerve fibers as well as nerve cells.

Of practical importance is the further fact that each of these nodes contains special arteries. Pathologists and clinicians are already at work to connect special forms of arrhythmias with a sclerosis of these special arteries.

From the physiological work we have to mention the experiments of Humblet and especially of H. E. Hering, who succeeded in cutting the bundle of His in the excised mammalian hearts which were kept alive according to the present new methods by perfusion with a Ringer solution. The heart beats presented then a complete block, as the term now goes, that is, ventricles and auricles were beating in different rhythms. Of four hearts thus experimented upon by Hering there was a complete block in three, while in one there was no success. The hearts were examined by Tawara who found that in the three successful hearts the bundle was cut, while in the one failure the bundle was not cut.

Experiments of great interest were performed by Professor Erlanger,[1] then at the Johns Hopkins Medical School. By a specially devised clamp he succeeded in compressing the atrioventricular bundle of the hearts of living dogs—of course, under deep anesthesia—exactly in the same manner as Gaskell did on the hearts of coldblooded animals, and with exactly the same results. Moderate compression caused a slowing of the transmission of the wave of contraction from the auricle to the ventricle. Stronger compression changed the normal rhythm to two, three or four beats of the auricles to one of the ventricles. Still stronger compression led up to a complete block. While the auricles continued to beat in their former rhythm, the ventricles stood still for a while, then they gradually commenced to beat in a rhythm entirely of their own.

Besides their theoretical value these experiments, as we shall see later, are of great practical importance, inasmuch as they throw light on the nature of some of the pathological cardiac arrhythmias in human beings.

Here I wish to say again a word on the work of Stanley Kent. Everybody now knows His and his bundle, but very few know of the share which Kent had in the detection of that bundle. Kent's publication on the bundle appeared at least simultaneously with that of His. Furthermore, Kent was apparently more correct than His in the description of the structure of these fibers, and in his important reference to their embryonic character. Now, in studying original articles, I discovered that Kent also performed the experiments of Erlanger apparently by the *same method and with the same success.* They are mentioned in Kent's article which was published fifteen years ago.[2] He says there that by using a suitably constructed clamp he was able to

verify for the mammal all the effects described by Gaskell for the frog. This is exactly what Erlanger has done. I do not know who and where Kent is, I do not even know whether he is alive. But I want to do justice to his work. In the anatomy and physiology of the conducting system of muscle fibres of the mammalian heart Stanley Kent was ahead of his time. But fate deprived him of the credit and fame due to him. Now permit me to add, impressively, that these remarks should not be interpreted as containing a shadow of reflection upon the work of Erlanger. Any one who knows this investigator will not doubt for a moment that he was not familiar with the brief, hidden-away statement of Kent. If he had known it, he would have been the first one to state it. The plans of experimentation were entirely original with Erlanger, and we all know how they came about. It was while he was carrying on his splendid studies of the case of Stokes-Adams disease given to him by Osler,[8] that he planned and executed his now celebrated experiments on the mammalian heart.

Now, let us return to our main issue.

The followers of the myogenic camp, to which now the great majority of physiologists all over the world seem to belong, believe to be now in possession of sufficient facts to warrant the following conclusions.

It seems to them established that neither the origination of the impulses for the rhythmic contractions of the heart, nor the conduction of these impulses to any part of the heart have anything to do with nerve cells or nerve fibers. The conception of the myogenic theory is that the automatic generation of the impulses as well as their conduction are carried on by muscle fibers. At an early embryonic stage the heart appears as a simple tube, the walls of which are composed of muscle fibers which differ structurally from the muscle fibers of the adult heart and which are endowed with the property of automatic rhythmic contractions. In the course of the further development this tube is converted into the divided chambers of the adult heart and the muscle fibers assume another structure. However, some small part of the original embryonic tissue is preserved. This tissue is the sinoventricular system of conducting fibers, or the bundle of His with the nodes of Tawara and Keith. In normal conditions the stimulus is originated automatically at the mouth of upper veins, perhaps in the node of Keith, from where it is transmitted through the persistent embryonic fibers first to the sinus, then to the auricles and from there to the ventricles. The spreading of the impulses in each section takes place very rapidly; the passing, however, from one section to the next occurs more slowly on account of the narrowness of the connecting bridge and on account of the embryonic character of the connecting fibers. The experiments made it evident that each section of the heart is capable of independent automatism which normally, however, is kept in abeyance by the impulses coming from the first station. The independent automatic mechanism of each chamber, however, make their appearance as soon as the conducting path from the primary station is blocked by some cause or other.

I am not sure that the physiologists of the myogenic camp have already made up their minds what to do with the nodes of Keith and Tawara. The clinicians of that camp, at least some of them, however, seem to be sure that the nodes are the seat of automatism. If this be the case, the myogenic theory would, so it seems to me, lose an essential feature of its original aspect and would have one essential point rather in common with the neurogenic theory. If the automatic generation of the impulse be restricted to the nodes and their conduction confined to the embryonic fibers of the conducting system, then the main muscle fibers of the adult would occupy the same position assigned to them by the neurogenic theory, namely, to contract at the behest of a power localized outside of themselves. The difference between the two theories would be that in one case the power is entrusted to the nerve cells and nerve fibers, and in the other case to the residuary embryonic nodes and fibers residing within the adult heart. I wonder whether this view will satisfy the original founders of the myogenic theory.

The myogenic theory so far has had all its own way. However, I have to record one discord in this harmony. In investigations carried on during the last few years in this country by Professor Carlson of the University of Chicago, important facts came to light which are decidedly inimical to the myogenic theory, at least in its universal application. In the course of his studies in Woods Hole, Carlson[9] discovered positive evidence that in Limulus, the horseshoe crab, the conduction of the stimulus for the movements of the heart is carried on by nervous elements and not by muscle tissue. The heart of Limulus, which is nearly half a foot long, consists of various segments; they are connected by a thick nerve cord which runs the entire length of the heart on the dorsal surface, and by two lateral nerves. Carlson established the facts that complete transverse section of the heart at any place, while leaving the nerves intact, does not interrupt the movement in any parts of the heart. On the other hand, leaving the heart intact and cutting the nerves, abolishes the movements in the part of the heart distal to the place of section. Here the automatic generation of the impulses as well as their conduction to the various segments are undoubtedly carried on by the nervous elements and not by the muscles, in other words, are of neurogenic origin. Furthermore, Carlson found in the embryo of that animal that here, too, as in many vertebrate animals, the heart pulsates before there are any nervous elements within its tissue. Nevertheless the nerve cells and nerve ganglia, after they reach the heart, assume the entire control of the heart beat.

This last observation shows at the same time that the fact of the heart of the embryo beating at a certain stage before there are any nerve ganglia cannot be taken as a final proof that the nerve cells in the adult heart cannot have a share in the management of its affairs. Considering that just this observation of His and Romberg in the vertebrate heart has been the main support of the myogenic theory; considering further that the other supporting fact, namely, the presence in the heart of parts which have no ganglia and which are nevertheless capable of rhythmical pulsations is not convincing either, since with the newer histological methods nerve cells and nerve fibers were found in all these tissues; remembering also that according to Tawara and Keith the nodes as well as the bundle contain nerve cells and nerve fibers; considering all this and a good many more points, one cannot help feeling that the myogenists have not as yet completely proven their case.

There is still another side of the myogenic theory in its newest aspect which should invite some re-

flection. In medicine we are accustomed to think that embryonic residues are pregnant with pathological possibilities and that the adult organism is much safer without such ontogenetic legacies. The myogenic theory teaches us that our very life depends upon them. I wonder whether a day will come when some pathologist would advance the theory that all the cardiac troubles come from this bundle of His. The fibres being embryonic, might degenerate more readily, so it could be claimed, and thus bring disaster to the physiological elements which are imbedded in them and upon which the heart's normal action depends exclusively.

However, I am not standing here before you as a warrior taking sides with one of the camps. I consider my function to-night simply as that of a war correspondent, telling the news from the battlefield. And here I can truly report that the myogenists have won the day, the majority of the physiological and medical investigators are converted to their views. I can also say that the theory amply justifies its existence by its productivity. Fruitfulness is the only criterion and the only requirement of an efficient theory. The myogenic theory recently exerted a wholesome influence upon medical investigation. As long as it is capable of being productive and useful, it will continue to reign and hold the stage.

I have stated before that the credit for developing and establishing the myogenic theory belongs essentially to two men: Engelmann and Gaskell. I may add now that even the spreading of this teaching among clinical men can be traced to a degree to the influence of these physiologists. Perhaps I may say a few words about it.

Engelmann has pursued his experiments on the heart, as stated before, in the nineties of the last century. He was then professor of physiology in Amsterdam and made his communications to the medical societies and academies in Holland, and published them in the biological and medical journals of that country. The first important clinical paper based exclusively on the results of Engelmann's studies was published in 1898 by Wenckebach, who is professor of medicine in Groningen. In 1903, Wenckebach published his well-known book on the arrhythmias, which is based entirely on the myogenic theory. Towards the end of the nineties, Engelmann was called to the chair of physiology in Berlin. Soon after, we find the senior leader of medicine in Berlin, my old teacher, Von Leyden, delivering an address on the myogenic theory and its importance to medicine. The occupant of the second chair of medicine, the brilliant Kraus, we find devoting all his energies to the application of the newer results in cardiac physiology to the clinic. Due probably to the influence of the above-mentioned celebrated trio, His was called to the vacant chair of medicine in Berlin, the very same His, the father of the bundle. No wonder that all Berlin, and with it all medical Germany, is converted to the myogenic theory. Engelmann's connected presentation of the entire problem in the Deutsche Klinik was probably another potent factor for the success of the theory in Germany.

One of the foremost leaders in the new branch of medicine is James Mackenzie. In his articles in journals, in his book on the pulse, and especially in his recent book on the heart, he proves himself to be a most enthusiastic, orthodox adherent of the myogenic theory. These views he had an opportunity to imbibe by his close association with the English physiologists, among whom the myogenic theory found warm adherents many years ago—thanks to the teachings of Gaskell.

Next to Wenckebach and Mackenzie, H. E. Hering has to be mentioned as one of the most active investigators in the new line of pathological research. It is perhaps not an accident that his activity in this line developed after he spent some time in England with the leading physiologists of that country. However, Hering's present allegiance to the myogenic theory is quite doubtful again.

The Cardiac Arrhythmias.—We shall now turn our attention to the pathological side of our problem, to the arrhythmias. Irregularity of the heart, or rather of the pulse, has been a favorite subject of study of clinicians who especially cultivated the functional side in pathology; men like Traube, Riegel, Potain, Kussmaul and others. Many observations have been collected. We thus find in the medical literature a good number of terms purporting to designate the various types of pathological pulses. To mention only a few and at random: The pulses bigeminus, trigeminus, intermittens, deficiens, alternans, paradoxus, bisferiens, interceditens. Each of these designations describes at best only the simple phenomenon of the irregularity. The newer investigations are directed to the study of the nature and origin of the cardiac arrhythmias underlying the various irregularities of the pulse. These studies led to an attempt of a new and perhaps simple classification of all the arrhythmias. The modern interpretation of the various phenomena of cardiac irregularity, which, it must be said, is far from being simple, is based upon the newer knowledge gained in the researches upon the physiology of the cardiac rhythm and is attained essentially by the analysis of grahpic records obtained from various parts of the circulatory system.

In the following I shall attempt to outline in the briefest possible way in the first place the few facts in physiology, the knowledge of which is indispensable for the understanding of the modern interpretation of the arrhythmias; I shall then discuss very briefly the methods employed in studying the human arrhythmias. Finally I shall discuss the classification and interpretation of the arrhythmias as they are advocated at present by the leaders in this new field of clinical research.

A Few Physiological Facts.—I have already mentioned before the term extra-systole. Most of the results achieved by Engelmann in his classical studies upon the heart of the frog were obtained by the extra-systole method. The meaning of extra-systole is simple. When a regularly beating heart is stimulated by a single short stimulus, that heart responds by a single contraction, a systole. By this method a number of pecularities, they are called laws, were found, peculiarities of the intrinsic nervous system, say the neurogenists, of the heart muscle, say the myogenists, or of the embryonic system within the adult heart, say the latest myogenists. But we shall now leave the theories completely out of consideration. The most important peculiarity is the so-called *refractory period.* It was first observed and described by Kronecker, it was later systematically studied by Marey and was finally worked out in many details by Engelmann. Refractory period means this: When the heart contracts normally, or by an extra-systole, it loses for the time being the ability to respond with a contraction to a stimulus. The heart returns to the normal state only gradually, beginning at first to

respond only to a strong stimulus and that only after a long latent period.

In connection with the refractory period there is another peculiarity of the heart of interest; it is the phenomenon known as the *compensatory pause*. The pause following an extra-systole is longer than a normal diastolic pause, it is longer by so much as to make up the loss of the preceding diastole. For instance, if an extra-systole occurs just at the middle of a diastole, the length of the compensatory pause is then equal to a normal diastole and a half.

With these two phenomena is connected a third one, the so-called *post-compensatory systole*. The first systole after an extra-systole and a compensatory pause is larger than a normal systole. I shall not enter into any discussion of the nature and cause of these phenomena, we have neither time nor space for that, but the facts themselves ought to be clearly remembered by every practitioner, as their knowledge is indispensable in interpreting practical phenomena.

Extra-systoles can be produced at the ventricle, at the auricle, and at the sinus. When an extra-systole is produced at the sinus, this systole is not followed up by a compensatory pause, the length of the following pause is only that of a normal diastole. Neither is there the characteristic compensatory pause when the extra-systole is produced in the auricle. However, here the following pause is slightly longer than a normal diastole. I shall repeat that the compensatory pause is characterized by this formula: compensatory pause plus the diastole preceding the extra-systole = 2 normal diastoles. The knowledge of the above details helps localize the cause of an arrhythmia due to an extra systole. I shall say here that according to Mackenzie, in human beings an extra-systole has its origin in the bundle of His, either in the part located in the ventricle or in the part located in the auricle, or it is located in Tawara's node. The allorrhythmia which is caused by extra-systoles which have their origin in Tawara's node is called by Mackenzie nodal rhythm.

Two other peculiarities of the heart muscle I have to mention. Both were established by Bowditch and by Kronecker. One peculiarity is the so-called All or None Law, and it means this: while, when a skeletal muscle is stimulated, the contractions with which it reacts are proportionate with the stimulus, that is, a weak stimulus causes a weak and a strong stimulus a strong contraction, the heart has only one kind of a response to all degrees of stimulation. A stimulus which is just strong enough to cause a contraction will cause the strongest contraction which this heart can make under the given conditions; stronger stimulation will not cause a stronger contraction. The conditions, of course, will influence the strength of response. The degree of vitality, nutrition, temperature, etc., will influence the degree of contraction.

The other peculiarity is the absence of tetanus. A skeletal muscle will respond with a tetanus, that is, with a continuous contraction, to a continuous rapid stimulation. The heart, at least that of vertebrates, responds only with a single contraction, and a continuous stimulation will cause only a series of discrete contractions. This depends probably upon the refractory period; each contraction prevents the further effect of the stimulation until the refractory period is worn off. It should be added, however, that a continuous stimulation is capable of affecting the tonus, that is under continuous stimulation the relaxation of the heart during the diastole becomes less and less complete.

The investigations of Gaskell and Engelmann brought into prominence the necessity while considering the heart's action to distinguish the following various properties:

1. The rhythmicity, that is, the capability of the heart to generate automatically rhythmic impulses.

2. The conductivity, *i. e.* the ability to conduct a given impulse from one place in the heart to another.

3. Excitability or irritability, *i. e.* the ability to receive or respond to an adequate stimulus; it is this property which determines the threshold of a stimulus, so that a heart which possesses more of that property, or in other words, is more irritable, is more ready to respond to weaker stimuli.

4. The contractility, *i. e.* the ability to react to more favorable conditions with stronger contractions.

5. The tonicity, that is, the degree of contraction which the heart possesses during the diastole.

It is a question whether the last-named property is not simply a product of irritability and excitability. The distinction of the other properties is a necessity and their knowledge is of practical importance. It is a question whether the different properties run parallel and are present in all parts of the heart. The question is an intricate one and the details are not settled; I shall therefore not enter into a discussion of them.

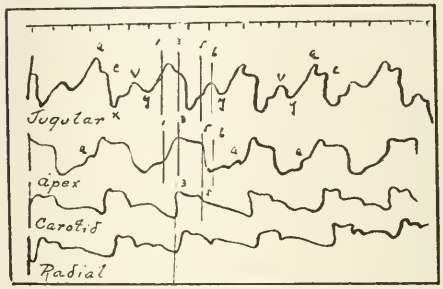
With reference to these properties as well as for other reasons the relation of the vagus and accelerator nerves to the heart have to be discussed briefly. It is generally agreed upon that the vagus terminates within the heart in nerve ganglia which are connected with the muscle fibers by means of postganglionic nerve fibers. The nerve fibers of the accelerators, however, terminate directly in the muscle fibers. There is no doubt that the accelerator fibers act upon the auricles as well as the ventricles, even when a heart block is present. The vagus fibers act undoubtedly upon the auricles; their relations to the ventricles, however, are not very transparent, and opinions differ with regard to several points.

With regard to the action of these nerves upon the heart again the above-mentioned properties have to be distinguished. The vagus fibers inhibit or decrease and the accelerator fibers increase: the rate of beats, the conductivity, the irritability and contractility. Engelmann introduced here a new nomenclature, and since it is now often in use even in the clinical literature, I shall record it here. The nerve fibers which influence the rate Engelmann calls chronotropic, those which influence the conductivity he calls dromotropic; those which influence the irritability he calls bathmotropic, and those which influence the contractility he calls inotropic. Engelmann assumes that each quality is attended by a special set of nerve fibers. I believe that in this regard Engelmann stands alone in his opinion.

There are, of course, many more physiological facts which are employed and will be employed in the elucidation of clinical phenomena. However, the few data given above are most frequently employed by the present clinical investigators, and will afford sufficient aid to those who wish to follow intelligently the current literature on that subject.

Methods.—From the foregoing statements it is evident that for the study of the rhythm of the heart, the knowledge of the contractions of the auricles is as important as that of the contractions of

the ventricles. Formerly the arterial pulse was the sole guide for a recognition of the rhythmic activity of the heart. Aside from the fact that it gave no hint as to the condition of the auricles, it gave no information even of the left ventricle when its contractions were not capable of sufficiently influencing the distant arteries so as to produce a palpable pulse. In this regard auscultation has given better results, as at least the ventricular contractions never escape its notice. But the heart sounds or murmurs mark only the beginning and the end of the contraction of the ventricles; of what happens during this time in the auricles and of what happens in all parts of the heart during diastole, auscultation gave very little information. Great hopes were entertained when sphygmography was introduced, the objective and lasting record was expected to divulge a lot of the heart's secrets. But nearly as great as the expectation was the disappointment. Too much was expected of it; the sphygmogram can tell only what the left ventricle does during the last part of its contraction. The history repeated itself when the cardiograph was introduced, and it was in so far even worse as there was a great diversity of opinion regarding the interpretation of the elevations and notches on the curve. In our time a great deal of activity has been displayed to obtain as much objective information as possible regarding the condition of all chambers of the heart during the entire heart cycle. And now the sphygmogram occupies a prominent position on account of the safe landmark which it contains. The chief wave indicates positively the opening of the aortic valves. The cardiogram again indicates the entire time of the contraction of the left ventricle. Furthermore, it was found that the cardiogram contains also a mark which indicates the beginning of the normal auricular contraction. Besides the proper utilization of the old methods, new methods were developed. Tracings of the jugular pulse tell the entire story of the right auricle. Liver tracings tell the same story and a part of the story of the right ventricle. Minkowsky, on the basis of my statements, made 26 years ago, introduced the method of obtaining tracings from the oesophagus which should tell all about the pulsations of the left auricle. Einthoven, after inventing a very sensitive galvanometer, introduced the method of obtaining photographic records from the electrical changes which take place during auricular and ventricular contractions. The few experts who have employed it speak well of it. However, neither this method nor the obtaining of curves from the oesophagus are for the present of any great practical value. The method which is in vogue now is the obtaining of a phlebogram from the jugular vein simultaneously either with a sphygmogram or a cardiogram. Either of the last-named graphic records has a definite landmark, indicating the opening of the aortic valves. It corresponds to the peak of the first, main elevation in either of these records. In writing the phlebogram exactly above one of these two records a perpendicular line will indicate the exact location of the time of the opening of the aortic valves upon the tracing from the jugular vein. In the normal tracing it corresponds with the elevation which is designated as wave "C." These means of identification are very important, as the waves upon the jugular tracing are sometimes far from being characteristic. When using the sphygmogram from the radial artery for identification, 1/10th of a second has to be added, that is, the time which takes the pulse to travel from the aorta to the wrist. It can not be my purpose to attempt here to describe in detail the procedures employed in these methods. My aim is to present briefly the principles of these methods. I shall, however, reproduce here normal tracings for the purpose of elucidating the terms employed in the analysis of these curves.



The first tracing from above represents a normal jugular phlebogram, or, as Mackenzie calls it, the auricular form of the jugular pulse. Wave "a" indicates the ventricular diastole. Wave "v" is normally produced by various causes. The drop from "v" to "y" is a distinct landmark, it is caused by the opening of the tricuspid valves. These designations were introduced by Mackenzie and were accepted by Wenckebach and other leading students of the subject. There are some controversies as to the mechanism by which the various waves are produced. For instance, Mackenzie believes that wave "c" is simply transmitted from the underlying carotid artery, while Morrow and others believe that it is produced by a positive venous wave. Wave "v" is the most disputed one, and some writers have other designations for it. We shall, of course, not enter into any discussion of these controversies. It is sufficient to know that there is practically no difference of opinion regarding certain landmarks, namely, that wave "a" marks the auricular systole, wave "c" marks the ventricular systole and slope "v-y" marks the opening of the tricuspid valve.

The normal venous pulse which is reproduced here is also designated as the *auricular* form of the venous pulse. This distinguishes it from the *ventricular* form of the venous pulse which occurs in certain pathological conditions to be mentioned later. It is characterized mainly by the absence of the "a" wave and by the presence of a high "c" or "v" wave.

The other three curves represent a cardiogram and sphygmograms from the carotid and radial arteries. There is nothing new about them, except that the slight wave marked "a" preceding the systolic elevation on the cardiogram is interpreted as indicating the auricular systole.

In pathological conditions which lead to various arrhythmias there are various changes which manifest themselves in the jugular pulse. There are changes in the number of waves and their character, and there are also changes in the length of the intervals between the individual waves, especially in the length of the "a-c." There are also changes in the relations between the phlebogram and the sphygmogram or cardiogram. The careful analysis of all these changes is the method chiefly employed in arriving at a diagnosis as to the nature and lo-

cation of the cause of each individual cardiac irregularity.

Types of Cardiac Arrhythmias and their Interpretation.—The irregularities of the heart are at present generally divided into the following five types:

The respiratory type; the irregularities caused by extra-systoles; the irregularities due to a disturbance in the conducting system; the pulsus alternans and the perpetual irregular heart. This classification was introduced by Hering, who employs the following terminology: Pulsus respiratorius, pulsus extrasystolicus, pulsus transmissorius, pulsus alternans and pulsus irregularis perpetuus. The classification as well as the nomenclature were made by Hering, independent of and without regard for any theory. Mackenzie, on the contrary, strives to employ terms which should express his theoretical views. The ryhthm of the perpetual irregular heart he terms: *nodal rhythm* and the respiratory type, Mackenzie classifies as sinus irregularities.

Pulsus Respiratorius.—The least pathological of the irregularities are those which are presented by the respiratory type. The rate of the beats of the heart vary normally with the respiration, the beats being accelerated with the inspiration and retarded with the expiration. In some cases this difference is greatly exaggerated, and during inspiration, when the pulse becomes rapid and small, it seems sometimes completely to disappear under the finger. Under these circumstances this irregularity gives the impression sometimes of a real pathological arrhythmia. It occurs during convalescence after infectious diseases which, in combination with the bradycardia which often appears at this stage, causes grave suspicion as to the condition of the heart. It occurs also in neurasthenia and in certain cerebral diseases. The phenomenon is met with more frequently in children. Mackenzie designated it previously as an infantile type.

In some cases the heart is abnormally slowed like in meningitis or convalescence. In these arrhythmias the relations of the auricles to the ventricles remain unaltered. The change affects the origin of the rythm; hence the term sinus irregularities of Mackenzie. The increase or decrease of rate is accomplished essentially by shortening or lengthening the diastolic phase of the cardiac cycle. These irregularities have their origin in decreased or increased irritability of the vagus center in the medulla. An injection of atropine abolishes this arrhythmia. The nature of this arrhythmia is easily recognizable. Forced respiration increases the irregularity and holding the breath for a while abolishes it. This type of arrhythmia should offer no difficulty in diagnosis and cause no concern regarding prognosis.

Pulsus Extrasystolicus.—The irregularities caused by extra-systole present an interesting and practically important type. The experts on our subject claim that extra-systole is the cause of the majority of all cases of cardiac arrhythmias. It is now generally agreed upon that the various irregularities which were formerly known under the terms of pulsus bigeminus, trigeminus, quadrigeminus, bigeminus continuous, or premature, abortive or "frustrane" heartbeats, are caused by extra-systoles. It is only ten years since the idea was grasped that extra-systoles may occur also in human hearts, and that it may be the cause of some of the cardiac arrhythmias. The first intimation of this thought was given by Wenckebach in 1898. It gives me pleasure, however, to state that at about the same time with Wenckebach, and surely entirely independently of him, the occurrence of extra-systoles in men, with illustrative cases, was described in this country by Professor Cushny, then at Ann Arbor and now at the University College, London. A few years before, Cushny (with S. P. Matthews) demonstrated the production of extra-systoles in the mammalian heart. I have stated above how extra-systoles are produced in the experiments on hearts of animals. We are as yet in the dark as to the nature of the stimulus which causes the extra-systoles in men, but there is no doubt that they do occur, and occur very frequently. It is now established that they can take place either in the ventricle, or in the auricle, or in the junction between the auricle and ventricle. Some describe cases in which the extra-systoles took place at the junction between the veins and the auricles—sinoauricular junction, as it is called. Mackenzie assumes that the extra-systoles take place in the various parts of the system of the left-over embryonic tissue; that is, that it takes place either in the ventricular, or in the auricular part of the bundle of His, or in the node of Tawara, and also in that of Keith. Interesting methods of diagnosis are worked out for the localization of the production of the extra-systole in each case. It will be impossible to enter here to any extent upon the intricacies of this subject. I wish, however, to remind you of that which I stated above regarding the refractory period and compensatory pause. In the human heart also refractory periods and compensatory pauses follow extra-systoles. When an extra-systole occurs in the ventricle, the next normal impulse which comes in regular order from the auricle fails to cause a contraction of the ventricle on account of the refractory period which follows the extra-systole. The diastole which now follows the extra-systole has the length of a compensatory pause. You remember the formula I have given above for the characterization of the compensatory pause; it was this: The sum of the two diastoles before and after a ventricular extra-systole = two normal diastoles. This formula helps to diagnosticate the location of an extra-systole in the ventricle, since extra-systoles which occur in any other parts of the heart are not followed by the characteristic compensatory pauses.

When, in consequence of an extra systole, auricle and ventricle contract simultaneously, which occurs mostly when the extra-systole is located in the atrio-ventricular area, the simultaneous contraction of both chambers often causes a visible pulsation of the veins in the neck, and on the tracing from the jugular vein there is no "a" wave, and the "c" wave appears as one large elevation. This curve represents, as stated above, the ventricular form of the venous pulse.

Leaving the question of localization out of consideration, it may be stated that the occurrence of an extra-systole presents no diagnostic difficulties. It is usually recognized by a premature beat in the radial pulse which is followed by a long pause. If the palpitating finger misses the second pulse on account of its small size, auscultation will reveal the heart sounds belonging to the extra-systole. In many cases the first sound belonging to the extra-systole is characteristically loud. Of special interest are frequently the subjective sensations of the patients. Some patients are conscious of a transient fluttering, some feel that the heart has stopped, others again are shocked by a big heartbeat, which

means that some feel the occurrence of the extra-systole, some become aware of the compensatory pause, and others again are especially affected by the strong post-compensatory systole. In neurotic persons the shock is followed by great exhaustion.

Extra systoles occur frequently in hysterical or neurasthenic persons; but they occur also in patients with suspected myocardial disease, in elderly arteriosclerotics, occasionally in obese persons and in patients exhausted from a febrile infectious disease. Excess of coffee or tobacco hastens the appearance of extra systoles, especially in nervous, neurasthenic individuals. The presence of the above described subjective symptoms speaks for the nervous origin of the extra systoles in those patients. Some deny that extra systoles can be caused directly by nervous stimulation. But the assumption that nervous individuals are prone to manifest extrasystolic arrhythmias does not include the claim that these systoles were produced by stimulation of nerves. The occurrence of extra-systoles is connected with an increased irritability of the cardiac tissues, so that subminimal stimuli become effective. In the course of infectious diseases or in the degenerative processes of the heart chemical substances may develop which increase the irritability of the heart tissue; in localized degeneratiions the irritability of the tissue may be correspondingly localized also. Coffee, tobacco, and other drugs may increase the irritability. So is the irritability increased also in certain hysterical or neurasthenic individuals; and again, either the irritability of all the tissues or only of certain tissues is increased. The stimuli which produce the extra-systoles may be frequently present, but only in such small degrees that they usually remain subminimal and hence ineffective. When the irritability of the heart is by some cause or another increased, the stimuli suddenly become effective. The nature of the stimuli may in some cases be of a purely mechanical kind. Mechanical stimuli are very effective in stimulations of hearts of animals.

The foregoing analysis is well illustrated by the following observation. In a neurasthenic patient with extremely sharpened senses and irritable tissues, who suffered greatly from the subjective symptoms accompanying the extra-systoles, these attacks would often come on when the stomach was filled with food or with gases. When the patient was in an irritable state, the supine position would bring on attacks of extra-systoles; "she would feel how her heart was touching the spine." In both instances it was a mechanical stimulus which affected the irritable heart. Around the time of the menstrual period the attacks would be more frequent and more distressing. With the onset of the menopause, however, the attacks became reduced by at least 80 per cent.

According to the above presented conception, it is not so much the production of new stimuli as the increased irritability of the heart which is responsible for the occurrence of extra-systoles.

Pulsus Transmissorius.—The arrhythmias which have their origin in disturbed conductivity are by far less frequent than the foregoing types of arrhythmias. The various forms of disturbances follow pretty closely the disturbances seen in the experiments by Gaskell on the frog and tortoise and by Erlanger on dogs. Moderate disturbances cause only a retardation of the passage of the impulses from the auricles to the ventricles which may lead to an occasional dropping of a beat. Stronger disturbances lead to a greater disproportion between the beats of the auricle and those of the ventricle, so that two, three or four beats of the auricle would be followed by only one beat of the ventricle. Still greater disturbances of the conducting mechanism may lead to a complete dissociation of the ventricles from the auricles, the ventricle continuing in a rhythm of its own. The disturbance in the conducting system may be caused by organic lesions; however, in moderate manifestations of the disturbances these may be caused by effects of the vagus upon the conducting fibers and also, as some claim, by digitalis. Cases of moderate disturbances of the conduction occur in convalescence from infectious disease, especially from articular rheumatism.

Great interest has recently been aroused by the cases of Stokes-Adams disease, in which at the autopsy in some cases organic lesions were found at the bundle of His. Such patients suffer during life from bradycardia or rather from slow pulse, because only the ventricle then beats very slowly, the auricles beating twice or three times as fast. These patients are subject to epileptoid attacks during which time the heart may stand still for a minute or two. The most plausible explanation is apparently this. In the intervals the patients are suffering from partial block, hence the slow pulse, and the disproportion between the auricular and ventricular beats. At the time of an attack the block for some reason or another becomes temporarily complete, the ventricle then stands still for a while. The attack passes off either through the ventricle starting to beat with its own rhythm or the cause for the complete block has disappeared again. The literature on Stokes-Adams disease—some now add Morgagni's name to it—is pretty large now, and I shall not dwell further on this subject.

I shall add that from our present knowledge of the anatomy of the conducting system it is evident that a disturbance of conduction might take place also between the node of Keith and the bundle of His or the node of Tawara.

For a diagnosis of disturbance of conduction tracings from the auricle and apex ought to be obtained. Cases of very slow pulse should suggest strongly the presence of an incomplete heart block.

Pulsus Alternans.—Pulsus alternans is not a new type; it was described by Traube in 1872. The only new thing about it is, perhaps, that it is not a pulse but a heart alternans. It is not a disturbance of rate, but of the size; a strong beat alternates with a weak one. It is due to a disturbance in the contractility of the heart muscle, it is inotropic in Engelmann's terminology. It seems it can be produced by large doses of digitalis. The alternans indicates weakness of the heart muscle and presents a grave form of arrhythmia.

Pulsus Irregularis Perpetuus.—The perpetual irregularity presents also a grave type of arrhythmia. According to Mackenzie this type is characterized by the completeness of the irregularity and its permanency, by the disappearance of the presystolic murmur which was previously present, by the disappearance of the small auricular wave from the cardiogram and by the change of the venous pulse from the auricular to the ventricular form, that is, the "a" wave disappears and instead a large wave appears. Mackenzie assumes that in these cases a break occurred between Keith's and Tawara's nodes, with the result that the atrio-ventricular node (Aschoff-Tawara) assumes now the regular function of the rhythm production, hence

the term nodal rhythm. As a consequence of this new arrangement the auricle contracts, so Mackenzie assumes further, simultaneously with the ventricle. Other writers believe that the auricle is paralyzed in these cases, a view which was previously entertained, in fact, originated by Mackenzie himself.

This type of arrhythmia occurs in cases of advanced stenosis (and insufficiency) of the mitral and tricuspid valves, and also in advanced cases of cardiosclerosis.

INFANT MORTALITY.

COMPARISON OF THE PAST AND PRESENT.

By WILLIAM LELAND STOWELL, M.D.,

NEW YORK.

VISITING PHYSICIAN TO NEW YORK CITY CHILDREN'S HOSPITAL AND SCHOOLS.

O fairest flower, no sooner blown but blasted,
* * * * * * * *
But oh, why didst thou not stay here below
To bless us with thy heaven-loved innocence?
To slake his wrath whom sin had made our foe,
To turn swift-rushing black Perdition hence,
Or drive away the slaughtering Pestilence?
—*Milton*, 1625.

Foreword.—A babe in the household is a well-spring of joy, notwithstanding that the greatest of poets speaks of one as a "muling, puling infant." The birth of an heir to the throne is telegraphed over the kingdom and to foreign lands. The royal mother and the frontier mother rejoice alike. Raphael's most beautiful canvas is that of "The Mother and Child."

Why is it all? Simply because we all see in the child the possibility that he may attain to our ideal position, a throne may be, a seat among the mighty in business, art, state, or profession. An individual baby is a small bit of matter, but potentially very great. Small wonder then that family, state, and nation are anxious about him. France notably among the nations, because her birth rate has been falling so low.

The subject of infant mortality is as old as the practice of medicine. At various times it has demanded special attention, sometimes in one country, sometimes in another. The earlier writers making children's diseases a special study gave statistics to a slight extent, but mostly gave opinions based upon experience, than which there is no better teacher. During the past generation, however, statistics have been collected in most civilized countries so that comparisons can be made with a degree of fairness. In our own land the census returns have been reasonably full and accurate each decade, but there have been no intercensal figures on a large scale until the year 1900 and since. Now the figures of the registration area comprise about one-half of the population (48.5 per cent.) of the United States, namely, 40,000,000 in sixteen entire States, 90 per cent. of the population in cities of over 8,000 inhabiting the other States. The study of the mortality statistics in their entirety and in the analysis usually presented with them by the authorities gives us the opportunity to compare the earlier days with the present, also to compare city with country, various ages and other factors. Further analysis makes it very easy to determine what special diseases carry off the infants. The object of this paper is to follow out such a study to see wherein we have gained, where we have lost; to determine what the influences were that caused the rise or fall, and if possible lay plans for improvement in the future.

Pre-Natal Causes.—Infant mortality may be fairly considered as beginning before birth. Guillemot and Devillieres claim that 20 to 25 per cent. of pregnancies fail to mature. The birth rate, and its changes, is shown in the accompanying table. It will be seen that the birth rate in the United States was 33.6 per cent. per 1,000 living fifty years ago, while now it is 27.2 per cent., a considerable part of which is due to foreign immigration rather than to American born mothers.

TABLE I.

BIRTH RATE PER 1,000 POPULATION

Countries.	Years.	Birth Rate.
England and Wales	1851-1860	34.1
	1901-1905	28.4
France	1851-1860	26.3
	1894-1900	22.2
Germany	1851-1860	35.3
	1891-1900	36.1
Italy	1871-1880	36.9
	1891-1900	34.9
United States	1851-1860	33.6
	1891-1900	27.2
Sweden	1851-1860	32.8
	1891-1900	27.2

Illegitimacy is also a factor. Illegitimate children may be as healthy at birth, but are so frequently neglected by the mother or sent to overcrowded institutions that they die in large numbers. In Glasgow in 1873 the death rate of legitimate children was 154 per 1,000, while the illegitimate rate was 293 per 1,000. It is interesting to note that the number of illegitimate births in England has fallen from 6½ per cent. in 1860 to but 3 per cent. at present. Deformities such as spina bifida or patent foramen ovale, hydrocephalus, etc., naturally lessen the likelihood of children living beyond infancy.

Heredity.—There are [illegible] vorable constitutional tendencies aside from the inherited diseases, such as syphilis. The offspring of tuberculous parents or those suffering from any constitutional disease will be born with a constitution having little power of resistance against the same or other diseases. The effects of habits or morals of the parents are visited upon the infant, for example the children of drunkards have an unstable, nervous system, are subject to convulsions and epilepsy or become idiotic. Most of the mentally defective in institutions for feeble minded and idiotic are of alcoholic parentage.

Race.—The race problem enters naturally into the study, but not extensively. Before our civil war the proportion of children to women of childbearing age was about the same in the negro and white race. In the decade 1880-1900 there was a decrease of 160 children born to 1,000 negro women, while the decrease of children born to white mothers was 75

per 1,000 women. As a large proportion of negroes in our country are poorly housed and fed, we are not surprised that they die in large numbers. The death rate of negro children in Washington is seven times that of white children.

The following table shows the trend of deaths in several countries during the last thirty years:

TABLE II.

Death Rate Under One Year Per 1,000 Living.

	1876-1880.	1895.	1893-1902.
England	145	150	152
France	163	170	158
Prussia	205	210	199
Italy	249	190	173
Switzerland	189	190	145
United States	166	—	165.4

TABLE III.

Deaths Under One Year Per 1,000 Deaths in the United States.

					Registration Area.	
1860	1870	1880	1890	1900	1906	1907
207	229	231	234	191	202	190

A glance at these tables shows that the English speaking countries have made very scant progress with infants under one year. Death rates reached their maximum about 1890, since which time there has been a general decline. The epidemic and contagious diseases figure most largely in the mortality waves, and infectious diseases tend to prevail together.

Table IV sets forth the percentages according to method of feeding:

TABLE IV.

Death Rate in Infants' Hospital According to Methods of Feeding.

1902	7.47	62.14	....	16.67	1902	*2.17

*Note.—Only a few cases remaining in the institution.

Institutional Mortality.—The realization of the necessity for public care of the city's infants seems to have come over philanthropists and physicians with great force between 1865 and 1870. In 1866 the New York Infants' Hospital was opened. About the same time the New York Infant Asylum, a private, Protestant institution, was organized, and also the New York Foundling Hospital under Roman Catholic auspices. In order to have a basis for views concerning the care of infants which would influence their mortality, I selected as a basis the history of the Infants' Hospital of New York City, commonly called the Randall's Island Hospital. The Infants' Hospital first consisted of a collection of infants taken from the almshouse, penitentiary, and from the City Hospital, or Island Hospital, as it was then called, on Blackwell's Island, all of which were institutions for adults. These were placed in a new building erected on Randall's Island in 1868. The classification was such that the records showed the total number treated, with the mortality, the foundlings and the orphans with their mortality, and children with mothers. The first five years of the hospital showed an annual aggregate of 1,166 patients treated, with a mortality of 36.7 per cent. In the first five years the orphans died with an average mortality of 55 per cent., while the mortality of the mothers' children was 16 per cent. The next five years showed orphans and foundlings with a mortality of 44.6 per cent., while the mothers' children had a mortality of 12.4 per cent. During the third quinquennial period, the mortality of foundlings and orphans was 56.8 per cent., and the babes with mothers 12.6 per cent. It seems to be a universal rule that the mothers' children have about four times the chance of life that the orphan or foundling has.

In 1875 the Hospital, being badly crowded, it was determined to board some of the infants with families in the country, Westchester County. This was called "farming out." From that time on, from 55 to 80 babies were farmed out each year. The mortality among these was noted as 14 per cent. in 1875, 21 per cent. in 1885, 48 per cent. in 1888. It was discovered in 1883 that the expenses of farming out the babies was 42 cents a day, while it cost but 29 cents to keep the infants in the Hospital. It was therefore thought wise to discontinue farming out, but the crowded condition of the Hospital led to the return to the former policy in 1885. From this time the custom prevailed and failed by turns. In 1898 a definite effort was again made to place the infants to board. A committee from the State Charities Aid Association joined with the Guild of the Infant Saviour, and the committee thus formed took in charge the matter of placing out the foundlings. During that year, 1898, 61 were taken from Randall's Island, of whom 34, or 55.7 per cent., died. The next year 36 were so boarded out, with the mortality of 58 per cent.; 1901 was a more successful year, 40 boarded out, with a mortality of but 27 per cent. The figures concerning farmed out babies show remarkable fluctuation, as much as those in the Hospital, but in the main the mortality was lower than for the same class of infant remaining in the institution. Comparing the total mortality of the quinquenium 1898 to 1902 with the mortality of the first five years of the Hospital, we find a decided gain, 22 per cent. instead of 45 per cent.

There is a still greater gain in the last five years even among mothers' children over the first five years of the same class, 5.5 against 16.12 per cent. The average mortality of the foundlings from 1897 to 1901 was 47 per cent., a gain of 8 points as compared with the five years 1868-1872. In seeking causes for the fluctuation of rates, and also to determine what was the prevailing plan for caring for each class of children, I have gone carefully over the history of the institution. It seems that children were bottle-fed with various proprietary foods, but in the main milk was the standard diet, both in the early and the later years of the institution's history. In 1890 sterilized milk was in use, as the notes of the Medical Board show in a report on the manner in which the milk was sterilized and carelessly prepared. It was then put under the direct control of a managing nurse, with the result that there was great improvement in the condition of the children. In 1891 all the bottle-fed babies were put in one ward under a responsible nurse instead of under the care of the workhouse women or the mothers of other children. The number of wet-nurses was increased in 1892 and they were or-

dered extra diet. In 1893 there are again notes on the sterilizing of the milk. It was sterilized in bulk, being brought directly from the cows belonging to the Hospital and sterilized in the steam cooking caldrons of the kitchen. In 1896 Percentage Feeding was introduced, the milk being prescribed with proper proportions of fat, proteids, and sugar for each individual child. The bottles of modified milk were then pasteurized for twenty minutes at a temperature of 170°. This was done in the large steam caldrons in the kitchen, and later in clothes boilers especially heated by gas. In 1898 there were many changes at the Infants' Hospital which brought about a great fall in the mortality. First, the number of babies wet-nursed was increased from 20 in 1897 to 139. In 1898 the main Hospital building underwent complete change, being practically rebuilt except the outside walls. During this time many of the infants were taken to one-story pavilions on another part of the Island, 824 were discharged, *i. e.* two-thirds of the whole number treated instead of the usual one-half. The improvement in their condition was marked after that change alone.

With the beginning of the year modified milk was prepared from Walker-Gordon cream. Beginning in January of that year all infectious cases were removed from the Island as soon as discovered, and turned over the care of the Health Department. Boarding out was resumed in April, 61 babies being sent to individual homes in the country, as previously mentioned. The institution also received the gift of a copper sterilizing plant which made more easy and simple the work of sterilizing large quantities of milk than it had formerly been. The result of these many changes and improvements was a reduction of the mortality to 19.8 per cent. Though it did not remain at this low figure, it never rose to a greater height than 27 per cent. thereafter. It might be recalled, however, that the mortality in 1875 and 1885 was only 28 per cent. and a fraction These changes, every one of which was a help, show that we should avail ourselves of every possible means to reduce mortality, and that while no one is very powerful, several become all powerful.

Overcrowding.—Overcrowding of population leads to many faulty conditions of hygiene in general, and the personal care of children in particular. As the density of population increases the mortality rises. This is made particularly clear by tables, one of which shows the density of population in England and Wales during 1851 to 1866. This is by square miles over the entire country, and shows the death rate per thousand population for all ages, especially that for children under five years. It will be seen that the mortality increases more in the case of young children than at any other ages.

TABLE V.

Density per square mile..	166	186	379	1718	4499	12359	65823
Rate, all ages..	16.9	19.1	21.9	24.8	28.0	32.9	38.6
Rate, 5 years..	37.8	47.5	63.0	82.1	94.0	111.9	139.5

The mortality statistics, to be thoroughly appreciated, should be divided into city and country. The census figures of the registration area of the United States for 1901 to 1906, show that the mortality in rural districts was 14.1 per cent. deaths from all causes per 1000 of population, while the urban rate was 17.3 per cent.

TABLE VI.

DEATHS FROM DISEASES OF EARLY INFANCY PER 100,000 POPULATION—NEW YORK STATE.

Years.	Cities.	Rural.	In Registration Area.
1901.....	70.9	39.8	20.722
1902.....	71.0	39.0	21.811
1903.....	74.0	42.7	22.514
1904.....	76.0	42.5	24.001
1905.....	77.5	47.6	23.617
1906.....	81.8	47.3	29.743
1907.....	82.2	49.4	30.637

This in general accords with what we have found in detail specific instances.

As an example of the effect of city density, we have a table compiled largely from data furnished by Dr. Guilfoy, of the New York City Department of Health, showing the population per acre in a number of tenement house blocks, with the population under five years of age, and all ages, the death rate of each class, and the rate of mortality of certain diseases common in childhood. This will be readily understood and correctly interpreted, except possibly as to the tuberculosis in the adults. The small number of deaths in some blocks may be due to the fact that adults are sent to the hospital, while infants and small children in a larger proportion are kept at home to be cared for by the family.

It should be remembered that density per acre is not necessarily a reliable standard, as it is possible

TABLE VII. DEATHS IN 1905 AND 1906 IN CERTAIN BLOCKS FROM PRINCIPAL DISEASES. POPULATION AND DENSITY, RATE PER 1,000 AT AGE—PER W. H. GUILFOY.

for a large number of people to be housed on a given area of land under hygienic conditions; for example, the Ansonia, New York's largest apartment hotel. This covers one and six-tenths acres of ground, contains 2,500 rooms, and 2,000 persons, making a density per acre of 1,262. This is almost as dense in relation to the area as the Chrystie street block, having 1,280 persons to the acre. The conditions other than area are as diverse as possible, the Ansonia being situated near the Hudson River between Central Park and Riverside Park, all rooms opening outside, not into air shafts, but courts open to the street, and everything about the building of the most modern and hygienic pattern possible. The building has sixteen inhabitable floors, so that in reality the persons living here occupy twenty-six acres of floor area. In the seven years since the building was opened, there has been no infant death there, nor has an employee, of which there are four hundred, given up work because of tuberculosis. This shows that under modern methods of building in large cities it is possible to have a density of population without a high death rate. However, the general statement is true concerning working classes and the tenement population. A safer criterion is found in the analysis of persons living in a definite number of rooms. For example, Neumann in Berlin, in 1903 investigated 2,701 infantile deaths; 1,792 occurred in one-room dwellings, 754 in two rooms, 122 in three rooms, and 43 in larger dwellings. These statistics also go to show that air, light, and sanitation go hand in hand with the health conditions that will be expected in few rooms of large dwellings as contrasted with the crowded quarters. The smaller the number of rooms, the larger the number of deaths is the rule.

Value of Nursing.—It is generally admitted that the natural food for young infants is their mother's milk. It has been customary from earliest times to advocate a wet-nurse only when a mother was physically unable to nurse her child.

Dr. Harris, physician to William and Mary, in the early part of the eighteenth century, wrote as follows: "It is grievously to be lamented that so many Mothers not only of high Rank but even of the common Sort can with so much Inhumanity and more brutish Cruelty desert their tender Offspring and expose them to so many Dangers of mercinary Nurses who are greedy only of the profuse Rewards bestowed on them at Christening and so being weary of their present Employment perform it Negligently while they are looking out for a new Prey. Let us make a Survey of the Advantages that permit Mothers so commonly to sacrifice their beloved Offspring. They are the more free Enjoyment of Diversions, the greater Niceness of adorning their Persons, the opportunity of receiving impertinent Visits and returning those insipid Favours, the more frequent Attendance on the Theatre or the spending the greater Part of the Night at their beloved Cards."

That is exactly such a statement as may be heard in the twentieth century medical lecture. The women of to-day are but a replica of their forbears.

The advantages of the mother's milk for the babe are evident in comparing the death rate of mother's children with those wet-nursed, or brought up artificially on milk or prepared foods. The Infants' Hospital supplies data to make this perfectly clear. See Tables IV and VIII.

An example of the value of mothers' nursing their own offspring can be found in the history of our American Civil War, in 1861-5. Wars and the nursing of infants may seem to be far apart, but during the war cotton was not shipped from this country to England in the usual quantities. As a result the factories there in large numbers were closed. The women who do so large a proportion of the factory labor had perforce to remain at home. The result was that their infants were nursed regularly and had a mother's care. This gave rise to a great falling off in infant mortality in the manufacturing cities.

During this period 24 per cent. of the population became objects of charity, and the general death rate was low. After the close of our war and the reopening of the mills, the death rates rose to their usual height.

TABLE VIII.

Wet-Nursing vs. Bottle Feeding—Death Rate of Orphans Wet-Nursed and Bottle-Fed at the Infants' Hospital, New York.

	1897	1898	1899	1900	1901	1902	1903	Total

Percentage of deaths	73.1	33.40	46.10	61.70	48.85	62.14	45.21	*53.76*
Mother's children	499	578	462	483	554	495	324	3,395
Mother's children, died	68	44	28	34	29	36	28	267
Mother's children, per cent	13.6	7.6	6.0	7.0	5.2	7.47	8.9	*7.8*

This table exhibits clearly the difference between wet nursing foundlings or orphans and bringing them up on the bottle. In general terms we may say that the mortality among mothers' children is less than 10 per cent., while among orphan children wet-nursed it is a little higher, and in the orphans brought up on a bottle four times the fatality of those wet-nursed.

Relation of Diarrhea to Manner of Feeding.—Newsholme gives figures concerning 10,308 homes. In these homes occurred 121 deaths due to diarrhea among infants. Of this number 6½ per cent. were suckled, 36 per cent. fed on cow's milk, and 30 per cent. on condensed milk, the advantage to the nursed baby being six to one over that fed upon cow's milk.

From earliest times it has been customary in some institutions to board out a portion of the children in homes, preferably in the country. In 1872, farming out was begun from the Infants' Hospital. From 55 to 80 and occasionally more were so boarded in Westchester county, just north of the city. The mortality varied from 14 to 58 per cent. Farming out of babies has been the habit of the New York Foundling Hospital for many years, as many as 1,000 being boarded out all the time. The mortality of this institution was, in 1879, 29 per cent.; in 1906, 32 per cent. This last mortality is greater than that of the institution formerly, and has been explained as being due to so many infants

being received in a diseased condition requiring such careful and skillful treatment, cases that were formerly sent to the Infants' Hospital. It must be true that the class of patients is different, because this same hospital in 1902 had a mortality of only 21.6 per cent. and in 1903, 23.2 per cent. There have been no epidemic diseases in recent years to cause the change.

Infanticide.—In the list of causes of infant death, we commonly find a statement that child insurance is a factor, it being claimed that the mothers of poor children may neglect them in order that they may realize on the insurance in the event of the death. This seems a libel on the humanity of mothers, be they ever so ignorant or poor. That infant insurance is not a factor in this country can be readily proven. Insurance in the United States does not begin until the child is one year old and upward. The Medical Director of the Metropolitan Insurance Company informs me that in 1895 they had in round numbers 800,000 children insured under ten years of age. The experience of the two other large industrial insurance companies, the Prudential and the Hancock, are similar to the Metropolitan, therefore will be treated together. In these companies there has never been a single death of a child brought about by reason of its insurance. The mortality of insured children is less than the general mortality. The experience of the London Prudential has proved this in England, and the Metropolitan in this country. For instance, at the age of two years next birthday, according to Farr's table, there would be 65 deaths per 1,000 of that age, whereas the Metropolitan's experience has been only 49 deaths per 1,000. In England, in 1890, there were insured 4,150,000 children under ten years of age. Infants are insured there almost from birth. As the amount of insurance paid on the life of an infant increases in proportion to the length of time of the insurance, the payment being weekly, it is poor business policy to allow children to die if they are insured. Insurance upon adults having a definite sum for each premium presents a different proposition. We know that death of adults has been sought for their insurance. Infanticide is a factor in infant mortality and gives us a shock of horror as the numbers appear in cold print, but happily the number has been diminishing for the past ten years.

Infants are neglected and many wilfully destroyed; for instance the coroner's physician of this city supplies the figures for the years 1906 and 1907:

TABLE IX.

	1906	1907
Infanticide	6	4
Atelectasis	23	37
Suffocation of babies due to clothing or overlying	5	9
Marasmus	224	117
Unknown babies abandoned or reported on soon after death	71	137

Many of these cases are undoubtedly criminal although proof is usually lacking. But in a large city of this kind, with so large a number, it is interesting to note that the matter of insurance can not be considered a factor, either from the company's standpoint or that of the coroner.

Infanticides in the United States

1894	340	1898	248
1895	269	1899	182
1896	300	1900	159
1897	321	1904	153

Specific Diseases.—The causes of death of infants under a year of age are easily compared with the other ages. It was formerly assumed that the mortality of infants was one-eighth that of the mortality at large. Infant mortality for the registration area for 1906 was 20 per cent. of the total mortality instead of 12½ per cent. as was once thought to be normal. The census returns give us much valuable information for large areas, and are not so misleading as local reports may be. Grouping the infant deaths since 1900 produces a table of facts full of suggestion. Of twenty-five diseases tabulated, a few are especially worthy of comment. Typhoid fever since 1900 has declined somewhat. Malarial fever and influenza have also diminished. Smallpox, although the cases are exceedingly few, only 66 for the area, has increased. Measles and scarlet fever, remain the same. Whooping cough has improved somewhat, also dysentery and diphtheria.

Pulmonary tuberculosis has fallen off slightly, although not so markedly as in adult practice. In 1906, 10 per cent. of the total mortality was due to pulmonary tuberculosis. Only 3 per cent. of the deaths from pulmonary tuberculosis occurred in children under five years of age. This makes the mortality exceedingly small from tuberculosis when we recall that 28 per cent. of all deaths occurred under five years. If it be true that tuberculosis in children is most often due to the bacilli that may be in milk they should die largely from abdominal tuberculosis. According to the reports in the census office for the years 1901 to 1905, the deaths from abdominal tuberculosis number 3 per cent. of the deaths from all forms of tuberculosis at all ages. In 1905 there were 373 deaths from abdominal tuberculosis in children under 5 years, *i. e.* two-tenths of 1 per cent. for that age. In 1906 there were 465 such deaths under 5 years, or six-tenths of 1 per cent. In each year they constituted less than one-fifth of the abdominal cases. The frequency of involvement of certain portions of the body under 5 years differs from the total or adult proportions as shown below:

	Under 5 Yrs.	All Ages.
Tuberculosis of lungs	.37	.88
Tuberculosis, meninges	.47	.05
Tuberculosis, abdominal	.08	.03

Deaths from Tuberculous Meningitis per Million Living, England and Wales.

1861-1870	301	1891-1900	216
1871-1880	284	1901-1905 (5 yrs.)	185
1881-1890	234		

Reduction of 40 per cent. in 55 years, but less than in pulmonary tuberculosis (55.5 per cent.).

It may be remarked in passing that tuberculosis in children is almost wholly of the human type, not of the bovine type (Dr. Park).

The general mortality throughout our own country and foreign lands has been steadily falling in recent years. This is largely due to the increasing knowledge of the causes of disease and the dissemination of such among the laity. Schools, health journals, and Boards of Health are all lending a hand and together with physicians are educating the public.

Table X, from the paper by Sidney Phillips, shows most clearly the trend of disease in England for fifty years. Although it is not confined to infants and young children we here have the diseases which seriously affect them.

Table XI indicates in like manner the progress

made in controlling preventable diseases in New York City.

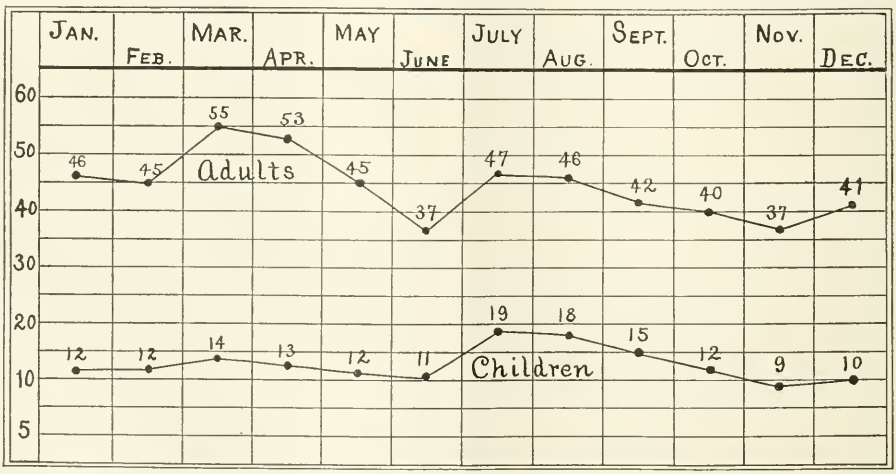
Infectious Diseases.—The pathologists have been especially active in recent years, the germ theory having changed our views of many diseases, not only those which we knew as infectious, fevers a generation ago, but adding diphtheria, rheumatism, pneumonia, tuberculosis, some forms of meningitis, and various forms of intestinal troubles that were formerly classed as diarrhea and cholera-infantum. Finding and isolating Eberth's bacillus, the germ of typhoid fever, the Klebs-Loeffler bacillus of diphtheria, the menigococcus and pneumococcus has enabled us to intelligently wage war against these diseases, either to prevent their spread or to curtail their progress when present. Graphic charts showing the yearly number of cases of infectious disease occurring show rise and fall like the waves of the sea. These tides of infection make the study of epidemiology of very great interest, and an important part of the study of infant mortality, because infants even at the age of one year or less are affected by these infectious diseases. We find in studying the contagious diseases that the number of children attacked increases in proportion to their exposure out of the home, for example at school. However, with young infants we find a large mortality due to disturbances of the digestive system which comes from causes within the home. Some of these are recognized as infective, for example dysentery, due to the Shiga's bacillus. Pneumonia prevails at all ages, and having an air-borne cause, it, with bronchitis, carries off large numbers of young infants. For example, in 1907, more than 14,500 infants died from pneumonia alone, in the registration area, and 4,370 from bronchitis.

Violence.—The number of cases of death due to violence in infants and young children has increased enormously, which shows a peculiar moral condition of the country or else unusual change in the manner of reporting deaths by violence. Diseases of the kidneys, Bright's disease for example, remains practically the same. Diseases due to the circulatory system are about the same. Veneral diseases have increased relatively and actually 1,299 deaths are reported for 1907. It is not apparent how this has come about. An increase of 40 per cent. in five years needs explanation and correction. We do not like to think that the morals of the country are degenerating so rapidly, but the facts remain that the deaths due to venereal diseases have increased very markedly. A study of the individual diseases and the death rate would lead us to congratulate ourselves on the management of infectious diseases. Probably the increased efficiency and thoroughness of health boards as mentioned is a factor in this, but the digestive diseases, diarrhea and enteritis included, are in a large measure due to infection by means of the food supply. Here we are losing ground since 1900.

TABLE XII.

Deaths by Months in the Registration Area in 1900. (The Figures Denote Thousands.)



In March and April pulmonary deaths predominate and occur chiefly among the adult population. In July and August diarrheal deaths are highest and are chiefly among the very young.

Season of the Year.—Factors to be taken into account are the time of year and the atmospheric conditions as well as the character of the food. The relation of these to each other is very close, for in hot weather, July, August, and early September, conditions are such that food easily deteriorates, milk becoming sour and indigestion and diarrhea resulting. Moreover the milk is more likely to become infected in hot weather as this is the season that the domestic fly flourishes. It has been noted that when there was an epidemic of diarrhea the domestic fly was also prevalent and doubtless played a large part in spreading infection. The various bacteria also flourish in hot weather as the *Bacillus coli communis*, the *Bacillus enteritidis* of Gaertner, the *Bacillus acrogenes*, and others. In fact there are forty bacteria which have been identified in the intestines, and several streptococci. Newsholme gives figures concerning ten thousand homes with analysis of the deaths from diarrhea in babies. Of the 121 deaths, 6½ per cent. were nursed, 36 per cent. given cow's milk, 30 per cent. condensed milk. As high as 18 per cent. of diarrhea deaths have been found among breast-fed infants, showing that enteritis may occur when the food supply is ideal.

The percentage of deaths due to diarrhea and enteritis has not diminished at all in the last six years.

TABLE XIII.

Percentage of All Deaths Due to Diarrhea and Enteritis.

Annual Average, 1901 to 1905.	1902.	1903.	1904.	1905.	1906.	1907.

Deaths Under Two Years of Age in Registration Area per 100,000 Population from Diarrhea and Enteritis.

Year.	Deaths.	Rate.
1900	33,479	...
1901	28,523	91.2
1902	26,903	84.3
1903	26,697	82.1
1904	30,315	91.5
1905	33,032	97.8
1906	42,581	103.9
1907	41,563	99.5

—(Mort. Stat., 1906 and 1907, Table III.)

What Is Being Done.—Day Nurseries have been established in the large cities, New York having 62, London 55, and Paris 66. Madam Coullette's Restaurants for Nursing Mothers have proved of great value in Paris. The New York Department of Health, Bellevue and some other hospitals send out nurses to instruct the mothers wherever there is a new-born infant. The city and country homes have accomplished great good, for example, at Coney Island and the Rockefeller Institute. Quarantine of the homes or schools, clean milk, certified, perhaps pasteurized, all are factors. London has a daily supply of one-quarter of a pint per capita, New York City three-quarters of a pint per capita. If it all goes to babies, ours should be the better. Last year about fifty societies sent representatives to a committee organized by the Board of Health of New York whose business was in every way possible to lessen infant death rate, by instruction, recommending proper food, places where medical advice could be had, etc. If all the leading charitable societies in all our cities were to combine as here, great good would be accomplished.

Fresh Air Work.—Fresh air philanthropy was begun in this city by Rev. Dr. Muhlenberg in 1849. It has grown so that now there are fifteen general and twenty-five denominational societies in New York. Forty of our cities have like agencies so that they report 1,200,000 day trips a year, not to mention the fortnightly outings which reach the thousands. These outings are a great factor in the welfare of the young children as well as infants.

Advice to Mothers.—One of the best methods to preserve infant life is that begun in Paris in 1893 by Variot, the "Consultations des nourrisons." Mothers are required to return to the lying-in hospitals each week to report upon the condition of their infant. Nursing has increased greatly since the consultations became general. Bresset reported 61 per cent. of mothers nursing their offspring in 1899, but this was increased in five years to more than 81 per cent.

The New York Association for Improving the Condition of the Poor has an ideal plan in the Caroline Rest Fund which centers its attention upon the mother. Their nurses instruct the tenement mothers before confinement as well as advising after the child arrives. This work is new but the results published in 1908 concerning 337 cases are encouraging as the infant deaths in cases visited before confinement were not one-third the number occurring in cases visited only after the birth. The same study of patients shows a mortality of 17 per cent. in cases conducted by midwives as compared with 8 per cent. where physicians were employed. This argues well for knowledge and prophylaxis *vs.* know-nothing and do-nothing.

The following table illustrates the result of the efforts we are making. It is encouraging in many ways and suggestive of lines upon which to work in future. It shows clearly that the ratio of progress has been greatest in epidemic diseases and the least in those of early infancy. This is exactly as might be expected, for to one class we are all alert, while to the other we give almost no heed.

TABLE XV.

Deaths per 100,000 Population in Registration Area U. S. A.

Classes of Causes of Death.	Number in 1900.	1900 1	Increase (+) or decrease (—) from: 1901-2	1902-3	1903-4	1904-5	1905-6	1906-7	1900-7	Ratio of Gain.
All causes, all ages	1755.0	—99.0	—61.9	+17.7	+52.1	—47.0	—10.7	+40.0	—109.7	.06%
Epidemic diseases	166.2	—10.1	—18.1	+ 6.2	—14.3	—14.1	+ 6.8	+ 4.0	— 39.6	23 %
Other general diseases	312.4	— 3.4	—12.0	— 8.7	+16.7	— 7.0	—10.0	+ 4.1	— 4.7	1.5 %
Diseases of respiratory system	250.2	—25.0	— 7.7	— 4.6	+14.3	—26.6	— 5.3	+13.3	— 42.5	16 %
Diseases of digestive system	220.2	—25.0	— 0.4	— 3.6	+11.4	+ 4.0	+ 6.3	— 7.4	— 23.1	10 %
Diseases of early infancy	76.9	—10.7	+ 2.2	+ 0.8	— 3.2	— 2.4	+ 2.6	+ 0.8	— 3.5	4.5 %

It is hardly necessary to point out that the lessons of this table are found in the last column, the ratio column.

In Berlin there was opened last year the Empress Augusta Victoria House for the reduction of infant mortality; an institution where every form of information pertaining to infant mortality will be gathered as well as given out. There has been in-

corporated in New York "The Infants' Science Academy" for the scientific study of infants, their health, care, diseases, and physical development, and for the interest of mothers in all that pertains to the care of infants.

Just now, in this year of grace, 1909, a bill has been introduced in Congress to form a Federal Children's Bureau to deal with facts of birth rate, infant mortality, physical degeneracy, illigitimacy, and other juvenile matters. When this bureau is in operation much valuable statistical matter will be gathered.

Early Infancy.—According to the international classification of causes of death, early infancy includes only those under three months of age. In 1907 there were more than 30,000 deaths in early infancy in the registration area. In the first group of the list are congenital debility, jaundice, atelectasis, infanticide, atrophy, sclerema, etc. In the second group are cellulitis, inflammation of the umbilical cord, umbilical hemorrhage, or cellulitis. In the third group are exposure, neglect, privation, starvation, and lack of care.

The first group will be seen to be due to maternal influences, the second to infections at or soon after birth, the third to social conditions.

Many lives might be saved from group one if those who are to become mothers could be properly educated, nourished, and cared for before delivery. We have a society of Sanitary and Moral Prophylaxis making a fine effort to prevent and overcome venereal diseases. We need Maternity Prophylaxis circles to inform young women, and men as well, of the needs and privileges of young mothers.

Great care is exercised in breeding fine cattle, fast horses, dogs with proper muzzle, fancy birds, and poultry. For many years the government has expended vast sums of money in raising fishes and vegetable products and sending forth the information about them. Let us do as much and more on behalf of the infants.

What Might be Done.—Most young parents and but few with families know the requirements and dangers incident to infancy. Social settlements and church clubs should conduct the training of man and woman not wholly manual training. Teach the parents that are to be. The general practitioner should realize his responsibility in instructing young mothers without waiting to be called for specific diseases. Mothers, or those about to become mothers, should not be permitted to work in factories until in perfect health.

There is abundant knowledge already lying dormant. It should be given to the young people. Thousands of the youth of our land do not get beyond the High School in our educational system. I recently examined all the books on physiology and hygiene in the library of the New York City Board of Education. Not one of them alludes to infants or children as being different from adults in structure or development of body and brain. The mysterious period of adolescence through which the youths are passing is not hinted at in text book or school room. Outside the school room there are enough hints of sex relation not always delicately expressed. Matrimony and maternity of course are never mentioned. Why not have every graduating high school class given a lecture by a mature and wise physician or educator, who may speak wisely, recognizing the influence of the sexes upon each other, dealing with the institution of marriage in its physical and social aspects. Warn against sentimental affection where health of body and mind are more important. Urge the wisdom of preventing child labor and long hours of work for women when they should not work at all in factories and shops.

Boys and girls in their teens are very quick to be interested in large subjects, are inclined to think they know everything. All the facts possible should be given them to insure a sturdier lot of infants in the next generation.

Conclusion.—Graham says that 50 per cent. of the infant deaths are preventable. If this be true, the physicians of the United States should be indicted for homicide in 50,000 instances a year. It is not enough to complacently watch the death rate go down in some instances, it is our province to make it go down by our skill in treatment, or better by prophylaxis, and not take praise where the credit belongs to the mildness of season or the absence of epidemic. We need to study physiology more closely, especially the action of the heart and lungs, and the mysteries of metabolism.

Improved sanitation will, naturally, include inspection of the tenement, with a study of the methods of keeping food, especially milk. Hygiene of a general sort taught in the schools makes an impression on the children which they will not forget when they are adults. It is hardly necessary to assert again that babies should be nursed by their mother, and if not should be given milk prescribed in proportions or formulas on prescription by physicians and not according to chance rules of the laity.

INSTANTANEOUS RADIOGRAPHY IN LESS THAN ONE HUNDREDTH SECOND; A NEW METHOD OF RADIOGRAPHY.*

By FRIEDRICH DESSAUER,

ASCHAFFENBURG A. M., GERMANY.

The endeavors of Rosenthal, Rieder, and others to shorten the time of exposure are well known. By systematic work they were successful in making good Röntgen negatives of the thorax in 1 to 5 seconds without using an intensifying screen, and with such even in fractions of a second. If I am not mistaken, Rosenthal has even taken a radiogram with intensifying screen in 1/25 second, show-

*A paper read at the Fifth International Roentgen Congress.

ing in distinct outlines the shadow of the heart of an adult. This picture could be seen at the Congress of Amsterdam.

At the same Congress Mr. P. H. Eykmann, from The Hague, showed his radiograms of the act of deglutition in man, laying much stress on the necessity of solving the problem of actual instantaneous radiography. It is important to define the conception, "Instantaneous Radiography," more precisely. By the term momentary radiography only such work should be called in which the time of exposure is so short that the action of the heart or any other slight movement which the patient might make does not disturb the distinctness of the picture.

A real instantaneous radiogram, therefore, must be taken in less than 1/50 second. But it would be still better to reduce the entire time of exposure to 1/100 or 1/200 of a second. I have endeavored to solve this problem by a series of experiments, which I propose to explain in the following, although the results must as yet be regarded as only partial.

First, I must once more revert to Mr. Eykmann's work. He was, so far as I am aware, the first to conceive in full measure the importance of this problem and to emphasize it; the first, too, to promote it by constantly endeavoring to interest physicists and technicians with whom he was acquainted in its practical pursuit. In the *Archiv für physikalische Medizin und medizinische Technik* he describes his adventures on these trips and the work done by the authorities visited.

A discharge (single spark) of the new apparatus for instantaneous röntgenograph.

Mr. Eykmann visited me several times during my experimental work in my laboratory at Aschaffenburg, and gave me some valuable hints. It is chiefly due to his continuous urging that, after many failures, I always again took up the experiments, modifying them as found necessary. I would, therefore, thank him here heartily.

The problem of shortening the time of exposure in radiography to 100 or 200 parts of the time required in those exposures which hitherto have been erroneously termed "instantaneous" is undoubtedly soluble. In fact, it has been solved already in principle. I have made a series of pictures of the extremities of the thorax, the left superior part of the lungs, the heart, which I have all done in less than 1/100 second. These were only slightly, some even not at all, underexposed.

But they are not as good as well made time radiographs. On the other hand, they have been done without any special care, with cheap tubes, without careful adjustment of the tubes; besides that, an intensifying screen has been used in making them, and this, as is well known, reduces the quality of the pictures considerably. I used the Schleussner plate, as mentioned, with intensifying screen, but without any other auxiliary. My first endeavor was to satisfy myself that such short exposures were possible. To improve the quality of the pictures is a special task, which seems to me to be quite possible. Also the intensifying screen will soon be superfluous.

With regard to the technique, I can at present only say the following: The problem is to generate for a very short time an extremely powerful stream of cathode rays in the tube. The first surprise was to find that quite ordinary tubes, without special backing of the anticathode, will stand this strong stream perfectly well. During the most brilliant illumination of the tube one sees a spot on the anticathode becoming red hot. However, as the time is so extremely short, the anticathode is not destroyed, so far, at least, as my experience goes.

It has proved to be serviceable to increase the size of the anticathode, an alteration the importance of which I emphasized already more than a year ago.

For generating the impulses of discharge there are several physical possibilities, the factors always being the same, viz., capacity and transformer, or transformer alone, or direct generation of high-tension impulses of current. I was successful, after many trials, with a combination of capacity and transformer. Figure 1 is a photograph of such a single impulse, which manifests itself in the shape of a spark.

One of course has a right to question the time of such extremely short exposures which are said to be done by automatic switching. Rosenthal rightly stated last year that such measurements are incorrect. The time of exposure is not equal to the time during which the primary current flows through the circuit, but rather equal to the time of the illumination of the tube, measured from the initial flashing up to that of the entire extinction of the light. This time can be measured in an exact and entirely adequate manner by means of a rotating film. A motor, whose number of rotations is known, turns a film which is enclosed in paper impermeable for light. Before this film is placed a piece of lead foil having a narrow slot. Through this diaphragm Röntgen rays fall on the film; the time of the illumination of the tube is then calculable by the breadth of the stripe shown on the film after development, the amount of rotations of the motor, and the diameter of the circle in which the film was rotating.

This method of radiographing in a very brief time opens up a new possibility in Röntgen technique which I would at least mention: the röntgenological technique becomes very much more simple. It is no more necessary to fix the patient carefully. The entire manipulations in radiographing do not require more trouble than the pulling of the trigger of a gun. The rest is done quite mechanically, a mechanical contrivance switching the current on and off; this in my model, used hitherto, consists of a spring. The only manipulations are to cock the trigger and to pull it; that is no more trouble than is necessary in ordinary instantaneous photography. Movements of the patient during this short time are impossible. Before he could make any, the radiogram is finished.

It is the task of the very near future to introduce this real instantaneous radiography into röntgenological practice. There are very many practical advantages connected with it quite apart from the scientific aspects of the method, which can at present hardly be calculated, but which should neither be over- nor underestimated (I am thinking of kinematography of the heart, for instance). To-day I am able to state as the results of my ex-

perience the possibility of taking actually serviceable instantaneous radiograms with exposures which are from 100 to 200 times shorter than those hitherto considered normal, *i. e.*, in 1/100 or 1/200 of a second, as against 1 to 10 seconds hitherto.

ECONOMY IN MAJOR ANESTHESIA; MORE PARTICULARLY AS TO ETHYL-CHLORIDE.

By R. H. M. DAWBARN, M.D.,

NEW YORK.

Ethylchloride, whether employed by itself for major anesthesia or prefatory to the exhibition of ether, has come to stay. Steadily it has grown in popularity, and with ordinary care and precaution is remarkably safe. One of the best known of several men of this city exclusively anesthetists, and who is anesthetist for one of our largest hospitals, told me a couple of years ago that unless the surgeon insists upon laughing-gas before the ether he no longer gives it, preferring the ethylchloride-ether sequence to any other. For himself, it avoids the lugging about of the heavy nitrousoxide canister; for the patient, while ethylchloride is not, like nitrous-oxide gas, entirely free from odor, still it is unobjectionable. I personally have never come across a patient who sickened at the smell of ethylchloride; however, possibly there may be such, and both to cover its odor when desired, and the more pungent and generally offensive smell of ether, it seems a good plan to follow (as lately I have been doing) a bright suggestion for which I have to thank Dr. Morris Stark of this city, namely, to carry as a part of my anesthesia kit a small vial of the genuine Oriental sandal wood oil. A single drop rubbed along the edge of the facepiece of the inhaler makes itself very evident above any other odor. Similarly, I have known a single drop anointing the lips of an ether-nauseated patient to settle the stomach remarkably.

A few years ago a firm of manufacturing chemists requested me to experiment at the City Hospital for the purpose of determining what size of little glass capsules containing ethylchloride would be best to manufacture, with the idea in mind that each one should suffice for at least the accomplishment of a primary anesthesia in any average adult; this I did, and recommended the 5 c.c. little glass retainers which since have been upon the market. These are intended to be used exclusively in conjunction with the air bag method of anesthesia. Each of these little containers ends in a long drawn point, and they are delivered wrapped in cotton. From two to four are placed within the rubber bag when anesthesia is about to be begun. So extremely volatile is this drug that, were one to snap off the glass point outside and then endeavor to convey it within the bag, however quickly the motion were made, all of it would be lost. Therefore the writer suggested the plan now customary, *i. e.*, to snap off the point within the bag, the glass capsule being seized and held securely through the thin rubber. The cotton which is wrapped about the end of the retainer to be snapped across protects the bag from any injury.

This method is an excellent one from every point of view except from that of economy. These little tubes cost 25 cents apiece. This would frequently make the expense for an operation of some length, for this purpose alone, $1 to $1.50, since from four to six of these small containers (20 to 30 c.c.) might be required.

The main purpose of the present article is to direct attention to ethylchloride major anesthesia along the same lines, at a saving of 50 to 75 per cent. in expense. The method about to be described is simplicity itself; and, indeed, for this reason may very likely have suggested itself to a number of others already. It will, however, or it should as a matter of economy, relegate the new 5 c.c. tubes to the back shelves. I refer to the employment of a large (say, 50 c.c) tube of ethylchloride. It should, however, first be tested, watch in hand, to see how many seconds are required, when the cock is opened its widest, to allow, say, 5 c.c, to escape. With the 50 c.c container, made of glass, this can readily be observed by the sight; one can see the ethylchloride as it runs. Given, however, one of the steel receptacles, it will be necessary to have the firm from which the receptacle is bought work out the question of the number of cubic centimeters which escape per second from their individual container. Or else the surgeon can do it himself, quite readily, as follows: The weight of the empty 50 c.c container being known, as well as the weight of this amount of ethylchloride (obtained simply by weighing the full container upon arrival), it only remains, using scales of a reasonable degree of delicacy, to tell by the difference in weight just how much ethylchloride has escaped from the open tap in any given number of seconds.

With the usual receptacle of 50 c.c. capacity it will be found that for each five seconds that the tap is wide open, nozzle downward, one cubic centimeter of ethylchloride will have escaped into the rubber bag holding the container, or approximately this amount.

Obviously, the same ethylchloride tube is just as good for the purpose of freezing (local anesthesia); so that the physician who has obtained any good make of ethylchloride, in a receptacle of reasonably large size, is now equipped efficiently for anesthesia of whichever kind may be desired, either major or minor.

Of course, however, freezing is a very poor way to accomplish local analgesia except simply to open a boil or a felon. Where any dissection is contemplated we do not wish to work upon tissues as rigid as a board—which they necessarily are while frozen. For anything beyond a single knife thrust, therefore, either cocaine (one-half of 1 per cent. within the skin proper, and one-fourth of 1 per cent. beneath that level) or else eucaine B—say, 2 per centum (I have known twice this strength to cause sloughing of the tissues infiltrated with it); or, finally, naming the third of the local anesthetics which the writer would choose, among a dozen or more obtainable now, one of the most recent, *i. e.*, quinine and urea. This is without poisonous effects. At least none have as yet been observed, in whatever dosage. It occurs as a white powder. Ten grains emptied into an ounce of water makes a 2 per cent. solution. Differing from cocaine, it is not injured by boiling. For curettage of an ulcerated surface or other reason, even a 15 per cent. solution has been applied without the least objectionable effect. Apparently a few minutes' longer waiting for complete benumbing effect is necessary, however, than is the case with the other chemicals named.

105 West Seventy-fourth Street.

SMOKED TORICS—A MENACE TO HEALTH.

By PERCY R. WOOD, M.D.,

MARSHALLTOWN, IOWA.

Prevention of disease is in keeping with the spirit of our profession. The smoked toric coquille prescribed as a shade for weak and sore eyes is productive of much harm. It has an unmeasured and irregular refraction index ranging from one-twelfth to one-half diopter minus.

When we recall that in a neurasthenic individual the accurate measurement and correct adjustment of this slight correction when indicated relieve various pathological local conditions as well as reflex functional neuroses the indiscriminate prescribing of an undetermined and unindicated refraction medium must appeal to the thoughtful as exceedingly inconsistent, unjust, and unprofessional. To illustrate the therapeutic influence of slight corrections I quote two cases from my own files.

Case I.—Mrs. D., Marshalltown, consulted me June 15 last with a severe conjunctivitis complicated with corneal ulceration and iritis. She was wearing: R. + 75 cyl. ax. 90; L. + 50 cyl. ax. 90.

Under a cycloplegic I found and prescribed the following: R. — 25.sp. + 75.cyl. ax. 90; L. — 25.sp. + 50.cyl ax. 90.

Recovery was prompt. Please note the very small minus spheres which were added and the consequent results.

Case II.—H., Baxter, nine years old. Consulted me January 23; had chronic blepharitis. Suffered three years with nocturnal enuresis that had baffled medicinal therapy, also had indigestion, constipation, and insomnia.

I prescribed his full correction, which was: R. + 25.cyl.ax. × 80; L. + 12.cyl.ax.90.

Note the astigmatism against the rule in one eye and the small correction in the other. Local symptoms abated as if by magic, and in less than six weeks the functional disturbances had also disappeared. If such slight errors induce serious pathological lesions in sound eyes, what may be expected in those already diseased? Naturally increased activity of local and systemic pathological lesions and especially if associated with a temperament sensitive to ocular irritation. This is precisely what happens. The sufferers ascribe the discomfort and increased inflammation to the disease and seek relief in darker glasses.

These glasses are recommended by the profession, and, I am sorry to state, by some oculists as well as by jewelers, opticians, department stores, and cheap venders everywhere. They are a menace to health. The proper kind being plain and possessed of no refracting power.

Differential Diagnosis Between Neurasthenia and Various Affections of the Nervous System.—T. A. Williams tries to indicate pathognomonic differences which, even in the early stages, will enable the clinician to distinguish the hebephrenic form of dementia precox, hysteria, mythomanic, and suggested neurasthenias, including the false gastropaths, psychasthenia, and the anguish neuroses, from the true idiopathic neurasthenia. The criterion employed to distinguish hysteria is its susceptibility of production by suggestion and removal by suggestion-persuasion, as enunciated by Babinski. The latency of suggestion is shown, and also its power to produce secondary neurasthenia (in the false gastropaths of Dejerine) and even tics and obsessions simulating those of the psychasthenia of Janet. The criteria of the latter are indicated at some length, consisting mainly of the relative absence of fatigue, along with the presence of the particular stigmata, such as morbid fear, chronic inadequacies, altered sense of reality, and episodic agitations of motor, intellectual, and emotional content. The psychogenic origin of these distinguishes them from the similar complications of psychical nature which may occur during an attack of neurasthenia. Rest is without avail in these cases, psychotherapy is the indication, as it also is in the pseudoneurasthenia of vacuity of hysterical and mythomanic etiology.—*Archives of Diagnosis.*

Tuberculosis of the Cervix Uteri.—Deletrez states that primary tuberculosis of the cervix uteri is rare, the secondary or descending form being more frequent. It attacks especially persons from eighteen to forty years of age. Genital contagion from husband to wife is rare, and traumatism may only predispose to the localization of the bacilli. The appearance of the lesion is that of numerous vegetations about the cervix with ulcerations, and suggests cancer. In the secondary form there is infiltration of a circular nature about the os. Uterine tuberculosis resembles metritis, with ulcerations, syphilis, and cancer, and must be differentiated from these conditions. Prognosis varies with the form and localization of the lesion, and the occurrence of tuberculosis in other organs. Operation consists of amputation and cauterization when there is little tubercular tissue present, and hysterectomy when there is much. Recurrences are frequent.—*Annales de Gynécologie et d'Obstetrique.*

Seroimmunization and Serotherapy in Measles.—Francesco Cenci, in an epidemic of measles, obtained serum from a strong man who had recovered from the disease and injected this into four children who were exposed to the disease, while several brothers and sisters were left uninjected. All the children were left equally exposed to the contagion, and those who had been injected did not take the disease, while the others did. This showed that they had had conferred on them an immunity against the disease. This immunity lasted throughout the epidemic and for four months after it. In a second epidemic, occurring four years later, these four children had the disease lightly. Hence the immunity was only a temporary one. The author has also injected measles patients with antidiphtheritic serum to test its effects. He found that the fever fell, the respiratory symptoms decreased, and the general condition improved rapidly. In one case of bronchopneumonia all the symptoms improved at once and the child was entirely well in a few days.—*Rivista di Clinica Pediatrica.*

Necrotic Anginas and Perforations of the Palate in Scarlatina.—P. Lereboullet gives histories of five cases of perforation of the soft palate in scarlatina. This is a rare complication of scarlet fever. In most cases it has proved fatal, but of the author's patients all recovered. It generally affects children under five years of age. A false membrane similar to that present in diphtheria first covers the tonsils and pillars of the fauces. In this membrane examination shows no diphtheria bacilli, but only streptococci. The glands are sometimes not infiltrated, but the general condition of the patient is bad. The larynx is not affected, but the nasal fossæ may be involved. Fever is high. This lasts for some days, when the appearances rapidly change. The tonsils necrose and the palate may be perforated while the membrane clears up. There are no difficulties of deglutition or phonation. If death does not ensue the repair is rapid, the tissues showing little inflammatory reaction. The author believes that this condition is produced by the streptococci themselves, since no other bacilli are found in the exudation. Treatment consists of the usual general measures and lavage of the parts, with dioxide of hydrogen or antiseptic washes.—*La Progrès Médical.*

Advisability of Lactation During Acute Illnesses of the Mother.—G. Guidi, from an experience of thirty years in practice, together with experiments on animals, gives it as his conclusion that in many acute diseases of the mother it is advisable to continue lactation. Stopping it injures mother and child. The patient should be carefully watched, fed so as to give the necessary amount of nutritive material to the milk, and kept under the best possible hygienic conditions. As to the danger of infection of the child, it is slight. Either the milk has antitoxic properties, or the child is capable of producing antitoxic substances that protect it against the disease. The passage of bacteria into the milk does not produce infection of the infant. The child should not be kept in the room with the mother except when being nursed. Clinical observation and experimental study agree in showing that the germs do not infect the child.—*Rivista di Clinica Pediatrica*

MEDICAL RECORD.

New York, May 22, 1909.

THE EFFECT OF FEVER IN INFECTIOUS DISEASE.

THE medical profession is divided into three camps, so far as the interpretation of the effect of high temperature in infections is concerned: some consider it to be always harmful, others interpret it as a reparative reaction only, still others think that it may work both benefit and injury to the organism. In the *Münchener Medizinische Wochenschrift* of April 13, 1909, Dr. Fr. Rolly presents a most interesting critical study of these views founded upon extended personal investigation of the subject. Liebermeister represents the school that sees nothing but injury from high temperature, and the practical importance of such a view is seen in the fact that he and his followers have insisted upon the necessity of antipyretic measures whenever the temperature in the course of an infectious disease becomes high. Soon, however, experimental work showed that the bad effects attributed by Liebermeister to high temperature were due to other causes. Rolly together with Meltzer kept many rabbits in overheated cages for many days in succession; not one animal showed any changes in the parenchyma of organs that could be compared to the degenerations produced by infectious disease accompanied by fever. Though proteid metabolism is markedly increased in infectious fevers, high temperature plays but a subordinate rôle in this result, while moderate temperatures probably are of no influence whatever. It has been claimed, too, that high temperature has an unfavorable effect upon the appetite; so far as animals are concerned, however, no such effect was noted by Rolly and Meltzer.

That the changes in pulse and in respiration in infectious disease are due to the toxins produced and not to high temperature has been amply proved by many investigators. Welch has shown that prolonged hyperthermia produces no effect upon the functions of the heart and the blood pressure, while Romberg and Pässler have demonstrated that it is the toxins produced by infecting microorganisms that are responsible for vasomotor paralysis with lowering of the blood pressure leading to death in animals experimented with. Other experiments by Rolly and others have shown that neither the hemoglobin nor the cellular constituents of the blood are affected by prolonged artificial hyperthermia. So far as reaction to disease is concerned, their experiments tended to show that high temperature was favorable to the progress of the disease, for in animals it increased phagocytosis as well as the amount of agglutinins and other protective substances in the blood.

Rolly's final conclusion is that rise in temperature accompanying infectious disease is productive of more benefit than injury to the organism. It simply marks a very intense reaction to injury aimed at the destruction of the infecting agents or the neutralization of their toxins. Clinically, therefore, his views oppose any extreme antipyretic measures, whether medicinal or hydrotherapeutic. He would try to control only very high temperatures or such as are accompanied by marked nervous disturbance, and in no case would he have recourse to such measures as the Brand bath for typhoid fever, for instance, but be satisfied with mild drugs or with moderate application of hydrotherapeutic measures.

TUBERCULOSIS IN EARLY CHILDHOOD.

IN recent years the members of the medical profession, especially those interested in the diseases of children, have shown a decided tendency to increase the rigidity in the hygienic rules governing early childhood. Children who a generation ago would have grown up in the belief that each must eat his peck of dirt are now watched with the greatest care. Their hands are kept clean, their food is most carefully prepared, and under the care of many pediatrists they are allowed only toys which will withstand boiling. The purpose of this minute care is of course to keep the child from contracting disease through the ingestion of contaminated material, and by its means it is desired to decrease or eliminate the danger of the two great dreads of childhood, infectious enteritis and tuberculosis.

In *The Archives of Internal Medicine* for April, 1909, Dr. Martha Wollstein of the Babies' Hospital in New York gives a study which is of some interest in this connection and throws some light on the mode of infection of tuberculosis in early childhood. Although our efforts are so strongly directed toward clean hands, clean milk, and clean toys, Dr. Wollstein claims that in infancy the portal of entry of tuberculosis is almost universally through the lungs. In an analysis of 185 autopsies in infants showing tuberculosis in some form, it was found that of the total number of autopsies on the bodies of children under one year of age 12 per cent. had tuberculosis, between one and two years 36 per cent., and of those over two years 32 per cent. Though in most of the cases it was not possible to determine definitely the portal of entry of the tubercle bacilli, a few facts are suggestive. In one case only was the disease limited to the gastrointestinal tract, while in fourteen it was confined to the lungs or bronchial glands. Four other cases were of undoubted intestinal origin, forty of respiratory origin, and one of mixed respiratory and intestinal origin. The fact that the lungs were involved in 96 per cent. of all the cases is suggestive, but might be interpreted merely as indicating their greater predisposition to the disease.

While these statistics do not in any way suggest

that less care should be taken in the feeding of infants, they do impress upon one the necessity of care in purifying as far as possible the air that children breathe. The cases reported by Dr. Wollstein are taken from the poorest classes in the city and most of the children have had very little care of any kind, either dietetic or hygienic. For this reason it may not be quite fair to compare them with the cases under the care of skilled pediatrists. Nevertheless, if in these children who have had both bad food and bad air, the lungs are first attacked in such a great majority of cases it is safe to say that in other classes the same tendency must exist. Many children are of course brought up in clean rooms and in "pens" and are protected from dust as much as possible. This is, however, more frequently not the case, and the child during the second year—the age of greatest susceptibility to tuberculosis—is allowed to creep or run about almost at will. In the case of an active healthy child this is difficult to prevent, and it is not altogether well to try to do so, as the child must be allowed a certain amount of freedom for exercise. What can be prevented, however, is the accumulation of dust in the nursery, and scrupulous cleanliness of this room cannot be too strongly insisted upon. Dr. Wollstein's findings suggest that such cleanliness is, in the case of tuberculosis at least, of even greater importance than purity of the food.

THE PATHOLOGY OF SURGICAL SHOCK.

During the past few years there has been carried on a large amount of research on the subject of surgical shock and our knowledge of the clinical picture, causation, physiology, and treatment of this condition has been greatly increased, mainly through the work of Crile and his coworkers in Cleveland. Our knowledge has widened as to the reduction of blood pressure and cerebral anemia following extensive sensory nerve stimulation, and the influence of hemorrhagic anemia in intensifying the condition of shock. This has led to the use of adrenal extract, intravenous infusion, and finally to direct transfusion of blood in order to overcome the cerebral anemia and thereby either ward off or relieve the shock.

In the light of these advances in physiology it is of interest to note that the first step has been taken to attack the problem of shock from the standpoint of the cytological pathologist. This work, though carried out under the auspices of Crile, was actually done by David H. Dolley of the University of North Carolina, and an account of it appears as a preliminary communication in the *Journal of Medical Research* for April, 1909. Dolley's method was to shock dogs to varying degrees by roughly manipulating the intestines over periods of several hours, the animals being kept under ether anesthesia, and care being taken that there was no loss of blood. Portions of the cerebellum were then removed either *intra vitam* or immediately after death and examined by Held's modification of Nissl's methods. The results as described by the investigator were indeed striking and were marked by the distribution of the chromatic material and by the structural appearance of the cells themselves. In a mild degree of shock the Nissl bodies increased in number and the cytoplasm itself stained deeply. As the intensity of shock increased the chromatin rapidly disappeared from the cytoplasm but was replaced by that of the nucleus. The pictures illustrating the article show to a nicety all of the changes from an increased amount of chromatin to the conditions in which first the color leaves the cytoplasm, is replaced in part by that of the nucleus, and again disappears, to be once more replenished at the expense of the nucleolus, and finally to be lost entirely. At the same time the size of the cell gradually increases until in the last stage it actually bursts and lies dead. The author draws an arbitrary line beyond which he believes that the shocked cell cannot recuperate and makes differential counts of the numbers of cells in the various stages of disintegration.

The idea that surgical shock has any microscopic pathology is certainly new and of no small interest to surgeons, pathologists, and neurologists. The present article is entitled a preliminary communication and it is much to be hoped that it will prove to be only one of a series of investigations into this most interesting subject of the pathology of shock.

WEATHER CHANGES AND THE SUBJECTIVE SYMPTOMS OF DISEASE.

The well-known inclination of many patients to blame weather changes for the appearance of pain in connection with their maladies is usually discounted a great deal by the younger generation of physicians brought up on the modern views of the pathogenesis of disease and of its symptoms. Not infrequently, however, a physician himself, who has fallen prey to such a disease as gout or rheumatism, discovers some constant relation between any sudden increase in his discomfort and the changes in the weather; he is then unpleasantly converted to the belief that the clinical observations of more experienced men as well as the statements of patients are founded upon more tangible evidence than imagination.

Writing in the *Münchener medizinische Wochenschrift* for April 20, 1909, Ludwig Miller communicates the results of a careful study of this matter carried out upon a great number of patients in the hospitals and in private practice. He has found that many patients suffering from chronic rheumatism could foretell weather changes with almost the exactness of a barometer; painful sensations referable to the affected joints were felt invariably two or three days before the appearance of bad weather, whether marked by wind or by rain. Several patients affected with sciatica and others suffering from arthritis deformans could also trace all exacerbations of pain in their cases to the same cause; most of them were quite ignorant of the aim of Miller's investigations, reporting to him by mail any sudden increase in discomfort. In such cases, a study of the weather conditions showed the existence of an unmistakable relation between them and the symptoms complained of. Just as

evident was such relation in cases of locomotor ataxia in which lightning pains appeared and disappeared with barometric changes. No less an authority than Erb corroborated such findings in the case of this disease. Among other conditions that made "walking barometers" of patients were hemiplegia, extensive scars, amputation stumps, etc.

Miller considers one by one the possible factors connected with weather changes that may be held responsible for the clinical phenomena, among them changes in atmospheric pressure, disturbances in electrical conditions in the air, dampness, etc. In no case, however, can any single one of these be considered as the sole cause of the appearance of an exacerbation of pain in the class of patients studied by him. However that may be, the mere fact of such relation between the weather and the subjective symptoms of disease seems to be quite evident from his investigations.

A Test of Pancreatic Function.

Anatomically, the pancreas is so placed as to be but little open to examination by palpation through the external abdominal walls. Its secretion, too, being poured into the small intestine cannot be obtained for examination as readily as is the case with the gastric juice. It is not surprising, therefore, that with the recent increase of interest in pancreatic disease, there should have been devised numerous indirect methods of judging the function of this important gland. In the *Deutsche medizinische Wochenschrift* for April 22, 1909, Dr. Oscar Gross describes an interesting method of testing pancreatic function, founded upon the presence or absence of the specific pancreatic ferment, trypsin, in the feces. Making use of the fact that casein is easily precipitated from an alkaline solution by the addition of acetic acid, while products of its digestion remain dissolved, he added portions of the feces to be examined to such casein solutions. From time to time the addition of acetic acid served to indicate the progress of the digestion of casein if any had taken place. Several ingenious considerations are brought forward by Gross to show that the digestion of casein in such a case could be traced only to the effect of trypsin. In the first place, peptic action was excluded by the alkaline reaction of the mixture. Chloroform was added to the casein solutions to prevent the action of bacteria found in the feces. Erepsin was excluded by the fact that no digestion took place in dogs after extirpation of the pancreas, though, of course, erepsin continued to be furnished by the intestinal mucosa. Still more interesting was the observation that the addition of blood serum inhibited the digestion of casein, a phenomenon made intelligible by the recent discovery of the antitryptic power of the blood. Gross has examined a large number of stools by this original method and has demonstrated the presence of trypsin in all normal cases. The rate of digestion was somewhat modified by the kind of foodstuffs taken, a fact which corroborates the supposition that the activity of the various digestive glands adapts itself in every case to the demands made upon it at each particular meal. Intestinal and gastric disorders appeared to have but little if any effect upon the tryptic digestion of casein by the feces. It seems, therefore, that the test proposed by Gross really gives a fair idea of the secretory activity of the pancreas and of the presence of trypsin in the feces. It would be well to try it in every suitable case of suspected pancreatic disease, so that its value as a diagnostic measure might be definitely determined.

The Rectal Shelf.

An aphorism often emphasized by a certain professor of internal medicine is that "the first duty of a consultant is to make a rectal examination." The truth of this and the value of such a procedure is well shown in an article by George Blumer in the *Albany Medical Annals* for May, 1909, entitled "The Rectal Shelf." The author calls attention to the fact that a common site for metastases from gastric carcinoma is in the vesicorectal fold, and that a tumor growing in this location gives a definite picture of no small value in diagnosis. "If one passes the finger into the rectum in these cases the lower portion of the bowel is usually normal; it is not until the prostate gland has been passed that any abnormality is detected. Just above the prostate in some cases, in others at the limit of palpability, 2 to 4 cm. above, if the finger is passed along the anterior rectal wall it impinges upon a shelf of almost cartilaginous feel which projects into the rectal cavity." In some cases in which infiltration of the intestine has occurred an annular zone or signet-ring structure may be made out. The rectal shelf, however, differs from primary rectal carcinoma in that, though by its bulging into the lumen it may cause partial obstruction, there is no ulceration of the mucosa or passage of blood or pus. This observation of Blumer is of interest and should prove of value in the diagnosis of certain obscure abdominal diseases. The condition, as occurring fairly early in gastric carcinoma, not only may throw light on the diagnosis of the disease but, as its presence shows that metastasis has taken place, may be of value in prognosis and as a contraindication to gastrectomy.

News of the Week.

Public Health and Marine-Hospital Service.—An examination of candidates for admission to the grade of assistant surgeon in the Public Health and Marine-Hospital Service will be held in Washington, at the Bureau of the Department, 3 B Street, S. E., on Monday, June 14, 1909, at ten o'clock. Candidates must be between 22 and 30 years of age, graduates of a reputable medical college, and able to furnish testimonials as to their professional and moral character. The examination is divided into physical, oral, written, and clinical. Upon appointment, young officers are usually assigned to duty at one of the large hospitals. After four years they are entitled to examination for promotion to the grade of passed assistant surgeon. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, and surgeons $2,500 a year, and are entitled to furnished quarters for themselves and their families. Further information may be procured from the Surgeon-General, Public Health and Marine-Hospital Service, Washington, D. C.

Tuberculosis in New York.—In reply to a statement made recently by Mr. Nathan Straus, that tuberculosis had largely increased in the last few years, and that present methods of dealing with it were ineffective, the Health Commissioner has

issued the following statement showing the number of new cases of the disease and the death rate per 1,000 of population:

Year.	Tuberculosis death rate per 1,000 population.	New cases of tuberculosis reported.
1900	2.79	11,977
1901	2.64	13,397
1902	2.42	12,346
1903	2.46	15,214
1904	2.50	18,723
1905	2.40	20,831
1906	2.45	20,085
1907	2.39	19,725
1908	2.29	23,325

These figures support the contention of the Health Commissioner that Mr. Straus's assertion is incorrect, and that the death rate has decreased, the large apparent increase in cases being due to the fact that tuberculosis is now always reported to the Board of Health.

Death Rate in New York.—During the week ending May 8, 1909, there were 1,560 deaths in New York City, a rate of 17.83 per thousand. During the same week of 1908, there were 1,483 deaths and the rate was 17.49. The largest increase in the number of deaths was noted among persons over sixty-five years of age suffering from pneumonia. There was a marked decrease in the number of deaths from diarrheal disease among children under five years of age, only forty-five having been reported during the week against sixty-two for last year.

Department of Hospitals.—The question of a change in the method of hospital control was one of the topics discussed at a meeting of the Conference on City Planning and Municipal Art in session at the Twenty-second Regiment Armory for the past two weeks. Commissioner Hebbard, Dr. W. G. Thompson, and Dr. C. L. Dana favored the removal of the city hospital system from the three municipal centers by which it is now controlled—the Department of Health, the Department of Public Charities, and Bellevue and Allied Hospitals—and the establishment of a separate Department of Hospitals. Mr. Homer Folks opposed such a consolidation and stated that in his opinion the faults of the existing hospital system could be obviated by the establishment of a Board of Ambulance Control. All the speakers urged the need of more beds, better equipment, and more accessible location for the various hospitals.

Laboratory for Metropolitan Hospital.—A pathological laboratory building is soon to be erected as an annex to the Metropolitan Hospital on Blackwell's Island. The building will be two stories high with attic, will be of brick with ornamental stone trimming, and will have a frontage of seventy feet and a depth of eighty-seven feet. The main floor will contain offices, a museum and specimen room, and an autopsy room. The second story will be fitted up for a library and a laboratory, and the attic will contain animal rooms.

A Dispensary Clearing House.—The various medical societies of Chicago contemplate a dispensary reform movement whereby the various organizations of the city will establish a central investigating bureau, cooperating with the charitable organizations in discovering applicants for aid who abuse medical charities. Under the plan contemplated, there will be no delay in furnishing emergency medical service to deserving or undeserving patients, and worthy individuals will be aided as freely and as promptly as before.

Chicago Lying-In Hospital.—According to the annual report of this institution, it is estimated that thirty per cent. of the blind wards of the State have lost their sight through carelessness at the time of birth. Thousands of mothers are permanently invalided through ignorance or carelessness of their obstetric attendants. Thousands of infants are lost at birth and thousands injured or crippled, so that they become public or private wards, the result of ignorance and incompetence. The practical obstetrical instruction in most medical colleges is so meager, according to this report, that the student is really harmed by it.

Gifts to Charities.—Through the death of Mrs. E. C. Magee in Rome recently, the estate of the late Senator Magee will become available for the establishment and maintenance of a free hospital on the site of the Magee homestead in Pittsburg.

The estate of the late Dr. Frank W. Draper of Boston, will eventually go to Harvard University. During the lives of the widow, children, and grandchildren, the estate, which amounts to about $100,000, will be administered as a trust fund for their benefit.

By the will of the late Hannah N. Maule of Philadelphia, bequests are made as follows: $3,000 to the Northern Home for Friendless Children, $3,000 to the Philadelphia Home for Incurables, and $2,000 to the Children's Seaside Home, Atlantic City.

New York Homeopathic College.—At the forty-ninth annual commencement of the New York Homeopathic Medical College, held at Mendelssohn Hall on May 12, the degree of M.D. was conferred upon sixteen graduates by Mr. Melbert B. Cary, the president of the Board of Trustees. On the following evening the Alumni of the College held their annual dinner at the Waldorf, about three hundred being present.

The Loomis Laboratory.—Plans for the remodeling of the Loomis Laboratory of the Cornell University Medical College in New York have been filed with the Building Department. The first, third, and fifth floors will be rearranged, and will contain offices for the professors and rooms for special laboratory work, physiological research, and photomicrography.

Dr. A. C. Abbott, President of the Philadelphia Bureau of Health and Bacteriologist in Chief to the Department of Charities and Correction, has submitted his resignation, to take effect on June 1, in order that he may resume active work as Professor of Hygiene and Bacteriology at the University of Pennsylvania.

Physicians' Club of Chicago.—At the annual meeting of this Club, held May 14, the following officers were elected: *Secretary*, Dr. George E. Baxter; *Directors*, Drs. Frank Billings, William Cuthbertson, Henry T. Byford, Edwin B. Tuteur, Henry B. Favill, and Charles L. Mix. The directors will select a chairman for the organization at a future meeting.

Medical Society of New Jersey.—The annual meeting of this society will be held at Cape May on Wednesday, Thursday, and Friday, June 23 to 25, 1909.

The Ohio Homeopathic Society, in session at Toledo on May 5, elected the following officers:

President, W. H. Humphreys, Toledo; *Vice-Presidents,* H. F. Staples, Cleveland, and W. W. Ensley, Dayton; *Secretary,* R. G. Keiser, Columbus; *Treasurer,* T. T. Church, Salem.

The Macoupin County (Ill.) Medical Society, at its annual meeting, recently elected the following officers for the ensuing year: *President,* Dr. E. K. Lockwood, Virden; *Vice-President,* Dr. Morgan, Nilwood; *Secretary-Treasurer,* Dr. H. A. Pattison, Benold.

Société Internationale de la Tuberculose.—In May, 1910, this society, which is presided over by Professor Lancereaux, will distribute to authors submitting the best essays on the subject of tuberculosis, the following prizes: 1. a prize of 300 francs; 2, a prize of 100 francs; 3, two prizes of 50 francs each; 4, two gold medals with diplomas of honor; 5, three silver medals with diplomas of honor. Authors desiring to enter the competition should send their manuscripts to M. le Dr. Georges Petit, Secrétaire Général de la Société Internationale de la Tuberculose, 51 rue de Rocher, Paris, before the 1st of January, 1910.

The Late Dr. Murray.—At a recent meeting of the New York Obstetrical Society the following resolutions were adopted:

Whereas, by the death of Dr. Robert A. Murray this Society has lost one of its oldest and most esteemed members, a fine type of the old-fashioned, upright practitioner,

Resolved, that we feel keenly the absence of a loyal, big-hearted friend, as well as of one who possessed to an unusual degree skill and sound judgment as an obstetrician. A man of sterling integrity, he was the friend and counsellor of a large circle for nearly thirty-five years. He was a familiar figure in this community and a constant attendant at our meetings, giving us the fruits of his experience. We sorrow over the fact that his kindly face and genial presence will never again be with us.

Resolved, that these resolutions be inserted in our minutes and that copies be sent to the family of the deceased Fellow and to the leading medical journals.—Egbert H. Grandin, George W. Jarman, Henry C. Coe, Committee.

Obituary Notes.—Dr. Melchert H. Garten, a prominent practitioner of Lincoln, Neb., died suddenly from angina pectoris, at his home on May 6, aged 63 years. Dr. Garten was graduated from Rush Medical College in 1871, and after practicing for some years in Dover, Ill., moved to Lincoln, where he built up a large practice in diseases of the eye, nose and throat. He was a member of the American Medical Association and of the State Medical Society, being in attendance at a meeting of the latter when he was taken ill.

Dr. James Henry Payne of Boston, Mass., died at his home on May 14, aged 85 years. Dr. Payne was born in Albany and was graduated from the University of New York in 1849. Until 1860, he practised in Bangor, Me., where he had a notable experience with Asiatic cholera during the epidemic in that city in 1849-50. Since 1860 he had made his home in Boston, where he had a large practice.

Dr. Joseph H. Plunkett of McComb City, Miss., died at his home on April 29, of kidney disease, aged 46 years. He was a graduate of Tulane University, New Orleans. 1890, and a member of the Mississippi State Medical Association.

Dr. James J. Foster of Milwaukee, Wis., died at his home of disease of the liver, on April 30, aged 40 years. Dr. Foster was graduated from the Wisconsin College of Physicians and Surgeons in 1903, and was a member of the American Medical Association.

Dr. John D. North of Jackson, Mich., the oldest practicing physician of that town, died at his home recently, aged 75 years. Dr. North was graduated from the medical department of the University of Michigan at Ann Arbor, in 1859, and was formerly a surgeon of the Jackson, Lansing & Saginaw Railroad.

Dr. J. J. Burroughs of Houston, Texas, died on May 3, after a long illness, aged 79 years. After graduating from the University of Tuscaloosa, Ala., Dr. Burroughs studied medicine at New Orleans School of Medicine, from which he was graduated in 1860. Later he also received degrees from Bellevue Medical College, 1875, and from Jefferson Medical College, Philadelphia, 1876.

Dr. William Peale Brewer, a veteran of the Confederate Army, and a distinguished physician of New Orleans, La., died on May 3, aged 67 years. Dr. Brewer was graduated from the Medical College of Virginia in 1864.

Dr. William H. Schultz of Lebanon, Ind., died at his home on May 7, aged 69 years. He was graduated from the Medical College of Indiana in 1870.

Dr. Theodore Miller of Califon, N. J., died at his home on May 14, aged 60 years. Dr. Miller was graduated from the medical department of New York University in 1873.

Dr. Rachel S. Skidelsky died at Philadelphia of pneumonia on May 14 at the age of 53 years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1894. She was much interested in various public movements.

Dr. Margaret Richardson died at Norristown, Pa., on May 15 at the age of 91 years. She was a graduate of the Woman's Medical College of Pennsylvania.

Dr. Wm. Bird died at Chester, Pa., on May 13. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1880.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

TROPICAL SCHOOL'S NEW LECTURES—TROPICAL SOCIETY ON BERIBERI — IMMUNIZATION — BRAIN, RIGHTHANDEDNESS, AND SPEECH—LIVERPOOL SCHOOL'S EXPEDITION—WAR ON RATS—TANTALUM.

London, April 30, 1909.

The School of Tropical Medicine, always to the fore, has now arranged to hold advanced courses in protozoology, arthropodology and helminthology. There is also to be a course of general medical zoology. The object is to train the students in so practical a way as to enable them to undertake, without assistance, original investigations at home or abroad.

The Society of Tropical Medicine and Hygiene, which is closely associated with the School, has been discussing the etiology of beriberi. The rice theory, which has been frequently put forward and rejected, and again revived in Japan and rejected, was once more represented at the society. Dr. L. Braddon, Surgeon of Negri Sembilan in the Malay States, claimed that the disease is not produced by all rice, but only by that prepared in one way, viz., the white, uncured rice—sifted, hulled, screened, and then polished and sized. This, he holds, will in time produce beriberi. But fresh rice dried in the sun and stored in dark bins, and then each day's amount taken and hulled by pounding in a wooden mortar before cooking, as is the custom in

Malay, does not produce the disease; nor does that cured by the Indian method, viz., soaking for twelve hours, then heated with water on a slow fire till the grains burst, afterward dried in the sun and winnowed. It is thought the grain is thus sterilized in the husk, and so any organisms thereon destroyed. The Chinese, who are the chief sufferers, always eat uncured rice. Dr Braddon cited experiments in institutions by feeding one group on cured and another on uncured rice and after a year reserving the diets with results confirming his view. The true cause of beriberi was, he held, feeding on uncured rice which had been husked and stored for some time and on which an epiphyte had developed and was a nerve poison.

Dr. A. R. Wellington of Sarwak had also a paper. He said the disease was unknown among the Dyaks in the interior of Borneo; but when they came to Sarawak they suffered as much as the Chinese. In Simanggang Gaol the disease had been checked by feeding on fresh rice. At Brocketon mines where it was once rampant it was now absent, though no change had been made in the rice, and in other mines the experience was the same. Examples of infection had been noted, and there were cases which seemed due to place infection. He had investigated the bed-bug theory, but found no evidence that these or other parasites carried the infection. But he added that since bugs had been exterminated in the Kuching Hospital there had been no fresh cases. It would seem, therefore, from Dr. Wellington's experience one can draw no definite conclusions.

Dr. Carnegie Brown said beriberi had been got rid of in the Japanese Navy by general sanitary improvements and the addition of animal food to the diet without any change in the rice ration. A disease which could not be distinguished from beriberi was seen in persons who did not eat rice; on the other hand, rice was the chief food of large communities living in the endemic area but not suffering. But the evidence of asylum neuritis, ship beriberi and similar conditions was important and it was not answered by denying they were beriberi. In Italian ships rice was largely consumed and beriberi was unknown; in Norwegian ships rice was not eaten and the disease was common. In the districts dealt with by Dr. Braddon thousands of Chinese households lived on rice and none of the members suffered; but if one of them went to a mine, hospital, asylum, or gaol he was likely to be attacked. Dr. Braddon's feeding experiments were, however, very striking.

Colonel Leishman had always thought the clinical features pointed to protozoal infection; but careful researches did not support the view, and it looked as if there was some association with rice.

Dr. James Maxwell said that in Formosa they met with cases, although the people lived in their houses and always husked their rice at the time of using it.

Dr. G. C. Low considered ship beriberi was not a distinct disease.

Dr. T. S. Kerr said no fresh cases occurred in the institutions of the straits settlements after the introduction of the husked rice.

Sir Patrick Manson said Dr. Braddon's theory was strongly supported, though not complete. The discussion is to be continued at the next meeting.

The questions connected with the bacillus of acne have for a long time disturbed our dermatologists, but seem to be for the most part settled by a recent research in the laboratories of St. Mary's Hospital by Dr. Alex. Fleming. From this it would appear that the different organisms previously described are probably only one, although that might be mixed with others, and perhaps present different appearances. The difficulty of obtaining a pure culture was overcome by Gilchrist, of Baltimore, some ten years ago, and the bacillus he found constantly present he thought differed in some points from that described by Unna. The view which seems to be prevailing now is that these and others are not essentially different. Whether they can alone produce suppuration may still be doubted, as recognized pyogenic organisms are so apt to be present. But Dr. Fleming reports that a pure culture inoculated into the skin of a susceptible individual produced a pustular folliculitis, and examination of the pus from it showed no other organism. He found the bacillus constantly present, and, frequently, the only organism present in the pus. Further, he has carried out vaccine treatment with success. In some cases an autogenous acne vaccine succeeded after the failure of an ordinary stock vaccine; but this is only in accordance with what occurs in the employment of other vaccines, such as streptococcus. The acne vaccine can be mixed with other organisms if such are present in the pustules.

Sir Almroth Wright has been instructing the Authors' Club on "Immunization." He told the members he regarded our civilization as incomplete and more or less a make-believe. The rôle of bacteria was most formidable, and when we thought we had conquered them by sanitary measures we had only been fighting one small part of infective disease. Though smallpox, typhoid, and dysentery killed fewer people in England than ever, they were by no means the most serious evils caused by bacteria. These were the chronic diseases which sooner or later every one met with. Estimates of losses to business from fogs were circulated in newspapers; but no one reckoned the cost of influenza or tubercle, which must be got rid of before we could call our civilization complete. The first great movement in immunization was inoculation against smallpox; but that had its dangers until vaccination arrived. Then came the work of Pasteur, who said if this process prevented one disease, why not another? Most of his work was prophylactic; but now we have reached the idea that immunization might be effective therapeutically. This aims at assisting nature in developing strong resisting agents in the presence of disease. The method has been gradually extended to one disease after another.

Dr. F. W. Mott, pathologist to the County Asylums, concluded on Tuesday two lectures which he delivered at the Royal Institution on "The Brain in Relation to Righthandedness and Speech." In regard to the question whether the two hemispheres were distinct or not, he said he had found little, if any, difference in weight except in diseased conditions. The left hemisphere was concerned with dexterity and speech, but there was no preponderance in its weight, nor was there any greater complexity in its structure. He could not endorse the opinion that the left hemisphere received a larger supply of blood than the right. Nor could he admit another opinion that the heavier organs, as the liver, etc., being on the right side, determined mechanical advantages leading to righthandedness in 98 per cent. of the population. That view was disproved by the fact that in cases of complete transposition of the visera the persons had not been lefthanded. The brain acted as a whole in thought by virtue of a sort of bridge between the two hemispheres. With regard to speech he discussed two opinions as to its origin—the one which attributed it to instinct and the other to slow evolution. Lantern slides were employed to illustrate some points.

The Colonial Secretary has sent to Sir Alfred Jones, chairman of the Liverpool Tropical School, a copy of a communication from the Governor of Jamaica expressing warm appreciation of the value of the work done by Mr. Newstead, who was sent by the school last year to conduct experiments for checking the ravages caused among cattle by ticks. Mr. Newstead employed a system of spraying the animals with such excellent results that the Director of Agriculture has reported that the tick problem in Jamaica can now be cheaply and effectively controlled. Lord Crewe, as Colonial Secretary, expresses his satisfaction at receiving so welcome a report.

In Parliament on Wednesday it was stated for the Government that the agreement with Germany about sleeping sickness related only to Uganda and German East Africa. The investigations in Nyassaland have not so far revealed the presence of the tsetse fly, so the Government considers they have reason to hope that such an epidemic as wrought havoc in Uganda will not extend to Nyassaland.

A bill has been introduced into Parliament the object of which is to reduce the number of rats, and so the enormous destruction caused by these vermin of foodstuffs—to the amount, it is said, of millions in a year. Founded on similar lines to legislation now in force in Denmark and other countries, it proposes to arm public authorities with powers to cope with the evil, while safeguarding private interests from damage. Local authorities when informed that a place within their jurisdiction is infected by rats are to inquire into the truth of such information, and, if found to be true, are to take such measures as may be deemed advisable for destroying the vermin. If the bill passes doctors and sanitariums will have a new weapon in their "war against rats."

Tantalum, long regarded as a rare metal, is now found in various parts of the world mixed with other substances and can be purified so as to be used for various industrial purposes. Its qualities should interest, as far as it seems likely, to be available for surgical appliances. It is being tried for knives, being, some think, equal to fine steel. Mr Alex. Siemens lectured

on it last week at the Royal Institution, and spoke of it as a nonconductor mixed with carbon, and said it can be hammered out into thin elastic wire, and its filaments, too fine to be seen at a short distance, can support a great weight. Slightly oxidized, it would make writing pen nibs, and its most successful use so far, he said, was in making filaments for incandascent lamps; in fact, there are a great number of tantalum lamps in use, but the actual consumption of the metal is very slight, owing to its atomic lightness. He showed by experiment that a tantalum lamp was better fitted to resist overheating than a carbon lamp, and had proved to be more economical. The disadvantages of tantalum are that in great heat it absorbs hydrogen and nitrogen and becomes brittle; but for many purposes which do not require a very high temperature it appears to be an ideal metal.

OUR VIENNA LETTER.

(From Our Regular Correspondent.)

TREATMENT OF HEMORRHAGE BY SERUM INJECTIONS—PAINLESS DENTISTRY—HEMOLYTIC ICTERUS OF THE WIDAL TYPE—INCARCERATION OF A PROLAPSED UTERUS—A MODIFIED OPERATION FOR CLEFT PALATE—AMYLOID TUMOR OF THE LARYNX.

VIENNA, May 10, 1909.

Dr. K. Wirth has recently tried the effects of serum injections in the treatment of hemorrhage, after he had very good results with the method in controlling an extensive hemorrhage in a patient suffering from hemophilia. He used horse serum for the purpose, the usual dose being 20 c.c. and the site of the injection being either the lateral abdominal walls or the thigh. In no case were any untoward results noticed. The method was used altogether in eight cases, in all of which very favorable effects were noticed, though other measures of controlling bleeding proved quite useless. The cases treated were those of hemorrhage following tonsillotomy, bleeding from the nose in arteriosclerotics, hemoptysis in tuberculosis, and hemorrhage from the bowels. As a rule a single injection was quite sufficient, the effects being quickly noticed. In suitable cases the serum was also used locally, cotton saturated with it being applied to the nasal mucosa in epistaxis, and enemata containing serum being given in hemorrhage from the lower bowel. The results in these cases were also very satisfactory.

Dr. Alfred Neumann has used a new procedure in painless extraction of upper teeth, consisting in the anesthetization of the nerves supplying the upper jaw. He injects cocaine and adrenalin solutions in three places in the jaw, one in the neighborhood of the last tooth at the angle formed by the deflection of the mucous membrane of the mouth, the second at the root of the tooth that is to be operated upon, and the third about the gums surrounding the defective tooth. The needle is in all cases pushed high up and only then the anesthetizing solution is expelled. Any dental measure can then be performed without pain. Alveolar spaces may be cleared out and teeth extracted quite painlessly, even in the presence of very extensive and severe periosteal inflammation.

Dr. Stejskal has had the opportunity of observing two cases of hemolytic icterus of the type described by Widal. One of the patients is a girl of eighteen years, who has been under observation for over one and a half years. Her disease has been developing for three years, having begun with feelings of lassitude, weakness, shortness of breath, headaches, etc. Remissions and excerbations of symptoms have been quite frequent in the course of the disease. Objective signs consist in extreme paleness, combined with jaundice, and an enlarged spleen, which has varied in size from time to time. The second case was that of a writer who has been affected since last July, presenting about the same signs and symptoms of disease. In both cases the malady was an acquired and not a congenital condition. It is differentiated from pernicious anemia by the absence of any extensive hemorrhagic phenomena, by the presence of hydrochloric acid and of pepsin in the stomach, and by the occurrence of thromboses. The variable size of the spleen helps to differentiate it from the anemic conditions accompanying splenomegaly. Dr. Stejskal could corroborate the hemolytic phenomena observed by Widal in such patients. The resistance of the red cells to osmotic and toxis influences is very much diminished in this affection, but this is probably dependent upon changes in the physical properties of the cells and does not appear to depend at all upon the hemolytic phenomena. Autoagglutination was not observed in these two cases.

Dr. Rosenberger of Budapest has recently operated upon a case of incarceration of the uterus complicated by a laceration of the vagina. The patient was a woman in the third month of her seventh pregnancy. She found herself suddenly unable to void urine, in spite of an overfilled bladder; next day she felt intense desire to go to stool and attempted several times to empty her bowels. Her efforts simply led to the appearance of a bladder-like tumor at the vaginal entrance, which was interpreted by the midwife as an impending abortion. The latter, therefore, simply encouraged the patient to continue straining, thinking thus to hasten the expulsion of the fetus. Her efforts, however, only served to increase the size of the prolapsed tumor. A physician was then called in and the patient was removed to a hospital. There it was found that the uterus, together with the left tube and ovary, had prolapsed between the thighs of the woman, while the right-sided adnexa could be felt in one fornix of the vagina. The prolapsed uterus was soiled with feces from the lower bowel, while the bladder was distended by two liters of clear urine. Total extirpation of the uterus had to be done, an extensive laceration of the vagina being found at the operation. Drainage with iodoform gauze had to be employed. The postoperative condition was for a time quite serious, but the woman finally made a very satisfactory recovery.

Dr. Winternitz of the Budapest Children's Hospital Stephanie has published a modification of the operation for cleft palate. He operates at one sitting, making use of two plates, made of aluminum, silver, or hard rubber, and perforated in two places. These plates are designed to press together the edges of the wound and thus relieve the tension on the central row of sutures. In five days these plates may be removed and then the button sutures may be dispensed with in a few more days. Winternitz has operated in twenty-five cases according to this method. He had much better success in operating upon infants under two years old than upon babies over that age. The former could be kept much quieter, slept better, and did not cry so much, so that less tension was exercised upon the fresh scars. The author, therefore, advises early operation, though not on babies under one and a half years old. In later age the soft palate does not develop properly and no abundance of tissue exists for a successful closure of the congenital gaps in the hard palate. If a harelip exists, it must be corrected before the split palate is operated upon.

Lénárt of Budapest operated upon a patient suffering from an amyloid tumor of the larynx and trachea. The patient was a man of 57 years, who has been hoarse for the last five years. Four years ago a small piece of tissue was removed for diagnosis and was pronounced to be of chronic inflammatory nature. Two years ago there appeared a reddish, flat tumor in the subglottic space under the right vocal cord; this tumor presented an uneven surface, was not connected with the vocal cord, stretched posteriorly to the interarytenoid space, and projected into the middle of the larynx. No inflammatory lesion could be observed anywhere in the body. The patient gave a history of a syphilitic infection, which occurred thirty years ago and was not followed by many symptoms. He has had two healthy children born to him since, and could do his work, which was that of a teacher, without any difficulty. He was treated for months by the administration of potassium iodide, but showed no signs of improvement. Radical operation was advised at the time, but the patient refused it. This year he returned for treatment, being able to breathe only through a cannula, the lower portion of the larynx being completely filled with the tumor mass. A radical operation was performed and the tumor, a large soft mass, projecting in every direction, was removed. The tumor was removed very easily, the surface of the larynx and trachea showing no signs of infiltration. The bared spots were skin grafted. Three days after the operation the patient could feed himself properly and four weeks later the cannula could be permanently removed. The patient recovered completely, he could breathe freely and his voice reassumed normal strength and sound. Histological examination of the tumor proved it to be of amyloid nature. It seemed probable that in this case the chronically inflamed tissues underwent amyloid degeneration during the long course of the disease.

Progress of Medical Science.

Boston Medical and Surgical Journal, May 6, 1909.

The Results of Operations for Cancer of the Tongue, Mouth, and Jaw at the Massachusetts General Hospital, 1890-1904.—The hospital records have been carefully searched by R. B. Greenough, C. C. Simons, and R. M. Green and 172 cases have been found; 112 were operated on, 50 were deemed inoperable, and 10 refused operation. Of the 112 operations of all varieties, 20, or 17.8 per cent., resulted in death within sixty days. Of cancer of the tongue and floor of mouth there were 98 cases, of which 62 were operated on and 36 were inoperable or refused operation. Of the 62 cases operated on, in 58 (93.5 per cent.) the end result is known. Sixty-two cases of operation gave an operative mortality of 8, or 12.9 per cent. Of the 58 cases in which the end result is known, 10 were free from recurrence three years or more after operation (17.2 per cent.). Of the 40 cases in which recurrence did take place after operation, in 38 death occurred before the lapse of three years after operation. Operations for cancer of the tongue involving section or resection of the jaw caused a much higher operative mortality and no greater percentage of cures than the intrabuccal operations. Of cancer of the lower jaw there were 40 cases; 28 operable, 12 inoperable. The operative mortality of 28 cases was 10, or 35.5 per cent. In 26 cases of operation the end result is known, and 5 cases (19.2 per cent.) were free from recurrence three years or more after operation. There were 14 cases of cancer of the upper jaw. Ten were operated upon and 4 were not. The end result is known in 9 of the 10 operated cases, and in each of these 9 cases death occurred within three years, although there were no deaths as an immediate result of operation. Cancer of the tonsil, soft palate, or fauces occurred in 11 cases, 8 of which were inoperable and 4 were submitted to operation. One case was alive and well seven years after operation (25 per cent.). There was no operative mortality. Cancer of the cheek occurred in 9 cases, 1 of which was inoperable. Of the 8 patients operated upon, 2 died of operation (25 per cent.) and none was cured.

New York Medical Journal, May 8, 1909.

The Value of the Roentgen Rays in Thoracic Lesions.—The paper of R. H. Boggs is illustrated with several skiagrams of familiar chest lesions. It must be confessed that the ordinary methods of printing skiagrams from blocks leaves much to be desired. The author says that from a series of more than eighty patients examined for pulmonary tubercle and in whom the diagnosis has been confirmed, either before or after, by other methods, he feels justified in concluding: (1) That the extent of the disease is more accurately determined by the *x*-ray than the physical findings alone. (2) That in doubtful cases the rays often afford sufficient information to make an accurate diagnosis. (3) That the rays are a useful method of recording the lesions and determining the progress made by treatment. (4) That the radiogram records nothing but variations in density and leaves the etiological factors to be determined by other clinical methods. (5) That frequently, when physical signs were present in one side, the radiogram would show infiltration in both lungs.

An Operation for Frontal Sinus Obliteration Avoiding Supraorbital Deformity and Nasal Scar.—A. E. Prince figures several instruments used by himself in operating and thus details his technical methods: (1) Intranasal preparation. Introduce a postnasal plug. Correct any considerable deflection of the septum, as a preliminary step. Remove the anterior end of the middle turbinal, preferably by means of forceps. (2) Clip and sterilize the eyebrow. Make a skin incision extending along the middle of the eyebrow from a point opposite the junction of the frontal, nasal, and maxillary bones. Omit the usual nasal extension of the incision which is made for the purpose of reaching the ethmoid cells, through an opening made by resecting a portion of the nasal process of the superior maxilla. This is not required. It is particularly undesirable to extend the incision along the side of the nose on account of the possibility of producing an objectionable scar. This is especially true when the underlying bony support has been removed. (3) Periosteal incision. The periosteal incision is made parallel to the skin incision. It extends somewhat under the skin at the nasal angle. Then it is separated from the roof and inner wall of the orbit. The trochlea remains attached to the periosteum, and is brought back into position with the closure of the incision, thus preventing diplopia or cyclophoria, which might result from its injury or dislocation from its attachment to the periosteum. (4) Removal of the sinus floor. The orbital contents are separated from the inner wall by means of a retractor, and the nasofrontal angle of the orbit is exposed. The bone is thinnest at this point, which is the usual location of spontaneous perforation, and opening and the anterior portion of the floor of the frontal sinus is removed. (5) Curetting. The septa are removed and all the mucosa of the frontal sinus is scrupulously curetted. All doubtful points of the surface are cauterized with pure carbolic or trichloracetic acid. The remote angles are inspected by a sinuscope—an instrument on the order of a myringoscope, except that the lamp is placed on the side of the instrument. The ethmoid cells are curetted through the opening below the frontal sinus and nasal cavity. The anterior wall of the sphenoid is best removed through the nose. (6) Closing of the wound. The cut edges of the periosteum are united with pyoktannin catgut sutures, care being exercised to insure correct replacement of the trochlea. Horse hair sutures are used to insure more perfect coaptation of the edges of the skin; perfect closure prevents air being forced through the wound, carrying infection from the nose. The wound is sealed with a strip of gauze soaked in collodion, which effectively closes and strengthens the line of union. The after-treatment is not essential, excepting that the patient must not blow the nose. The cavity is wiped out with cotton, saturated with a 25 per cent. solution of alcohol. Healing usually takes place by first intention, and granulations rapidly fill the cavity.

Pellagra.—J. J. Watson has studied 100 cases of the disease as occurring in Italy and South Carolina and gives details of one case. The disease is a chronic affection caused by eating Indian corn infected with specific microorganisms. The author then enters into a general description of the affection, going into the matter of the grain infection with great particularity. The maize theory is based on the following facts: (1) That maize is the staple cereal consumed by the inhabitants in pellagrous countries; (2) that pellagra is now recognized as a disease in every maize producing country; (3) that extracts made from damaged maize will produce in men and animals symptoms similar to pellagra; and (4) that symptoms similar to pellagra have been produced in animals by feeding them on damaged maize. The results of experimentation on men and on dogs are given. On 10 patients the following symptoms followed in varying combination the administration of tincture of bad maize: Diarrhea, increased appetite, soft feces, revulsion to food, weakness, lassitude, erythema, desquamation, and skin lesions. There was also a pronounced effect on the heart and kidneys. There was diminution in weight from four to twenty pounds. Two patients increased in weight six and eight pounds. Many of these symptoms lasted two and one-half months, and in one patient for nine months after the experiment was discontinued. Six of the men were accustomed to alcohol. Two of these had no symptoms and two resisted more than the others. One of the subjects was a victim of psoriasis and the skin disease was cured by the experiment. Since then the tincture of bad maize has been used by Lombroso as a treatment of psoriasis with success. Treatment is rather unsatisfactory. Fowler's solution has been given in increasing doses, also atoxyl, an arsenic preparation, hypodermically. Good hygiene and avoidance of all articles containing Indian corn and hydrotherapy all conduce to improvement.

Journal of the American Medical Association, May 8, 1909.

The Insane Diathesis.—Sanger Brown insists on the importance of early recognition of the signs in the child, youth, or convalescent, that indicate a predisposition to insanity. They may show themselves in physical defects, but these are not of themselves conclusive. Hereditary influence is generally distinct and frequently conspicuous, and in a majority it is mainly material and similar. Children of this type are more liable to such nervous disorders as convulsions, enuresis or chorea, are unsocial in many cases, and while sometimes apparently precocious in some directions, are likely to be backward in their studies. Extreme out-

breaks of temper, insubordination, selfishness, and cruelty are also often characteristic. These characteristics may, if not too marked, diminish or disappear with the onset of puberty, but they may be accented and new ones be added, especially in the sexual sphere. There is also, not infrequently, a certain sort of religiosity which may at the same time be associated with extreme selfishness and egotism. In adolescence, these individuals are agitators and impractical projectors, sexual perverts, etc., in short, they make up largely the class commonly known as "cranks," which grade easily into the insane and criminal classes. Treatment of these cases must consist in encouragement of the healthy development of the nervous system and the use of such measures as will promote the normal activity of the neurons. These last are mainly educational, moral, and disciplinary. With a condition so markedly hereditary as this, home influences are often not the best, and a well-regulated boarding school is preferable. In childhood, the first requisite of treatment is to secure obedience and the control should be firm though kindly. In youth the same influences should be continued and extra effort made to develop the judgment. The lifework should be chosen late and after careful scrutiny of the patient's talents and tendencies. Marriage between two persons with this temperament should be most earnestly discouraged.

A New Disorder from Heat.—W. H. Cameron gives his experience with the disorder known among mill men as "mill cramps," though they give the same name to any sudden painful seizure occurring while they are at work. The unfavorable circumstances under which he saw his cases have prevented a more satisfactory investigation. No toxemia or morbid condition was observable, such as could account for the symptoms, and no cause was ascertained except exposure to extreme heat. This was sometimes as high as 235° F., which seems almost unbelievable, and sometimes ignites the clothing, notwithstanding frequent saturation with water. Another point is that the patients have always been undergoing extreme muscular exertion and the attack occurred, not while they were engaged in work, but shortly afterward. Most of them have been hard drinkers, but there was no evidence to show that they were at all intoxicated at the time. In all the cases there was some indication, however, that the patients were a little out of condition and not at their very best for the kind of work in which they were engaged. It was a common observation, confirmed by his own experience in treating these cases, that one attack produced a predisposition to others, but he might have been somewhat mistaken in his suspicion of a certain natural predisposition or susceptibility. Like Edsall, he has never noticed any thermal change. The pulse is somewhat accelerated, but not more than might be expected in persons suffering intense pain, which is the most characteristic feature of the disorder. The entire length of the attack is from one to four hours, when there is a gradual lessening in the severity and frequency of the seizures for perhaps twenty-four hours. But the tendency generally is to a more or less rapid recovery, leaving only a slight muscular soreness. This is, however, only his experience with his cases. He has never seen the muscles of the face, neck, or back affected, or had a case where he thought the involuntary muscles were involved. He has heard, however, of fatal cases credited to spasm of the heart. With the severity of the symptoms one would suspect severe pathological changes, but the rapid complete recovery with no serious after-consequences is against this supposition. Edsall says that there are absolutely no blood changes, and superficial nerve disturbances as a hypothesis is untenable because if the nerve endings had been involved there would have been no constant pain. Unfortunately, Cameron has never been able to obtain a section of muscle for microscopic examination, and, so far as he knows, no such examination has been made. The treatment has puzzled him; he had not used anesthetics because he has found them injurious when the patient has just been undergoing severe labor. The fact that Edsall has found that chlorides are lacking in the urine may give a clue to the future treatment.

Rattlesnake Bite.—C. S. White reports in detail an account of a case of poisoning by rattlesnake bite which is of interest on account of the rarity of such observations, these accidents not happening often where they can be fully observed. The patient was bitten by a diamond rattler in the Washington Zoological Garden. Though the man received immediate attention, the wounded finger being ligated at once, freely incised and cauterized with a 1 per cent. solution of potassium permanganate, the infection extended as soon as the ligature was removed. It was not until over a month and the finger had been amputated that he was in condition to be discharged from the hospital, in spite of an active sustaining treatment; and he was then in a very subnormal and anemic condition. White reviews the subject of snake bites generally and their therapeutics. The patient was treated according to the Mueller method with strychnine and free stimulation. White says that while it may be taken by the advocates of that special method as an evidence of its efficacy the patient probably would have recovered regardless of the treatment used.

Infantile Pseudoparalysis.—F. C. Neff remarks that apparent paralysis in ailing children is not infrequent, and in the absence of signs of the causative disease it will be difficult to exclude true paralysis, such as anterior poliomyelitis, the cerebral palsies, various spastic paralyses, and other less common diseases of the nervous system. From his case records he groups such cases under three heads, giving illustrative examples of each class, namely, the paralytic symptoms of rachitis, of scurvy, and syphilitic pseudoparalysis. In each case treatment for the original condition relieved the paralysis. His conclusions are summed up in the following: "1. Pseudoparalysis is not rare in rickets, scurvy, and syphilis. 2. When it is the earliest symptom noticed in these diseases diagnosis is difficult. Other evidence should be looked for. 3. It would be hard to group three other such serious conditions of childhood which have so favorable an outcome under early treatment."

The Lancet, May 1, 1909.

A Fatal Case of Splenomegalic Polycythemia.—The patient of W. F. Umney was a woman of 34 years with transient hematuria but a persistent albuminuria. She had never had any rheumatic manifestations or evidence of syphilis. She had noted a bluish color in her complexion, more observable in cold weather, but her general health remained good, except that her menstruation was irregular. A diagnosis was at first made of chronic nephritis with unusual cyanosis. But this was soon discarded, as an enlarged spleen was found and a marked polycythemia, the red cells numbering even 11,000,000 per ccm. She continued in this condition without any obvious alteration for two years. Then chorea gradually came on, affecting body and limbs alike. The arms became edematous, and later other portions of the body. Cough appeared later and after a long illness she died in an attack of intense dyspnea. Thrombosis was one of the later features. No autopsy was allowed. The author discusses in particular the features of thrombosis and chorea. He considers it probable that the former first appeared in the smaller cerebral veins and that the chorea was directly caused thereby. The more general thrombosis he would regard as a logical occurrence in cases of this nature, but he has never noted its occurrence in the cases previously recorded. The cough and dyspnea were referable at their onset to thrombosis in veins and were not accompanied by any physical signs which could be appreciated.

Adenoids, Nocturnal Incontinence, and the Thyroid Gland.—L. Williams gives the histories of patients which go to show that adenoids cannot be regarded as a cause of nocturnal enuresis, but that when these two conditions are associated both are due to a common cause, viz., insufficiency of the internal secretion of the thyroid gland. The administration of thyroid extract will in a comparatively short space of time effect a cure of the enuresis and greatly relieve coexisting evidences of poor general health. In the author's hospital service he has seen twenty-five patients in all and only one failed to respond to the thyroid treatment.

Streptococcal Pericarditis and Colitis Following Tonsillitis.—J. S. Pearson reports two cases. Case I. was that of a healthy girl of 20 years, with lacunar tonsillitis and a history of previous bowel trouble. On admission to hospital her tonsillitis had pretty well cleared up, but she had a high fever and was evidently septic. She died in nine days, having developed a pericarditis and various pustular areas over the body. On autopsy the pericardial sac contained two ounces of thin pus with roughening and thickening of the pericardial layers. There was no endocarditis. The whole of the large bowel was studded with shallow irregular

ulcers. Case II. was that of a girl of 7 years, admitted to hospital with joint pains and a subsiding tonsillitis, with moderate fever. The latter increased, being considerably higher in one axilla than in the other. The child became apathetic and then very delirious, but finally pulled through. Both cases showed the *Streptococcus longus* in the blood. The author says that he has frequently observed in acute pericardial effusions a higher temperature in the left axilla than in the right. Such an occurrence would always suggest to him pericarditis. It may be present when the auscultatory signs are of doubtful significance.

British Medical Journal, May 1, 1909.

Acute Thyroiditis.—The patient of K. H. Jones was a Chinaman of 25 years, complaining of some stiffness and soreness of the neck and some dyspnea, but apparently not very ill. In three days his throat had become much worse and considerably swollen and a symmetrical enlargement of the thyroid could be easily made out. There was slight fever and considerable dysphagia. Iodine liniment was applied and half-dram doses of potassium iodide given in aromatic ammonia spirits three times daily. The author suggests that in these cases of sudden enlargement there may be some temporary lesion of the vasomotor nerves which control the blood supply of the gland. The patient referred to recovered in a week.

Alcohol as a Surgical Dressing.—J. G. Andrew has gradually given up the use of the conventional antiseptics and now confines himself to methylated spirits whatever may be the nature of the wound. He believes that gauze wrung out in spirits withdraws the moisture from the wound owing to the affinity of alcohol for water and thus removes the most essential factor for bacterial growth, viz., moisture. It frequently lessens the necessity for drainage and by its styptic properties shortens the time necessary for securing the smaller bleeding points.

A Fatal Case of Lead Poisoning Due to Diachylon.—The patient of F. S. Heaney was a married woman who, finding herself pregnant against her desire, took a quarter of an ounce of diachylon in mass, rolling it into nine pills and taking it in the course of forty-eight hours. In a few hours she began to have abdominal pains. These were partially relieved. Bowels did not move except by enema. In about a week the mental symptoms of insomnia, hallucination, fainting attacks, etc., came on. At this time she was seen by the author. She was pale, anemic, prostrated, with furred tongue, pulse 138, soft and full, constipated, with retracted abdomen, and scanty and frequent micturition. Magnesium sulphate was given and for awhile they seemed to relieve the constipation and delusions. Digitalis and strychnine were given for the heart. Seventeen days after taking the diachylon she had severe pain in the left shoulder and upper arm and next day the pain had gone, but the muscles of the arm were almost completely paralyzed. Sensation was diminished, but not completely lost. Two days later the same condition appeared in the right arm. Four days after she died in a fainting spell, preceded by a very rapid and irregular heart. The autopsy showed (1) acute inflammation of the mucous lining of the stomach and intestine, extending in some places to actual ulceration, and (2) acute fatty changes in the liver and heart.

The Indications for Nephropexy.—W. Billington regards this operation as a safe and satisfactory surgical procedure. Renal mobility alone is not an indication for operation. Local pain of sufficient severity to diminish working efficiency is an indication for operation. Chronic functional disturbance of the digestive system may be caused by movable kidney. Such cases often resist all kinds of general and medicinal treatment and are greatly benefited by nephropexy. The operation is also indicated in progressive spinal and cerebral neurasthenia occurring in association with movable kidney, when other measures have failed to cure or improvement is followed by rapid relapse. The operation is indicated further when movable kidney is associated with insanity.

Münchener medizinische Wochenschrift, April 20 and 27, 1909.

Coagulation Time of Blood.—Hartmann studied the coagulation of blood after gynecological operations, as well as in pregnancy and in labor. He used the method of determining the time of coagulation proposed by Bürker, which consists of mixing a drop of blood and of water together and then passing a rod through the mixture every half a minute until a thread of fibrin appears upon the rod. This is done in a special apparatus kept at a certain constant temperature. Hartmann has found that age had no influence upon the coagulation time. In pregnancy the coagulation time of blood appeared normal, this finding being opposed to usual teaching in the matter. Time of day also appeared to have no influence upon the speed of coagulation. Only after prolonged and bloody major operations it was found by Hartmann that the coagulation time of the blood was noticeably shortened. The effect of lumbar anesthesia used in most of the operations was excluded by the fact that no such change of coagulability took place in cases in which same anesthesia was used for nonbloody examinations, cystoscopy, etc. Differences in blood-pressure also appeared to be without effect upon the coagulation time of blood. It seemed, therefore, that loss of blood was the only factor responsible for the change in the coagulability of the blood after operations. The primary cause of the change seemed to lie in the suddenness of the loss of blood, for no such phenomena could be observed after bleeding in small amounts continued for a long time. The author thinks it quite probable that coagulation time of blood is quite a different thing from the coagulability of the blood; the latter is frequently increased, if clinical evidence is to be trusted, in cases in which the coagulation time does not seem to have been changed at all. The normal coagulation time, as found by Bürker's method, amounts to four and a half to four and three-quarters minutes, according to Hartmann.

Hot Air in the Treatment of Acute Purulent Inflammations.—Iselin says that the best treatment of purulent inflammations consists in the combination of usual surgical methods with the use of dry, hot air. The surgical treatment, consisting of incision and evacuation of pus, always precedes the baking process. The latter is begun on the day of the operation as soon as the patient has recovered from the immediate effects of the latter. At first the parts are baked twice a day, later only once a day, each sitting continuing for two hours. The bandages are removed before the hot air is applied; as little drainage as possible is used as soon as the wound begins to granulate. Any collections of pus or dead tissue are removed by gentle irrigations with saline solution. Bier's boxes are used as the apparatus for the baking; the effect of the hot air is shown by the formation of an artificial swelling of the parts, which, however, disappears during the night. An especially favorable effect of hot air is seen in the diminution of pain, which is testified to by the great majority of patients. Most of the cases treated by Iselin were suppurations of the tendons in the hand, and the results in such cases were most gratifying. In a few days the wounds assumed a healthy appearance, and in one or two weeks complete healing took place. The scars were usually quite soft and pliable. Of the seventeen cases of suppurations involving tendons destruction of a tendon occurred in only one case. Iselin considers that Bier's hyperemic treatment is much less effective than his hot air treatment. The former leaves much more room for mistakes in the application of bandages and caps, and may often do direct harm. Baking, on the other hand, may be safely applied in all cases in which preliminary incisions have been made. It is apparently a most effective method of assisting the natural processes of repair.

Syphilis Among Physicians.—Waelsch discusses the possibility of general syphilis appearing without the development of a primary sore, and reports four cases, all among physicians, in which this course of the disease could be observed. In all of them secondary luetic phenomena, including fever, sore throat, eruption, etc., were noticed, although a chancre has never been observed. The circumstances were such that failure to observe the primary syphilitic effect could not be considered. These cases lead Waelsch to grant such form of syphilis, called by the French *syphilis d'emblée*, really existed. He then discusses luetic infection among physicians acquired in the discharge of their professional duties; he had occasion to observe six such cases, which formed 50 per cent. of all extragenitally acquired cases of syphilitic infection observed by him in ten years. The seat of the primary sore was in all cases on the fingers, the disease usually beginning in the form of a paronychia, which proved quite obstinate when treated by the usual measures. This course of the lesion and the development of lymphadenitis usually led to a suspicion of the true nature of the case. The course of the disease was in all instances a benign one. Waelsch is, indeed, inclined to deny the truth of the frequent assertion that syphilis acquired in an extragenital manner is usually

very malignant in type. The author considers the prophylaxis of such infections with syphilis and warns against too much manicuring of the hands, which often leaves small wounds that serve as the sites of entry for syphilitic virus. In the presence of any larger cuts and abrasions of the skin the use of gloves is imperative in all surgical and obstetrical procedures. The treatment of any wound acquired in operating upon any person suspected of syphilis should consist of a thorough cauterization with the actual cautery; if a needle has entered the flesh it may be connected with an electric battery and the tissues about it destroyed by the current.

The Points of Origin of the Heart Beat.—Hering says that the normal point of origin of the heart beat lies at the mouth of the superior vena cava in the region of the terminal sulcus; here there has been found by Keith and Flack a peculiar nodule of muscle fibers differing from the rest of the heart muscle. In addition to this origin, cardiac pulsations may also originate in the neighborhood of the bundle of Tahawara, from which the pulsations are transmitted to the mouth of the inferior vena cava and thence to the whole auricle. The interval between contraction at Tahawara's node and the auricular impulse is shorter than that following the contraction at the Keith-Flack node. The former pulsations become evident whenever the pulsations at the Keith-Flack node become too infrequent, or stop altogether or are blocked in any fashion; in all such cases the conduction of the impulses must be regarded as abnormal in type. In cases of permanent irregular pulse it is quite probable that the heart impulse originates at the node of Tahawara.

Deutsche medizinische Wochenschrift, April 15 and 29, 1909.

Gout and Rheumatism.—His says that great uncertainty reigns in the classification and treatment of chronic arthrides, because of the limited knowledge of the etiology and pathology of these diseases. Alfred Garrod has made the term "gout" a specific one, and since his work it has been shown that the essence of the disease lies in a disturbance of purin metabolism, evidenced in the formation as well as in the destruction of uric acid; this disturbance leads to the excess of uric acid in the blood and to a peculiarly retarded elimination of this substance. Purin metabolism, however, does not explain all the symptoms occurring in gout, such as dyspepsia, myalgia, neuralgia, arteriosclerosis and the occurrence of granular contracted kidney. While etiological factors, such as alcoholism, play an important rôle, there is no question that an underlying constitutional fault, a disposition, a diathesis, exists in such patients. His classifies chronic arthritides as follows: (1) Chronic rheumatism, following repeated attacks of acute articular disease; (2) progressive chronic polyarthritis, occurring usually in symmetric joints, involving the small joints of the fingers and toes first, accompanied by slight fever or without a rise in temperature, and progressing in repeated attacks with intermissions; (3) monoarthritis, due to senility or to repeated trauma, a form described by Volkmann; (4) ankylosing affections of the spinal column; (5) Heberden's nodes. Pathologically, these forms may be classified under those beginning with the degeneration of the cartilage, affection of the joint capsule, occurring only later, and those which begin in the synovial membrane and then attack the cartilage. Arthritis deformans, spondylose rhizomelique, Heberden's nodes, and the dry form of chronic progressive polyarthritis belong to the first division; chronic rheumatism and the exudative form of chronic polyarthritis belong to the second division. The etiological factors to be considered in the study of chronic joint diseases are trauma, acute and chronic inflammatory disease, acute articular rheumatism, and infectious diseases. When all these are excluded there remain, however, a large group of arthritides, the cause of which is unknown. His reports a number of such cases, accompanying nephrolithiasis, arteriosclerosis, family type of gout, etc. Most of them seem to be related to family predisposition or diathesis. His has seen various arthritic changes during postmortem examinations of persons who did not give any joint symptoms during life. Such changes very often accompanied chronic disease, so that they may have been due to trophic disturbances. Many cases of chronic arthritis were then studied in reference to their purin, metabolism, and the latter was not found to correspond to the type recently described in cases of gout. His concludes his very suggestive paper by discussing differential diagnosis between gout and other forms of chronic joint disease. Involvement of the big toe is not necessarily limited to cases of gout. *X*-ray pictures help very much, for they usually show that the deformities of the joints do not leave large shadows in cases of gout, deposits of biurates not being marked by the photographs. The surest method of diagnosis is the study of purin metabolism and the examination of uric acid content in the blood. His concludes by pointing out the danger of keeping other but gouty patients on purin-free diet. In them impaired nutrition is often an etiological factor in the disease, and restricted diet simply accentuates such factor.

Cerebrospinal Fluid in Postdiphtheritic Paralysis.—Roemheld says that postdiphtheritic paralysis is often very similar in its symptoms to tabes dorsalis, which, as is well known, is accompanied by certain specific changes in the cerebrospinal fluid. He has made systematic examinations in one such case, and has found that the albumin of the cerebrospinal fluid was markedly increased, equalling the amount obtainable in paralysis of other nature, and in meningitis. The lymphocytes in the fluid were likewise moderately increased in number. Roemheld believes that these changes show that postdiphtheritic paralysis is not due to mere peripheral neuritis, but is occasioned by some central processes. The pathological elements in the cerebrospinal fluid gradually decreased in amount with the improvement of clinical symptoms. Roemheld urges systematic lumbar punctures, and study of the fluid obtained in cases of diphtheria, and of its sequelæ, so that the nature of the changes produced in the organism by the diphtheria toxin may be better understood.

Physiology and Pathology of the Large Intestine.—Rosenheim says that even though all parts of the gastrointestinal canal are interrelated, yet every division retains its individual function and independence. The different parts of the large intestine show altogether different conditions as compared with each other. Rosenheim has found by palpation that normally the cecum and the ascending colon are empty in the morning, if the last meal of the evening has been taken at 8 to 10 o'clock. At this time the sigmoid flexure is always distended with fecal masses. After the morning defecation, not only rectum and sigmoid flexure but the descending colon as well are found empty. The act produced no changes in the transverse colon. Soft masses of gruel-like consistency could be palpated in the cecum about five hours after breakfast. This condition persisted until night, that part of the bowel being apparently emptied during sleep. By six o'clock in the evening fecal masses could be felt in the sigmoid flexure in some cases; at a later hour this condition was always present. The rectum was empty in the evening. These observations show how far from simple are the circumstances in such a common affection as habitual constipation, for abnormality of function in any portion of the large intestine may be responsible for the affection. The diagnosis must therefore be an anatomical and not a functional one, and for this purpose the conditions as found by palpating the patient's intestines must be compared with the conditions outlined above. Rosenheim has found that frequently only the sigmoid flexure is at fault in causing habitual constipation. It was oftenest in a state of tonic contraction in such cases. Cecum and descending colon are much more rarely at fault. Repeated palpatory examinations must be made in order that the real seat of the trouble is correctly diagnosed. The importance of this for therapeutics is evident. One must, however, go still further and diagnose not only the seat but, likewise, the cause of the constipation. This may be found in various inflammatory conditions, such as gastritis, cholecystitis, chronic appendicitis, affections of the genital organs in women, etc. In addition, anomalies of position and neuroses of various sort may be the causative agents.

Blue Rays in the Treatment of Wounds.—Richter says that sunlight has been proved to have an undoubted healing effect upon various kinds of wounds. Dry air and sunlight are, however, not to be had everywhere, and Richter has found a good substitute by employing blue arc light. The apparatus consists simply of an arc light with a reflector and blue glass panes. The wounds are subjected to the effect of the light for one-half hour daily. Such exposures lead to very rapid drying of the wound's surface, followed by the growth of epithelium and the formation of a scar. Nothing but sterile dressings are employed between the sittings. Especially remarkable is the diminution in pain following the exposure to the rays. Richter sees the beneficial effects of the rays in the general hyperemia they produce. He had very favorable results in treating plain granulating wounds, suppurating wounds, and especially chronic leg ulcers by this method. The fact that no immobilization of limbs, nor rest from the usual occupations were required made the method especially acceptable to working people. The final results were always very gratifying, the scars being more elastic, soft, and less painful than after the more usual methods of treatment.

Book Reviews.

Guide to the Clinical Examination and Treatment of Sick Children. Second Edition. Greatly Enlarged and Rewritten. By John Thomson, M.D., Fellow of the Royal College of Physicians of Edinburgh; Physician to the Royal Edinburgh Hospital for Sick Children; Joint Clinical Lecturer on the Diseases of Children, University of Edinburgh; Hon. Member of the American Pediatric Society. With 160 Illustrations. Chicago: W. T. Keener & Co., 1909.

In his preface the author states clearly the object of his book, his intention being to write a work supplementary to the text books on general medicine and introductory to the special treatises on children's diseases. He follows the clinical method, approaching his deductions from the standpoint of a keen observer, and calling the attention of his students to points which only long experience teaches the ordinary man who has not been properly instructed. The early part of the book treats of the clinical examination and history and physiognomical diagnosis, followed by an excellent description of the normal and abnormal growth and development of the child. The succeeding chapters take up the examination of the various regions, the digestive, cutaneous, and urinary disorders, the blood and circulation, respiratory diseases, an extensive account of nervous and mental diseases, and the general diseases. A rather too limited space is given to infant feeding, considering its enormous importance. The concluding portions discuss therapeutics, baths, medicines, mechanical treatments, blisters, poultices, etc., and show how these must be modified to suit childhood. An appendix gives succinct accounts of caretaking, the incubation, infective period, and duration of infections in the acute contagious diseases, recipes, formulæ, etc. In this, the second edition, the writer has doubled the size of the first, and has adhered to the same methods of selecting what he considers of interest or importance rather than trying, often at the price of boring the reader, to make a complete collection of each and every item that has been or might be connected with pediatrics.

Experimental Researches on Specific Therapeutics. By Prof. Paul Ehrlich, M.D., D.Sc.Oxon., Director of the Königliches Institut für Experimentelle Therapie, Frankfort. The Harben Lectures for 1907 of the Royal Institute of Public Health. New York: Paul B. Hoeber, 1909.

Ehrlich reviews and to a certain extent here expands the ideas he has already published in technical German papers. He discusses, first, specific therapeutics, explaining in simple language some of the phases of the side-chain theory and the kinds of antibodies produced by the action of antigens on the cells of the organism. The second lecture is given up to a discussion of another form of immunity, that due to lack of nutritive material for the attacking parasite. This hypothesis of "atrepsy" has been used by Ehrlich to explain the disappearance of tumors in sensitive animals or the immunity which some of these animals show against inoculations of very virulent tumors. The third lecture is devoted to the mode of action of some of the therapeutic agents introduced by Ehrlich in the treatment of trypanosomiasis in animals, and the immunity which the trypanosomes can develop against these drugs.

Constipation and Intestinal Obstruction (Obstipation). By Samuel Goodwin Gant, M.D., LL.D., Professor of Diseases of Rectum and Anus in the New York Post-Graduate Medical School and Hospital; Attending Surgeon for Rectal Diseases at the New York Post-Graduate and St. Mary's Hospitals, and the German Polyclinic Dispensary. With 250 Original Illustrations. Philadelphia and London: W. B. Saunders Co., 1909.

Constipation is perhaps the most frequent ailment which the physician is called upon to treat; it is also the most difficult to cure, and is yet given the least attention in the college courses in medicine and therapeutics. A volume devoted exclusively to the consideration of constipation, and especially to the medical and surgical treatment of it, is therefore especially welcome. The fact that the book before us contains over five hundred pages shows that Dr. Gant has given an exhaustive account of the subject, drawing upon his large experience in functional and organic diseases of the intestines for illustrative material. The volume opens with a complete description of the anatomy and physiology of the organs and structures that may be involved in the production of constipation. Dr. Gant then considers mechanical constipation due to obstruction of whatever nature, its symptoms, its diagnosis, and the various means of treatment at our command. The descriptive chapters are very well illustrated, so that the matter considered is presented much more objectively than is usual in the books on intestinal and gastric diseases. Most space is devoted to the treatment of constipation, this being considered under the headings, educational and prophylactic treatment, psychic treatment, diet, exercise, external and internal hydrotherapy, massage, mechanical vibration, electrical treatment, and, finally, medical treatment." The latter chapter is accompanied by a large and extensive formulary, consisting of original prescriptions and of those culled from previous writers. The consequences and complications of constipation are then considered, much space being devoted to the various surgical conditions that may be met with in this connection. The book is so complete in this respect that the title does not really give justice to its contents, as almost all operations upon the intestines are described in the book. On the whole, Dr. Gant's volume is the best and most complete treatise on the subject that we have seen.

A Laboratory Guide and Outlines in Histology. Revised Edition. By Charles H. DeWitt, M.S. Anatomy and Histology, Chicago College of Medicine and Surgery, Histology and Bacteriology in Chicago College of Dental Surgery, Histology in Valparaiso University, Valparaiso, Indiana: Charles H. DeWitt, 1908.

The efficiency of a course in histology is very much enhanced by the use of a laboratory guide answering the aim and extent of the course. The best guide is usually the one prepared by the instructor to meet his own particular requirements, and this is what Dr. DeWitt's book purports to be. In addition to brief, yet sufficient, instructions in the technique of preparing various histological material, his guide contains descriptions of the appearances that should be noticed by the student, and a number of questions under each heading, directing the student's attention to important points. Instead of elaborate illustrations, such as are met with in textbooks, the author has illustrated his book by original drawings in outline, of the same character as the student may be expected to draw. A few microphotographs are also given, but they are rather mediocre in quality. The book is interleaved for additional note-taking or drawings. It covers the subject of elementary histology quite fully and should prove useful both to students and to instructors of the subject.

Practical Physiological Chemistry. A Book Designed for Use in Courses in Practical Physiological Chemistry in Schools of Medicine and of Science. By Philip B. Hawk, Professor of Physiological Chemistry in the University of Illinois. With two full-page plates of absorption spectra in colors, four additional full-page color plates, and one hundred and twenty six figures, of which twelve are in colors. Second edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co., 1909.

While the first edition of this work was an excellent guide for the beginner, the second has been so much amplified that it forms an admirable laboratory text for even the advanced worker in biological chemistry. A great many of the more recent tests have been introduced, especially in the chapter on the qualitative and quantitative analysis of the urine, which is one of the best in the book. The question and answer scheme, which was rather wearying in the first edition, has been largely given up, and the teacher is left to ask his own questions. The description of apparatus and methods is clear and full, and in the majority of cases is all that is needed to enable the student to proceed very largely by himself. It is unfortunate that more references to the bibliography of the more important subjects have not been given. Students may not often look up the original, but it is a habit to be encouraged. The writer also shows a tendency to be rather too polite in his treatment of some of the older methods, and refrains from expressing his opinions freely; for example, in speaking of the Heintz method for the determination of uric acid, he says: "It is believed to be somewhat less accurate than the method just described" (Folin-Shaffer method). Belief has but little to do with chemistry. If the Heintz method had been a satisfactory quantitative procedure, the Folin-Shaffer method, or rather the Haycraft-Folin-Shaffer, would not have been introduced. If a professor of physiological chemistry cannot be certain which of several methods is most accurate, how should a student be supposed to select? But apart from these slight defects, the volume is one of the most useful of its type, and furnishes a striking evidence of the great development of, and the widespread interest in, biological chemistry, especially in connection with medicine.

Society Reports.

THE AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-fourth Annual Meeting, Celebrating the Centennial of McDowell's Operation, held in New York City, April 20, 21, and 22, 1909.

THE PRESIDENT, DR. J. RIDDLE GOFFE, IN THE CHAIR.

AN Address of Welcome was delivered by Dr. Clement Cleveland of New York, which was responded to by Dr. J. Montgomery Baldy of Philadelphia.

Indications for Cesarean Section in Placenta Previa.—Dr. GEORGE TUCKER HARRISON of New York read this paper. While the cases in which cesarean section for placenta previa was justifiable were very few, they did occur, and when such a case presented itself, he maintained that vaginal cesarean section should be the operation of election. This was a surgically exact method. It fulfilled the requirements of quick scientific surgery, in that one could make a clean incision, deliver, sew up the incision, and get union by first intention.

Cesarean Section in Placenta Previa.—Dr. CHARLES JEWETT of Brooklyn, N. Y., said that in cases of complete placenta previa, when complicated with an undilated and rigid cervix, abdominal section claimed consideration. Certain of the more conservative sectionists accorded a place to the cesarean operation in these conditions when it could be performed in a hospital. But the benefits of a hospital environment obtained in a similar measure for obstetric delivery. Even in complete previal implantation, and with undilated cervix, bleeding was amenable to one or more of the usual obstetric procedures, gauze tamponade or water-bag within the cervix, or the latter passed through the placenta, podalic version, etc. With ligation of the uterine arteries, as proposed by Miller of Pittsburg, the author had had no experience. If its author's claims were borne out by further trial, nothing more was required for the management of the kind of hemorrhage under discussion. Abdominal section was a grave risk after much hemorrhage. In a greatly depleted patient it was almost surely fatal. Cesarean section, when once begun, must be carried to completion, whatever the condition of the woman. On the other hand, no shock attached to the introduction of a hydrostatic bag, and little or none to a Braxton-Hicks version. In nearly 25 per cent. the child was non-viable, and here extraction might be simplified by craniotomy. As between a skilful section and an equally skilful obstetric delivery, less shock should obtain in the latter. The principal claim for cesarean section in placenta previa was its diminished fetal mortality. Under obstetric treatment the death rate of the child was formidable. Many of the children were doomed to death, whatever the method of delivery. Of the possibly viable children, cesarean section might save many lives, but by no means all. Vaginal cesarean section had no greater claim to consideration than the suprasymphyseal operation. While it might offer quite as good a prognosis for the mother, the chances for the child were not so good, owing to the somewhat greater fetal risks in extraction through the natural passages. Not only was there little rational basis for cesarean section in placenta previa, but its claims received scant support from experience.

The Indications for Abdominal Cesarean Section in Placenta Previa.—Dr. HENRY D. FRY of Washington, D. C., said the principal dangers to be overcome by the obstetric treatment of placenta previa were hemorrhage, laceration of the uterus, and sepsis. Delivery from above avoided these dangers to a great extent, because removal of the infant and placenta by a cesarean section did away with the first and second stages of labor. Abdominal cesarean section, however, brought dangers of its own, such as shock, sepsis, acute dilatation of the stomach, and other postoperative complications. The indications for the classical cesarean section were primiparity, small vagina, rigid and undilatable cervix, and placenta previa centralis. This combination would be met with in about 5 per cent. of all cases of placenta previa; therefore, the purely obstetric management would best meet the indications in 95 per cent. of the cases.

The Advisability of Cesarean Section in the Treatment of Complete Placenta Previa.—Dr. FRANKLIN S. NEWELL of Boston said the advocates of cesarean section claimed the maternal mortality under the ordinary methods of treatment was so great that some change must be made. Hirst stated that in the hands of the general practitioner a mortality of approximately 40 per cent. was present in complete placenta previa, but thought that in the hands of experts the ordinary mortality should be in the neighborhood of 1 per cent., or, in other words, an accidental mortality. Other authorities admitted a mortality varying from 3 to 6 per cent. in a large series of cases, presumably under the care of experts. The maternal mortality from abdominal cesarean section for placenta previa was variously given as from 20 per cent. upward, even in expert hands, and it seemed probable that if this was adopted as the routine treatment by the profession as a whole, a constant high mortality would be maintained, since the results of surgery performed by the general practitioner were always worse than those obtained by competent abdominal surgeons. While the maternal mortality in the hands of an expert averaged from 3 to 5 per cent., in the hands of the general practitioner the mortality was 40 per cent. The fetal mortality in cases of complete placenta previa varied from 60 to 65 per cent. under the ordinary methods of treatment, and it would seem at first sight that this was an argument for the performance of cesarean section. However, anyone who studied carefully the causes of the fetal death rate must be impressed with the fact that no such improvement in statistics was to be expected as would seem probable at first sight. Recently, vaginal cesarean section had been urged as the best solution of the problem, and the advocates of this operation claimed that it was simple and easy for the trained surgeon, and carried much less risk with it than the abdominal delivery, but the author's feeling, based on a limited experience with the operation, was that it was not so simple a procedure, even in uncomplicated cases, as was commonly stated.

Cesarean Section in Case of Placenta Previa.—Dr. EGBERT H. GRANDIN of New York said that since, except when the patient could be kept under constant observation, the rule should be to empty the uterus as soon as the diagnosis was made, rarely would the question of section offer. Less radical means would suffice from the standpoint of the woman, and in marginal instances for the child. In central implantation near or at term the child might be disregarded, and unless the cervix was diseased, undilatable and not incisable, the question of cesarean section would not offer. Where time permitted, if the vaginal portion had merged, dilating measures sufficed associated with the Duhrssen operation. In marginal instances vaginal cesarean section might enter into consideration.

Sterilization in Cesarean Section.—Dr. JOHN OSBORNE POLAK of Brooklyn, N. Y., said the obstetric surgeon should sterilize the woman who was subjected to repeated cesarean section, (1) if she requested the procedure; (2) after a second section in the presence of the absolute indication, if the proper consent could be obtained; (3) if the pathological conditions present necessitated extirpation of the uterus in the interests of the patient's life and health, sterilization might be done, if necessary, without consent. In elective and uncomplicated hysterotomies, excision of

the proximal ends of the Fallopian tubes at their origin in the uterus and the occlusion of the severed ends by flattening them out and suturing them to the peritoneum on the posterior fundal wall, was the operation of choice. When infection, disease, or atony with uncontrollable hemorrhage of the uterus was present, hysterectomy or the Porro operation should be elected, in order to secure to the patient immunity from future conception and gestation. Finally, whenever possible, one or both ovaries should be retained, in order that an operative menopause might be averted.

The Justifiability of Sterilizing a Woman After Cesarean Section.—Dr. Charles M. Green of Boston said it was ethically and morally unjustifiable to sterilize a woman in performing cesarean section, even if she and her husband requested it. The burden of proof to the contrary rested with those who advocated it. Opportunity might properly be taken in performing cesarean section to remove pathological organs; and the result might be that the woman could never again become pregnant, as in bilateral salpingo-oophorectomy, or in hysterectomy for neoplasms. But in the presence of disease requiring total ablation of the pelvic generative organs, pregnancy could not again occur were the organs not removed. If the indications for cesarean section were absolute, and husband and wife were so informed, they might abstain from subsequent sexual intercourse and pregnancy. If the indication was relative and the disproportion of minor degree, the woman subsequently might be safely delivered of living children. A husband and wife might not ethically ask that either be sterilized with a view to preventing pregnancy and avoiding repeated section. If such a request was made and acceded to, not only was the operation morally wrong, but, in the event of a second marriage, might be bitterly regretted.

Dr. Albert F. A. King of Washington, D. C., said there were a great many cases of placenta previa that occurred all over this country for which the greatest surgical skill could not be obtained, and hence the question arose, What was the best treatment to pursue in these cases? We had to fall back on obstetric treatment.

Dr. Herbert R. Spencer of London, England, stated that some nineteen years ago he wrote his first paper on "The Diagnosis of Placenta Previa by Abdominal Palpation." At about this time Lawson Tait made a statement relative to the high mortality from obstetric methods of treatment of this complication of pregnancy, and suggested abdominal cesarean section. This was received with great ridicule everywhere by obstetricians in Great Britain, and Tait acknowledged that he had not done obstetric work for many, many years. The speaker looked the subject up in connection with the University College Hospital, in which there is a large maternity under his charge, the number of cases of confinement amounting to 2,500 to 3,000 a year, and found at that time that the mortality of women treated in their own homes and those treated at hospitals aseptically by his predecessor, John Williams, and his own slight experience after him, was about 6 per cent. Tait said the mortality under obstetric methods of treatment was 40 or 50 per cent. The speaker had had practically no experience with abdominal or vaginal cesarean section in the treatment of placenta previa. His own treatment had been usually Braxton-Hicks version, and leaving the case to nature, and usually the child was delivered without any further hemorrhage in the course, on an average, of three hours, but this resulted in a high fetal mortality.

Professor Hofmeier of Würzburg, Germany, stated that abdominal cesarean section in the treatment of placenta previa was limited to a small number of cases, for the reason that it was practically impossible for the general practitioner to follow out this method of treatment. The old method of combined version and slow extraction, which was generally accepted in Germany twenty-five years ago, and the treatment by means of metreurynters in cases of large and strong children, had given good results, and in spite of the results obtained by abdominal cesarean section in placenta previa, combined version and slow extraction was still a useful method of practice.

Dr. Charles M. Green of Boston desired to place himself on record as being in agreement with Dr. Fry and others, who took the position that cesarean section must have a limited application in the treatment of placenta previa.

Dr. A. Lapthorn Smith of Montreal said it was his earnest conviction at the present time that the mortality following abdominal cesarean section in the hands of experts in this country was almost *nil*. This operation was far preferable to accouchment forcé, which, in the hands of the general practitioner and some experts, had quite a high mortality. He hoped this Society and other societies would frown down upon accouchement forcé as a means of delivery in this and other cases, where cesarean section could be resorted to, with practically no mortality. If the woman was operated on before she was touched by septic hands, when the child was not viable, there was no reason for waiting to do abdominal cesarean section, as then the life of the child did not come into question. Cesarean section was a safe operation only when done by an expert.

Dr. Philander A. Harris of Paterson, N. J., said it was hardly in accord with his experience when he heard one of the speakers mention the extreme dangers of dilating the cervix with the hand. He had not done much obstetric work in the last few years, but in forty-odd cases which he attended before that time he had no trouble in dilating the cervix with his hand. Of this number of cases he lost only one by the employment of this method of dilatation. Fatalities sometimes resulted from the injudicious use of accouchement forcé. If one knew how to use the hand and took plenty of time, there was no occasion for a woman having hemorrhage and extensive laceration of the cervix.

Dr. E. W. Cushing of Boston did not think Dr. Green, or even the Boston Lying-In Hospital, had a right to determine whether a woman should be sterilized or not. If she had been malformed by nature and could not be delivered of a child without repeated surgical operations which involved the risk of life, and she desired to avoid that subsequent risk by having a sterilizing operation done, she had a right to do so.

Dr. Henry D. Fry of Washington, D. C., said that his rule was to explain the situation to the woman and her husband, and allow them to decide whether or not she should be sterilized.

Professor Hofmeier of Würzburg, Germany, said he had performed sterilization not only with the consent of the woman and her husband, but at their urgent request. He did not think it was possible for women to abstain from sexual intercourse and subsequent pregnancy, as indicated by Dr. Green.

Dr. Charles Jewett of Brooklyn, N. Y., performed cesarean section two months ago on a woman upon whom he did the same operation two years previously, and at the request of both the husband and wife he felt justified in sterilizing the woman.

Dr. Herbert R. Spencer of London, England, did not consider we were justified in deciding, in the absence of pathological conditions, such as fibroid tumors, cancer, or infection, that a woman should not have any more children. From a purely ethical standpoint, he could not see any difference between consenting to operate on a woman and prevent her from having children by this sterilizing operation and committing an abortion because she asked it. The so-called sterilizing operation was not always reliable. A distinguished abdominal surgeon in England had supposed-

ly sterilized a woman, but subsequently, much to her annoyance and mortification, she again became pregnant, and the speaker delivered her. He subsequently delivered this woman for the seventh time after the operation of so-called sterilization.

Dr. J. Montgomery Baldy of Philadelphia said that nature had so arranged matters that some women, apparently healthy, could not bear children. Pathological processes set in which rendered them incapable of so doing. A woman was not in this world to be a beast of burden, although she had reproductive duties to perform; and there might come a time when, after she had performed them to the best of her ability, nature had so deformed her, perhaps maimed her, that she no longer could be delivered of a child without a surgical operation; then she was the best arbiter as to whether sterilization should be done or not. His sympathies went out largely to women in this respect. They had a right to an exceedingly serious say in regard to many of these operations. If a woman, guided by the conscientious judgment of the physician, decided to be sterilized, the surgeon had a right to sterilize her and prevent reproduction in the future in this individual case, but this did not mean that the operation should be done on every woman who requested it.

Dr. Andrew F. Currier of New York placed himself on the side of those who believed that it was an injustice to a woman, aside from any desire she might have for children, to subject her repeatedly to an operation which risked her life. The mere physical conditions alone which resulted, or were likely to result, should influence us very materially in regard to the question of future pregnancy.

Dr. Seth C. Gordon of Portland, Maine, thought a woman had a right to say whether she should be sterilized or not. When she was subjected repeatedly to an operation which was known to be dangerous to life, in order to be delivered of a child, she certainly had a right to say whether or not sterilization should be performed.

Dr. C. C. Frederick of Buffalo, N. Y., had sterilized women at their request and that of their husbands, in cases in which cesarean section had been done for the absolute indication, with narrowing of the pelvis to a degree that it was absolutely impossible to deliver a viable child through the pelvis.

Dr. Albert F. A. King of Washington, D. C., said that self-preservation was the first law of nature, and preservation of the species was the second law. He agreed with those who had expressed the opinion that women and their husbands had a right to decide the question of sterilization.

Dr. J. Wesley Bovée of Washington, D. C., said the surgeon had not the right to act as he chose to produce sterility. The decision of the question rested largely with the husband and wife, and not with the surgeon. The surgeon had no right to remove a woman's possibility of future pregnancy except for grave pathological lesions in the organs of generation themselves.

Dr. William S. Stone of New York said that one of the impressions gained from this discussion was an exaggerated idea of the frequency of placenta previa. Personally, he never performed either vaginal or abdominal cesarean section for placenta previa. On one occasion, however, in a case of severe hemorrhage, where the placenta was normally implanted, he did a Duhrssen operation. He had no idea of doing it, until he found hemorrhage was profuse and the indication was to empty the uterus just as rapidly as possible, and it occurred to him at the time he could resort to the Duhrssen operation and deliver the woman quickly, which he did with success.

Dr. Reuben Peterson of Ann Arbor, Mich., said that if cesarean section was advised as an operation for this complication of pregnancy, the mortality in the hands of the general practitioner would be enormous. This should always be borne in mind. A safe procedure for the general practitioner was the Braxton-Hicks method, or the bag. Only a very small number of the cases he had seen presented indications for abdominal cesarean section. Vaginal cesarean section was totally unindicated in this class of cases.

Dr. George Gellhorn of St. Louis said that Dr. Fry had clearly shown that in only about 5 per cent. of the cases was cesarean section indicated in placenta previa. He wondered if this percentage could not be still further reduced if the Barnes bag, so widely used, was discarded, and instead the Champetier de Ribes, or the Pomeroy bag, used more generally, as he thought a number of cases would be successfully delivered which heretofore had met with failure. As to cesarean section, it was not only necessary to consider its mortality, but its morbidity, and in placenta previa this operation had certainly untoward complications or after-effects that should be emphasized. With reference to sterilization, he said there was a simple way of sterilizing the man by doing a vasectomy instead of sterilizing the woman. This simple operation could be done in a minute or so under local anesthesia; yet how many men would be willing to have vasectomy done on them? He though we should be more charitable and not do unto others what we did not want done unto ourselves.

Dr. Willis E. Ford of Utica, N. Y., said he hoped the Society would not go on record in favor of the sterilization of women, for if it opened the door, it might be opened still wider for other operations which ought not to be done.

What Shall We Teach the General Practitioner Concerning the Treatment of Abortion?—Dr. Frederick J. Taussig of St. Louis mentioned the never-ceasing argument as to whether the finger or the curette was preferable. The curette was still popular with the general practitioner because it required less technical skill for its use. The summarized experiences of many large clinics showed that no one method of treatment was available for all cases, but that each had its special field of usefulness. An attempt to construct a simple table of operative procedures varied according to (1) the stage of pregnancy at which abortion occurred (first six weeks, second six weeks, third to fifth month); (2) the stage of the abortion (imminent, inevitable, incomplete); (3) the experience of the physician in charge (country practitioner, city practitioner, specialist); (4) surroundings (country residence, city residence, hospital). The author demonstrated a new case of instruments especially designed for the treatment of abortion and miscarriage.

Dr. Joseph Taber Johnson of Washington, D. C., agreed with the author, and said that gynecologists and obstetricians had much to do with the effects of badly managed cases of abortion. The dispensary and charity hospital class of patients, who came for diagnosis and treatment, attributed their present ill-health to their last abortion, and by questioning them it was found that their cases were badly managed in the great majority of instances. As to whether the curette or the finger should be used to scoop out of the uterus the remains of an abortion, he agreed with the essayist that in the first six weeks, when the neck of the uterus was dilated only a little, it would be doing violence to the part to attempt to dilate to such an extent as to permit the index finger to pass into the uterus and scoop out what remained there. On account of the great damage done by the curette, he advocated, in the seventh and eighth weeks, that the woman be anesthetized and the finger introduced into the uterus instead of the curette, and the remnants of the after-birth or membrane removed. The finger was a much more intelligent instrument than the curette.

Dr. William H. Wathen of Louisville, Ky., said the placenta should always be removed immediately after the

delivery of the child, because delay in this regard was dangerous, and one never knew when danger was going to come. Speaking of perforation of the uterus with a curette, not only did practitioners perforate this organ, but they did not know when they used this instrument whether they had removed all the secundines or not. The curette should not be used under any circumstances to remove retained secundines, except in exceptional cases, but one should rely on the educated finger.

Dr. Thomas J. Watkins of Chicago said he not only followed out the old method of the use of the vaginal pack in cases where the uterus could not be emptied without a great deal of traumatism, but packed the uterine cavity. This should be done in all cases where the uterus could not be emptied without considerable traumatism, and especially where the cervix was not well dilated. This treatment could be extended even to the cases of infection.

Dr. Malcolm McLean of New York wanted to know how a man's finger had become so elongated and prehensile that he could reach the corners of the uterus and safely feel that he had removed all detritus. There were undoubtedly men, such as Dr. Wathen, who could do this. He could not. He thought the mistake was made very frequently by good operators, who thought they had emptied the uterus by the finger, but nature came to their rescue and emptied it afterwards of pieces of after-birth which otherwise might give trouble.

Dr. Eugene C. Gehrung of St. Louis said that if we waited three or four hours after the expulsion of the ovum, we would have very great difficulty in inserting the finger, while if it was done immediately it could be effected with great ease. When the finger was inserted into the uterus, if one took care to put the other hand on the fundus of the uterus, and pressed the area over the finger, the little spaces in the uterus could be cleaned out. He had succeeded in removing retained pieces of placenta in this way.

Dr. Joseph E. Janvrin of New York agreed with Dr. Watkins in regard to the propriety and the effectiveness of passing a small wad of gauze up into the cervix and tamponing the vagina thoroughly to excite contractile pains. This had been his method of treatment for many years.

Dr. Taussig, in closing, said that he presented his paper not as a subject for discussion by the Fellows as regards their own technique, but with regard to the technique that they would advise the general practitioner to use, and he thought in this respect they should be very clear and definite in instructions.

Latero-Lateral Anastomoses of Ileum and Sigmoid Flexure for Chronic Mucous Colitis.—Dr. George H. Noble of Atlanta presented a preliminary report of 27 cases in which he had resorted to this operation. The results showed cures in the majority of cases, considerable improvement in others, and little improvement in a small percentage of them. Mucous discharges were cured in the first series of older cases, and decreased in those recently operated on. Colic and soreness of the abdomen had been cured or relieved in almost all cases. Headaches from intestinal toxemia had also been relieved, and the general health of the patients improved to a greater or less extent in all cases, but in face of this fact, patients with constipation reported either cures or improvement in the mucous colitis.

Dr. Egbert H. Grandin of New York said a simpler method sometimes answered for the cure of mucous colitis, and this was the removal of the appendix. Since it had been his custom to take the appendix out, as a routine measure, whenever in the course of an abdominal section for other lesions the condition of the patient allowed the extra few minutes, he had noticed frequently that mucous colitis had disappeared. The removal of the appendix in one case cured a mucous colitis of twelve years' standing.

Dr. Lewis S. McCurtry of Louisville said that since a large number of men had been in the Philippines and contracted dysentery, this subject had received more consideration and had developed the rather surprising fact that as far north as Cincinnati amebic dysentery was indigenous. He had been surprised at the number of cases of amebic ulceration of the colon that had been discovered in people who had never been out of this country, nor even in any tropical climate. No operation had been more useful in the treatment of this class of cases than appendicostomy. He had seen in the hands of his colleagues half a dozen of these cases that had been treated by this operation in the last year, with good results. The scrapings from the ulcers, when examined, had been found to be literally alive with amebas.

Dr. Franklin H. Martin of Chicago said that perhaps there was a similarity between the operation described and the one suggested by Arbuthnot Lane, namely, the removal of the colon for the treatment of constipation. This operation provided a remedy for that part of the colon which was dead, leaving a portion of it unused by the Arbuthnot Lane operation.

Dr. J. Riddle Goffe of New York said, with reference to the presence of amebic dysentery below the Ohio River as having been discovered in the last few years, he had heard the explanation that it had been brought back by soldiers from the Philippines, and might have become indigenous at the present time from that cause.

Dr. Noble, in closing, said he purposely avoided saying anything about amebic dysentery and similar conditions for the reason that the treatment of them was so well known, and that so many operations had been done for their relief. As to the remarks of Dr. Martin, such a radical operation as the removal of the colon would hardly be justifiable in mucous colitis. That operation belonged to another disease.

Dr. Thomas J. Watkins of Chicago described the operative treatment of extensive cases of uterine prolapse and cystocele.

Dr. William M. Polk of New York described the suprapubic operation upon the pelvic floor for procidentia uteri.

The Choice of Time of Operation for Pelvic Inflammation of Tubal Origin.—Dr. F. F. Simpson of Pittsburg said that in his judgment abscesses easily accessible for evacuation without traversing the free abdominal cavity were often best treated by early drainage. In other instances, delay with definite but simple treatment would probably prove the better course. Many patients would thus have the normal functions of their organs restored and avoid operation. For the remaining cases which demanded operative relief, the writer was in the habit of choosing a time: (1) When the patient had recovered from her acute illness, and when her margin of reserve strength had been raised to its highest point of efficiency; (2) when her temperature had been normal for a minimum period of three weeks; (3) when the inflammatory exudate about the diseased tube had been completely absorbed; (4) when a careful pelvic examination was no longer followed by a decided or persistent rise of temperature.

Dr. Herman J. Boldt of New York said it was dangerous to operate during an acute suppurative salpingitis, and in ninety-nine cases out of a hundred it was possible to wait until the acuteness of the attack had passed. As to how long that took was a question; it would depend entirely on the condition of the patient. One might operate in the interval, if there was sufficient indication for operation. Whenever the Fallopian tubes were distended with pus to such an extent that one could readily palpate them through the cul-de-sac of Douglas, the tube should be opened and the pus evacuated.

Dr. J. Wesley Bovée of Washington, D. C., said he would not be so conservative as to wait three weeks, without a single rise of temperature during that time, before operating. His experience with such appendages had been that they did not return to normal; that rarely did they get into a condition for functionating, and that in most cases in which vaginal incision had been done for the emptying of pus the appendages and tubes required removal subsequently, and with them the uterus in some cases.

(*To be continued.*)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 25, 1909.

Dr. John O. Polak in the Chair.

Perforation of the Uterus by Curette.—Dr. C. Clarence Sichel reported the case of a woman, twenty-eight years old, married, who was admitted to the hospital with a temperature of 99.2° F. and a pulse rate of 96. An exploratory laparotomy disclosed a uterus that was torn from the fundus down to the right side of the cervix; there was also a puncture of the fundus uteri. The abdomen contained about a pint and a half of fluid blood. The uterus was rapidly sutured, the abdomen filled with saline solution, and the abdominal wound was closed by the usual method. The patient did fairly well until the next morning, when her condition rapidly grew worse. An arteriovenous transfusion was asked for, but no member of the family could be persuaded to be a donor. A failure of heart and respiratory centers brought the case to a fatal termination. It was learned that a curette had been introduced into the uterus, and pushed through forcibly, perforating the organ. As it was withdrawn the curette tore the lateral wall of the uterus down to the right side of the cervix. The puncture in the fundus was caused by the introduction of a sound.

A Series of Cases of Pyosalpinx.—Dr. Sichel reported these cases:

Case I.—This patient was admitted to the hospital on January 29, 1909, with a temperature of 99°, and a pulse rate of 68. She had a white blood count of 17,000, and the polynuclears were 85 per cent. The left tube was removed because of a pyosalpinx. Two weeks later she had a temperature of 100°, the white cells numbered 12,400, and the polynuclears were 79 per cent. A subcutaneous abscess was found, opened, and drained. She was discharged cured March 6.

Case II.—This patient was forty-seven years old, married, and was admitted to the hospital on November 11, with a temperature of 102°, pulse rate of 60 and respirations 20. The white cells numbered 20,000, and the polynuclears were 80 per cent. A right sided pyosalpinx was removed after it had ruptured. The abdomen was flushed with oxygen and drained abdominally and vaginally. She was discharged cured on December 13.

Case III.—This patient was forty-three years old, married, and was admitted to the hospital February 6, with a temperature of 103°, pulse rate of 100 and respirations 24. Her white blood count was 17,600, and polynuclears were 82 per cent. A left pyosalpinx was found and the diseased organ removed. She was discharged cured February 20.

Case IV.—This patient was thirty-two years old, married, and was admitted to the hospital November 30, with a temperature of 104°, pulse rate of 112, and respirations 28. The white cells numbered 19,800, and the polynuclears were 82 per cent. The left tube was removed, and the abdomen was flushed with oxygen and drained both abdominally and vaginally. She was discharged cured on December 24.

Case V.—This patient was twenty-three years old, single, and was admitted to the hospital January 19, with the history that a criminal abortion had been attempted two weeks previous. She had a temperature of 105.4°, pulse rate of 120, and respirations were 44. The white cell count before operation was 15,000, and the polynuclears were 85 per cent. Double pus tubes were found and removed. The white cells after operation numbered 11,000, and the polynuclears were 78 per cent. The temperature and blood count reached normal in five days, and the patient was discharged cured.

Case VI.—This patient was twenty-nine years old, single, and was admitted December 24, with a temperature of 102°, pulse rate of 90, and respirations 20. The white cells numbered 10,000 and the polynuclears were 77 per cent. The gonococcus was not found on admission, but subsequently. On February 11 a pus tube and cystic ovary were removed. The white cells before operation numbered 12,000 and the polynuclears were 71 per cent. The patient was placed on antigonococcic serum and was discharged cured on March 22.

Case VII.—This patient was twenty years old, single, and was admitted December 7, with a history that three days before a criminal abortion was done. The temperature was 101°, pulse 102, and respirations 32. She was curetted at once. The white cells numbered 10,000 and the polynuclears were 84 per cent. The vaginal discharge contained the gonococci. Venereal warts in the vagina were present and showed spirochetes. On December 11 both tubes were removed and the abdomen drained. On December 15 the white cells numbered 30,000 and the polynuclears were 85 per cent. On admission this patient showed signs of a beginning consolidation of both bases of lungs. The patient was discharged February 12 under protest. She had improved.

Dr. S. Wiener said that so far as the gonorrheal cases of pyosalpinx went, in the acute or subacute stage, it was hard to state how far the process had advanced and how much resolution would occur. The condition was somewhat similar to those cases of epididymitis or epididymo-orchitis, with chill and high fever; in such cases one would not think of doing an orchidectomy.

Dr. Rosenthal recalled a case seen a few years ago in which the uterus was perforated during attempts to dilate that organ. He said he had seen a number of cases of infection of the tubes, with high temperature, chills, rapid pulse, etc., which, after the application of an icebag for a week, had resulted favorably.

Dr. S. M. Brickner said he had seen fifteen or eighteen of these cases, five of them having occurred in the Mt. Sinai Hospital and in the hands of the house surgeon. All agreed that the perforation of the uterus was caused by the heavy stroke of the curette against the wall of that organ. All these were clean cases. Dr. Brickner referred to a paper published six years ago in Vienna in which was tabulated all such cases that had occurred up to that time. So far as the streptococcic infection cases were concerned, he said he could see no reason for removing the tubes, because the infection started in another place. He asked what good the removal of the tubes would accomplish if the infecting focus was left *in situ*. However, men had diverse opinions on this subject. Some operated upon these cases and the patient got well. Others waited and allowed the surrounding tissues to become accustomed to the bacteria. Dr. Brickner believed in the non-operative treatment of these cases if one excluded pelvic abscesses.

Dr. Sichel said that in his series of cases there was but one that was acute, or accompanied by acute symptoms, of gonorrheal origin. These pus tube cases were those in which there was no possibility of subsequent cure without operation. Such women became invalids for life, and a subsequent operation would have to be done some time or

other. In three of the cases there was an acute exacerbation on top of an old condition.

A Study of the Anatomy of the Sacroiliac Joint and Its Clinical Importance.—Dr. Fred H. Albee said that he had been very much surprised in reading the literature of the minute anatomy of the sacroiliac joint to find such a marked disagreement among the most prominent anatomists and gynecologists, and he was therefore induced to ascertain, if possible, by the dissection of a sufficient number of joints, the true anatomy. In a careful dissection of fifty specimens, a perfect joint, composed of all its elements, was found in each instance, and proved to be as constant in its size and relations as that of any other joint. The anteroinferior portion of the capsule was very thin, and this accounted for the fact that infection of this joint was very prone to discharge by this avenue into the pelvis and never through the very thick part of the capsule posteriorly. The lumbosacral cord passed in close proximity to the joint at its lower third, and undoubtedly was frequently involved in affections of this joint, thus explaining the presence of persistent pain in the distribution of the sciatic nerve. Sixteen of the cadavers were placed in Walcher's position, *i.e.* patient on the back with her legs hanging over the edge of the table, and the true conjugate diameter of the pelvis averaged an increase of 8 mm. (one-third of an inch). Walcher obtained 9 mm. on the living subject. Under favorable circumstances this joint would stand much abuse, as in the case of a symphyseotomy. This articulation was liable to all the infections of other joints and the prognosis was often serious; first, because it was very likely to be a metastatic infection from some other part of the body, and, secondly, because of the danger of spontaneous drainage forward into the pelvis. Six illustrative cases of relaxation of the sacroiliac joint were reported. Goldthwait's symptom was present in the majority of the cases. This consisted of pain in the region of the sacroiliac articulation, when the thigh was flexed with extended leg to a right angle or less. These patients never lay on the back, but on the side; this was an important point in assisting to differentiate relaxation of the sacroiliac joint from disease of the lower lumbar spine. Relief promptly followed the encircling of the pelvis with tight bands of adhesive plaster, or with long corsets with a webbing belt. Dr. Albee read the following conclusions: (1) The sacroiliac articulation had all the elements of a joint, and it therefore had a similar pathology. (2) It undoubtedly was the cause of many obscure and unexplained backaches and persistent sciaticas. (3) Its anatomy was such that drainage into the pelvis was very liable. (4) The anatomy of the joint was such that in case of symphyseotomy the sacrum and ilium swung open on the strong posterior ligaments as a door on its hinge, and little permanent damage to the joint was done. (5) A relaxation of this joint should be guarded against by support of the lumbar spine with pillows, etc., in cases of protracted postoperative convalescence. Undoubtedly many could recall instances of nature's warning in the form of a convalescent's backache, which the nurse had so readily relieved by a mere pillow rightly placed under the lumbar spine.

Dr. C. Clarence Sichel said the sacroiliac joint was of interest to the gynecologist in two ways: First, because of the anatomical conditions which existed in reference to the operation of symphyseotomy; secondly, because in conditions of this kind, as mentioned by Dr. Albee in his paper, the symptoms often simulated those of an ordinary dysmenorrhea, and one was likely to slip up in his diagnosis. He now had a woman whom he was treating for dysmenorrhea. She had pain of an intense character across her back, and he was glad to be able to examine her again with a view of changing his diagnosis to sacroiliac joint trouble. Recently Dr. Sichel had seen an interesting case with Dr. Wells. It was a postoperative case. She had been curetted several times and was sent to the hospital. She complained of pain over the sacroiliac joint, and had a high temperature. The only physical findings were the tense and tender uterosacral ligaments. The uterus was in perfect position. The blood examination showed nothing suggestive of any infection. Dr Wells suggested that the joint be cut down upon, and this was done. They then decided to leave her alone. The pelvis was tightly strapped and the relief was immediate. With this relief of pain and tenderness the temperature gradually subsided. The interesting point was that the only symptoms present were the pain over the uterosacral articulation when the thigh was flexed and the temperature.

Dr. William S. Thomas thought there might be some difficulty in differentiating Kernig's from Goldthwait's sign, and he asked if the latter was not present in cases of sciatica, or a neuritis of the sciatic nerve.

Dr. Albee said one must be very careful in stretching the sciatic nerve in these cases. With the symptom complex, the tenderness over the sacroiliac joint, the location of the pain, and the temperature, there was little danger of confusing the two conditions.

Dr. John O. Polak asked if the psoas muscle acted very much.

Dr. Albee replied that this muscle acted a great deal; when this muscle was cut there resulted an enormous increase in the anteroposterior diameter of the joint.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS

Missouri State Board of Medical Examiners.

Kansas City, November 23, 24, and 25, 1908.

ANATOMY.

1. Name all bones of the foot, giving articulations of same.
2. Describe the refractory media of the eye.
3. What constitutes the middle ear?
4. Give gross and minute anatomy of the kidney.
5. Give the histological anatomy of the skin.
6. Give the gross anatomy of the pancreas and give ferments of same.
7. Name all muscles attached to the scapula, giving function of same.
8. Describe the temporal bone.
9. Give coverings for direct and indirect inguinal hernia.
10. Describe and give minute anatomy of the pleura.

PHYSIOLOGY.

1. Describe leucocytes and give their function.
2. What is meant by hyperemia, and give its cause.
3. Give the relative value of different kinds of foodstuffs in the nourishment of the human body.
4. What part does the bile play in the process of digestion?
5. Describe the process of hearing.
6. Describe the process of glycogen formation.
7. Describe transfusion and give occasion for its use.
8. What is the effect of removing the spleen from healthy individuals?
9. Give the portal circulation.
10. Describe the muscles of the heart—differentiate from other muscular tissue.

CHEMISTRY.

1. Give the chemical properties of albuminous substances.
2. Give toxicology of chloroform taken by stomach; also by inhalation.
3. What is the formula for chlorate of potassium? Give two methods by which it may be obtained.
4. Tell use of thermometers. Give kinds used, and show how to convert readings in one scale into terms of another.
5. Relate what precautions you would take in case of suspected poisoning.

THERAPEUTICS.

1. Give the physiological and therapeutical action of veratrum viride.
2. Give the physiological and therapeutical action of phytolacca decandra (poke root).
3. Give the physiological and therapeutical action of carbolic acid.
4. Give antidote for carbolic acid.
5. Give the therapeutical action and uses of salicylic acid.
6. Name some of the emetics and their uses.
7. Name some of the principal laxatives.
8. Give the physiological and therapeutical action of baptisia.
9. Name some of the principal diuretics.
10. What is apiol, and for what purpose is it used?

BACTERIOLOGY.

1. Define fermentation, putrefaction, and ptomains.
2. What is meant by mixed infection?
3. What conditions are essential in order that infection may occur?
4. What is meant by agglutination? What is Widal's reaction of agglutination? Give its technique.
5. Give the general characteristics of the *Bacillus diphtheriæ*, and the pathogenesis of diphtheria.

PATHOLOGY.

1. What are the structural changes of the spinal cord in locomotor ataxia?
2. Give process of and termination of simple inflammation.
3. Discuss caseation.
4. What is scar tissue? Give process of formation and function.
5. Describe the pathological lesions and their locations resulting in calcification.

PRACTICE.

1. Give etiology, symptoms, and treatment in each of the following diseases: (1) Phlebitis, (2) Addison's disease, (3) Pneumatothorax, (4) Marasmus, (5) Herpes zoster.
6. Give cause and treatment of enuresis.
7. How would you diagnose pleurisy with effusion? Give treatment.
8. How would you diagnose mitral insufficiency?
9. Discuss hypostatic congestion.
10. Give various causes producing hiccough, and give treatment for same.

OBSTETRICS.

1. Describe post-partum hemorrhage, giving causes and treatment.
2. Define post-partum chill, puberty, and menopause.
3. Describe a normal case of labor, giving care of case before, during, and after delivery.
4. Describe puerperal septicemia. Give treatment.
5. Describe puerperal eclampsia, giving treatment.
6. Differentiate head, breech, and transverse presentations. Give management of transverse presentation.
7. Describe the signs of pregnancy.
8. Differentiate hydramnios from multiple pregnancy.
9. Define false pains, true pains, abortion, miscarriage, and premature birth.
10. When should the forceps be used in labor? Give method of applying the same.

GYNECOLOGY.

1. Define menstruation, amenorrhea, and dysmenorrhea.
2. Give causes, symptoms, and treatment of prolapsus uteri.
3. Define endometritis. Give treatment of each form.
4. Describe gonorrhea in the female. Give treatment.
5. Give uses of uterine sound. When is it contraindicated?

SURGERY.

1. Describe the clinical symptoms of a fractured rib. Give the ordinary complications and the symptoms by which we would recognize a pneumothorax associated with rib fracture.
2. Describe the clinical symptoms of osteomyelitis of the tibia.
3. Describe in detail an amputation at the ankle joint which is done after a crushing injury of the foot.
4. Describe the symptoms and treatment of a penetrating wound of the trachea.
5. Describe the boundaries of a scalp abscess and differentiate it from erysipelas of the scalp.
6. Describe the treatment of an open, oblique fracture of the humerus at the juncture of the lower and middle third.
7. Describe the symptoms of acute gonorrheal arthritis of the knee and give its treatment.
8. What are the clinical symptoms, how do you make the laboratory diagnosis, and what is the treatment for pyonephrosis?
9. Describe the symptoms and give in detail the treatment of cellulitis of the hand consequent upon an infected wound of the finger.
10. (*a*) Differentiate between a subphrenic abscess and an empyema on the right side. (*b*) Give the treatment of a subphrenic abscess.

JURISPRUDENCE.

1. What was the penalty for producing an abortion under the old or common law?
2. What is the penalty for producing an abortion under the laws of Missouri?
3. What is the penalty for giving advice and recommending medicines for the purpose of producing an abortion?
4. When is a physician justified in performing an abortion?
5. What are the constitutional and legal safeguards in criminal cases (as abortion)?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

MISSOURI STATE BOARD OF MEDICAL EXAMINERS.

Kansas City, November 23, 24, and 25, 1908.

ANATOMY.

9.

COVERINGS OF INGUINAL HERNIA.

DIRECT.	INDIRECT.
Skin.	Skin.
Superficial Fascia.	Superficial Fascia.
Intercolumnar Fascia.	Intercolumnar Fascia.
Conjoined Tendon.	Cremasteric Fascia.
Transversalis Fascia.	Infundibuliform Fascia.
Subperitoneal areolar tissue.	Subperitoneal areolar tissue.
Peritoneum.	Peritoneum.

10. "The *pleuræ* are two serous sacs enclosing and investing the lungs. Each pleura consists of a visceral and parietal layer. The *visceral* portion covers the lungs, and the *parietal* layer lines the inner surface of the chest walls, the upper surface of the diaphragm, and the sides of the pericardium. The visceral and parietal layers of the corresponding pleura become continuous in front and behind the root of the lung; and below the root a fold, the *ligamentum latum pulmonis*, extends downward along the inner surface of the lung to the diaphragm. The mediastina are formed by the visceral layers of each side approaching one another toward the median line.

"The limits of the parietal pleuræ are as follows: Each extends upward into the neck, forming a domelike process over the apex of the lung about two inches above the first costal arch; from this the pleura passes downward and forward to the posterior aspect of the sternoclavicular joint of each side and meets its fellow in the midline at the manubriogladiolar articulation; they pass down together to level of fourth costal cartilages, where *right pleura* passes vertically to level of seventh right costal cartilage in midline; then outward, crossing ninth rib in midaxillary line; then downward and backward along eleventh rib to reach spine at neck of twelfth rib. Behind, it passes upwards on right side of bodies of vertebræ to apex. At level of fourth costal cartilage the *left pleura* arches outwards, leaving uncovered part of anterior surface of pericardium, and lying about ¾ inch from the margin of sternum, to reach seventh costal cartilage, where it follows same line as on right, but is placed at a slightly lower level." (*Aids to Anatomy.*)

PHYSIOLOGY.

1. The *leucocytes* or white blood cells are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neu-

trophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their *functions* are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

2. By *hyperemia* is meant an increase in the physiological allowance of blood to a part. It may be due to an increase in the amount of blood entering the part, or to some obstruction of the outflow.

3. *"The relative value of foods.*—Dried proteins contain about 15 per cent. nitrogen, 54 per cent. carbon, 7 per cent. hydrogen, 22 per cent. oxygen, a little sulphur, and frequently some phosphorus. A large proportion of their carbon and hydrogen is available for combustion. Fats contain 75 per cent. of carbon, and a considerable quantity of hydrogen available for combustion; carbohydrates, 40 per cent. of carbon, with hydrogen and oxygen in the proportion in which they occur in water. If one gramme of protein is oxidized to the condition of urea, carbonic acid, and water, sufficient heat is liberated to raise the temperature of 4,100 grammes of water 1 degree centigrade. Its calorific value is therefore expressed as 4,100 calories, the unit of measurement—a calorie—being the amount of heat needed to raise 1 gramme of water 1°. The calorific value of 1 gram of fat is 9,300 calories; of 1 gram of starch, 4,100 calories. Thus the energy potential in protein and starch is the same; that in fat more than twice as great as that in either of the other foods." (Hill, *The Body at Work.*)

4. In the process of digestion it is the function of the bile: (1) to assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

5. "The waves of sound are gathered together by the pinna and external auditory meatus, and conveyed to the membrana tympani. This membrane, made tense or lax by the action of the tensor tympani and laxator tympani muscles, is enabled to receive sound waves of either high or low pitch. The vibrations are conducted across the middle ear by a chain of bones to the foramen ovale, and by the column of air of the tympanum to the foramen rotundum, which is closed by the second membrana tympani, the pressure of the air in the tympanum being regulated by the Eustachian tube. The internal ear finally receives the vibrations, which excite vibrations successively in the perilymph, the walls of the membranous labyrinth, the endolymph, and, lastly, the terminal filaments of the auditory nerve, by which they are conveyed to the brain."—(Brubaker's *Physiology.*)

6. Glycogen is chiefly formed from the carbohydrates. The liver cells act upon the dextrose into which the carbohydrates have been converted by the action of the ptyalin and amylopsin of the digestive juices. This *may* occur by a simple process of dehydration:

$$C_6H_{12}O_6 - H_2O = C_6H_{10}O_5$$

But the precise process by which it occurs in the liver cells is not known.

8. The *effect of removing the spleen* may be: A diminution in the percentage of hemoglobin and in the number of red blood corpuscles; an increase in the number of white blood cells, and enlargement of the lymph glands. There is some difference of opinion as to these results, but the above are the ones usually given.

CHEMISTRY.

1. The *chemical properties of albuminous substances*: Some of them are soluble in water, some are insoluble in water, and some are soluble in water provided certain salts are present; they are coagulable by heat, have large molecular weights, and are of unknown constitution. They are insoluble in chloroform, alcohol, ether, or benzene; they are composed of carbon, hydrogen, oxygen, and nitrogen; some contain phosphorus or sulphur. They give certain color reactions.

2. "No chemical antidote for chloroform is known. When it has been swallowed, stomach-lavage and emetics are indicated; when taken by inhalation, a free circulation of air should be established about the face; artificial respiration and the application of the induced current to the sides of the neck and epigastrium should be resorted to."—(Witthaus' *Essentials of Chemistry.*)

3. The *formula* for chlorate of potassium is $KClO_3$. Two methods by which it may be obtained: (1) By passing chlorine through a solution of potassium hydroxide; (2) by passing chlorine over a mixture of milk of lime and potassium chloride, heated to 140° F.

4. *Thermometers* are instruments for the measurement of temperature. The kinds used are: Centigrade, Fahrenheit, and Réaumur. To convert the readings in one scale into terms of the others:

$$C° = \frac{5}{9}(F° - 32) \qquad C° = \frac{5}{4}R°$$

$$F° = \frac{9}{5}C° + 32 \qquad F° = \frac{9}{4}R° + 32$$

$$R° = \frac{4}{5}C° \qquad R° = \frac{4}{9}(F° - 32)$$

5. "First of all, the physician should keep his suspicions to himself. In the next place, he should himself test the urine or feces, or both, and govern his treatment and his actions toward the patient and those surrounding the patient by the results of his examination. Should the case terminate fatally, he should at once communicate his suspicions to the prosecuting officer, and require a post-mortem investigation, which should, if at all possible, be conducted in the presence of the chemist who is to conduct the analysis.

"The following portions of the cadaver should be preserved: The alimentary canal from the cardia to the middle of the rectum, *unopened*, and the contents enclosed by ligatures at the esophagus, duodenum, and lower end of gut; the liver, including the gall-bladder; one kidney; the spleen; a piece of muscular tissue from the leg; the brain, and any urine which may remain in the bladder.

"Any suspected food articles, and any obtainable vomited matter are to be also preserved. All of these are to be placed in *clean* and *new* glass jars, closed with glass or cork covers or stoppers.

"Jars with metallic caps should never be used. Tapes or cords should be tied about the jar and cap, to which they should be attached by sealing wax bearing impressions of a seal, in such a manner that access can be had to the interior only after breaking the seals or cutting the tapes or cords. Great care must be exercised that no sealing wax can get into the jars. Each portion should be placed in a jar by itself."—(Witthaus' *Essentials of Chemistry and Toxicology.*)

THERAPEUTICS.

1. Veratrum viride. *Physiological action*: "On the skin it causes tingling, numbness, and anesthesia, and, applied to the mucous membrane of the nose and throat, violent sneezing and coughing. Internally it produces gastro-intestinal irritation, prolonged relaxation of striped and cardiac muscle, reduction of arterial pressure, depression of respiration, convulsions from stimulation of the spinal cord, free diaphoresis, and reduction of temperature."

Therapeutical action.—"As a circulatory depressant, given early, in croupous pneumonia, pleurisy, hepatitis, maniacal delirium, etc., with strong, bounding pulse and other sthenic conditions; in puerperal convulsions and the early stage of peritonitis, phlebitis and other inflammatory affections of the puerperal state; also acute rheumatism, tonsilitis, aneurysm, and wounds of the head, pericardium and peritoneum."—(Wilcox, *Materia Medica.*)

2. Phytolacca decandra. *Physiological action*: Cathartic, emetic, slightly narcotic, cardiac and respiratory depressant, irritant to throat.

Therapeutical action: In diphtheritic sore throat, tonsilitis, pharyngitis, rheumatism; also as a laxative, and for obesity. Locally it has been used for mastitis, varicose ulcers, eczema, and other skin conditions.

3. Carbolic acid. *Physiological action*: "Irritant; caustic; antiseptic; disinfectant; deodorant; parasiticidal; antizymotic; antipyretic; in solutions of moderate strength, locally anesthetic. The heart and respiration are at first stimulated and afterward depressed. Smokiness of the urine is a characteristic feature."

Therapeutical action: "As a disinfectant for surgical instruments, soiled linen, hospital apparatus, drains, privies,

etc.; as an application for burns, carbuncle, endocervicitis, lupus, condylomata, and various other conditions; as an injection for leucorrhea and gonorrhea in the female; as a local anesthetic. Its antipruritic and parasiticidal qualities render it useful in many cutaneous affections; and it is employed locally in hay fever, influenza, and nasal catarrh. In the treatment of wounds it has been largely superseded by more powerful germicides. Internally: gastrointestinal irritation; malarial fever, typhoid fever, scarlet fever, and other zymotic diseases; influenza; by hypodermic injection in tetanus and bubonic plague."—(Wilcox, *Materia Medica.*)

4. *The antidote for carbolic acid* is pure alcohol, or a soluble sulphate such as sodium sulphate.

5. Salicylic acid. *Action*: "Antiseptic; irritant; strongly cholagogue; antipyretic; diaphoretic; diuretic (markedly increasing the excretion of uric acid). In exceptional instances skin eruptions are caused, and in some individuals a train of symptoms analogous to those of cinchonism, and designated as *salicylism*, results from the use of salicylic preparations."

Uses: "Externally as antiseptic and stimulating applications and for the checking of abnormal perspiration; also in parasitic and other skin diseases. Internally, rheumatic fever (in which it seems to act as a specific); gout; migraine; sciatica; diabetes; cholelithiasis."—(Wilcox, *Materia Medica.*)

6. *Some of the emetics*: Apomorphine, ipecac, tartar emetic, zinc sulphate, copper sulphate, subsulphate of mercury, tepid water and mustard.

Uses: To empty the stomach, to remove poisons, to remove croupous membrane, to remove foreign bodies from pharynx or esophagus.

7. *Some of the principal laxatives*: Sulphur, magnesia, olive oil, cascara, tamarinds, figs, prunes, honey, cassia.

8. Baptisia. *Physiological action*: Laxative, emetic, cathartic, gastrointestinal irritant, antiseptic and stimulant of the glands of the gastrointestinal tract.

Therapeutical action: It has been used in typhoid, scarlet fever, smallpox, dysentery, and amenorrhea. Locally, for ulcers and gangrenous sores.

9. *Some of the principal diuretics*: Alcohol, digitalis, potassium acetate, potassium bitartrate, potassium citrate, ammonium acetate, lithium citrate, convallaria, squill, calomel, water, caffeine, sparteine, juniper.

10. Apiol is a substance obtained from the fruit of Petroselinum sativum; its other name is Parsley. It is *used* in cases of amenorrhea, scanty menstruation, dysmenorrhea; it is said to be an abortifacient.

BACTERIOLOGY.

1. *Fermentation* is a chemical transformation of *carbohydrates* as the result of the activity of microorganisms.

Putrefaction is the decomposition of dead *protein* material as the result of the activity of certain microorganisms.

Ptomains are the putrefactive products of dead animal tissue, or fluids; they are basic, nitrogenous, and resemble alkaloids in their action.

2. By a *mixed infection* is meant the association of two or more kinds of bacteria in a given diseased condition.

3. *In order that infection may occur* the following conditions are essential: (1) The host must be susceptible; (2) the microorganisms must be present in sufficient numbers; (3) they must be sufficiently virulent; (4) they must enter by the appropriate avenue of infection.

4. *Agglutination* is the property possessed by the blood or blood serum of animals (and men) whereby, after an attack of an infective disease, the blood causes "clumping" of the infective agent in liquid cultures to which the serum is added. It is particularly noticeable in the case of typhoid fever.

Widal's reaction of agglutination "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of the blood are taken from the well washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover glass, and this is inverted over a sterile hollowground slide and examined. A positive reaction is obtained when, all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes."—(From Thayer's *Pathology.*)

5. The *characteristics of the bacillus of diphtheria*: The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are nonmotile and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

PATHOLOGY.

1. In *locomotor ataxia* the posterior columns of the spinal cord and the posterior nerve roots are involved.

The posterior columns of the spinal cord are gray and shrunken, and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus. The process is destructive and progressive.

OBSTETRICS.

2. *Postpartum chill* is a chilliness or rigor experienced by the patient either during the third stage of labor, or shortly after labor is terminated. It is of nervous origin and has no pathological significance.

Puberty is the period when the child becomes sexually mature and in the case of the female when menstruation commences.

Menopause is the period when menstruation ceases.

5. *Puerperal eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death.

The *causes* may be: Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect elimination by the skin, bowels and kidneys.

The line of *treatment* as laid down by Edgar is as follows: For *preventive treatment*:—(1) the amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ.

The *curative treatment includes*: (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

7. *Positive signs of pregnancy.*—(1) Hearing the fetal heart sound; (2) active movements of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

Doubtful signs of pregnancy.—(1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

8.

HYDRAMNIOS	MULTIPLE PREGNANCY
The uterine tumor is more distinctly tense.	The uterine walls are not so uniformly distended and tense.
Fluctuation may be elicited.	Fluctuation is absent.
There is inability to palpate the fetal limbs.	A number of fetal limbs may be palpated.
The lower uterine segment is unusually distended, tense, and elastic; the presenting fetal part is recognized with difficulty.	There is no undue distention of the lower uterine segment; the presenting part of a fetus may be readily detected.
The fetal heart-sounds are faint or altogether absent.	The fetal heart-sounds are distinct; heart-sounds of different rates, corresponding to the two fetuses may be heard.

(From Dorland's *Obstetrics.*)

9. *False pains* are irregular uterine contractions which occur before the beginning of labor, and which may be either painful or painless, and which do not cause the "show," nor yet dilate the os.

True pains are uterine contractions occurring at the beginning and lasting through the first two stages of labor. They are usually very painful; they advance labor, dilate the os, and cause the "show."

Abortion is delivery of the product of conception before the twelfth week.

Miscarriage is delivery of the product of conception between the twelfth and twenty-eighth weeks.

Premature birth is delivery of the fetus between the twenty-eighth week and full term.

10. *Indications for the use of forceps* are: "1. *Forces at fault*: Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault*: Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault*: A.—Dystocia due to (*a*) occipito-posterior, (*b*) mento-anterior face, (*c*) breech arrested in cavity. B.—Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. *Accidental complications*: Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both."—(From Jewett's *Practice of Obstetrics.*)

GYNECOLOGY.

1. *Menstruation* is a periodical disturbance in the female, characterized by a bloody mucus discharge from the uterine cavity; it lasts during the period of woman's sexual activity, but is temporarily suspended during pregnancy and early lactation.

Amenorrhea is absence of menstruation.

Dysmenorrhea is painful menstruation.

5. The *uses* of the uterine sound are: (1) to demonstrate the mobility of the uterus; (2) to show the size of the uterus; (3) to show the presence of intrauterine growths; (4) to indicate deviations in the cervical canal; and (5) as an aid in the diagnosis of uterine displacements.

Contraindications: (1) The least suspicion of even the possibility of pregnancy; (2) menstruation; (3) acute endometritis; (4) malignant disease of the uterus or vagina; (5) acute pelvic inflammation.

JURISPRUDENCE.

2. If the woman dies, the person who committed the abortion is guilty of manslaughter in the second degree and punished accordingly; in case no such death occurs the person is guilty of the felony of abortion, and upon conviction may be punished by imprisonment in the penitentiary for not less than three years and not more than five years, or by imprisonment in jail not exceeding one year, or by fine not exceeding $1,000, or by both such fine and imprisonment. If the person convicted be a licensed physician or surgeon in the State, he is liable to have his license revoked by the State Board of Health.

3. The penalty for giving advice and recommending medicines for the purpose of producing an abortion is (in Missouri) the same as for producing an abortion. See Answer 2, above.

4. The chief conditions that justify the induction of abortion are: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of the fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head.

BULLETIN OF APPROACHING EXAMINATIONS †

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery.	Montgomery	July 13
Arizona*	Aneil Martin, Phoenix	Phoenix	July 5
Arkansas*	F. T. Murphy, Brinkley	Little Rock	July 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	Aug. 3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	July 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July 13
Delaware	J. H. Wilson, Dover	Dover	June 15
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington	July 13
Florida*	J. D. Fernandez, Jacksonville	Tallahassee	
Georgia	E. R. Anthony, Griffin	Atlanta	Oct. 12
Idaho*	W. F. Howard, Pocatello.	Boise	Oct. —
Illinois	J. A. Egan, Springfield	Chicago	June —
Indiana	W. T. Gott, Crawfordsville	Indianapolis	May 25
Iowa	Louis A. Thomas, Des Moines	Des Moines Iowa City	June 1 June 8
Kansas	D. P. Cook, Clay Center	Kansas City	June 7
Kentucky	J. N. McCormick, Bowling Green	Louisville	
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	
Maine	Wm. J. Maybury, Saco.	Augusta	July 1
Maryland	J. McP. Scott, Hagerstown.	Baltimore	June 15
Massachusetts*	E. B. Harvey, State House, Boston.	Boston	July 13
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Detroit	May 24
Minnesota	W. S. Fullerton, St. Paul	St. Paul	June 1
Mississippi	S. H. McLean, Jackson	Jackson	
Missouri	J. A. B. Adcock, Warrensburg	St. Louis	June 7
Montana*	Wm. C. Riddell, Helena	Helena	Oct. 5
Nebraska	E. J. C. Sward, Oakland	Lincoln	May 25
Nevada	S. L. Lee, Carson City	Carson City	Nov. 1
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord	June 29
New Jersey	J. W. Bennett, Long Branch	Trenton	June 15
New Mexico	J. A. Massie, Santa Fe	Santa Fe	July 12
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York. Albany Syracuse Buffalo	June 22
N Carolina	B. K. Hays, Oxford	Asheville	June 3
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	July 6
Ohio	Geo. H. Matson, Columbus	Columbus	June 9
Oklahoma*	F. P. Davis, Enid	Guthrie	July 18
Oregon*	B. E. Miller, Portland	Portland	July 6
Pennsylvania*	N. C. Schaeffer, Harrisburg	Philadelphia Pittsburg	June 22
Rhode Island*	G. T. Swarts, Providence	Providence	July 1
S Carolina	H. H. Wyman, Aiken	Columbia	June 8
S. Dakota*	H. E. McNutt, Aberdeen	Watertown	July 14
Tennessee	C. A. Abernathy, Pulaski	Memphis. Nashville Knoxville	May, 1910
Texas	C. B. Foscue, Waco.	Cleburne	June 22
Utah	R. W. Fisher, Salt Lake City.	Salt Lake City	July 5
Vermont	W. Scott Nay, Underhill	Burlington	July 13
Virginia	R. S. Martin, Stuart	Richmond	June 22
Washington*	K. Turner, Seattle	Seattle	July 6
W. Virginia	H. A. Barbee, Point Pleasant	Charleston	July 13
Wisconsin	J. Y. Stevens, Jefferson.	Madison	July 13
Wyoming	S. B. Miller, Laramie.	Laramie	June 23

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Results.—The following table (from the *Journal of the Medical Society of New Jersey*) will show the recent passes and failures in several States:

	Exam.	*Passed.*	*Failed.*
Arizona	8	5	3
Arkansas	30	18	12
California	62	34	28
Connecticut	20	15	5
Delaware	4	4	0
Florida	59	52	7
Georgia	32	30	2
Indiana	59	53	6
Iowa	33	26	7
Kentucky	43	19	24
Louisiana	21	13	8
Massachusetts	77	53	24
Michigan	13	9	4
Mississippi	101	31	70
Missouri	46	25	21
Montana	50	30	20
Nevada	6	6	0
Nebraska	18	16	2
New Hampshire	22	15	7
New Jersey	56	40	16
New Mexico	7	6	1
North Carolina	121	95	26
Oklahoma	44	34	10
Pennsylvania	80	69	11
Pennsylvania (June)	395	362	33
Rhode Island	13	9	4
South Dakota	35	32	3
Texas	60	59	1
West Virginia	31	28	3
Wyoming	1	1	0

North Carolina.—The North Carolina Legislature in 1909 meeting adopted an amendment to the Medical Laws, adding at the end of section 4498 of the revisal of 1905 the following: "*Provided still further*, that the said board may, whenever in its opinion the conditions of the locality where the applicant resides are such as to render it advisable, make such modifications of the requirements of this section, both as to application for examination and examination for license, as in its judgment the interests of the people living in said locality may demand, and may issue to such applicant a special license, to be entitled a 'Limited License,' authorizing the holder thereof to practise medicine and surgery within the limits only of the district specifically described therein. The holder of the limited license practising medicine or surgery beyond the boundaries of the district as laid down in said license shall be guilty of a misdemeanor, and upon conviction shall be fined not less than twenty-five dollars nor more than fifty dollars for each and every offense; and the said board are empowered to revoke said limited license, in its discretion, after due notice."

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending May 15, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	550	176
Diphtheria	318	32
Measles	1,578	32
Scarlet Fever	338	33
Smallpox	..	..
Varicella	167	.
Typhoid Fever	56	4
Whooping Cough	111	14
Cerebrospinal Meningitis	11	8
Malarial Fever	..	.
Totals	3,129	299

Hematogenous Origin of Pyonephrosis.—Fortunato Broccolo has studied experimentally in animals the production of pyonephrosis by ligation of one ureter and later injection into the blood of *Staphylococcus pyogenes aureus*. He gives us these conclusions: ligature of one ureter is always followed by hydronephrosis of the corresponding kidney, without any other cause. The dilatation of the pelvis is appreciable after six hours. As the transformation of the kidney into a sclerotic sac goes on the function is destroyed by destruction of the epithelial elements. Urinary stasis realizes all the necessary conditions for hematogenous origin of the infection. Pyonephrosis may be caused by the injection into the blood of pyogenic germs, provided they be in sufficient numbers, contain isolated forms, and the bacteria are of slight virulence. Infection occurs at the first injection. If the dose is exceeded suppuration will occur in the other kidney, the liver, and other organs. The opposite kidney never remains healthy, since the overwork required of it and the poisons to be absorbed always affect it also.—*Lo Sperimentale.*

The Treatment of Plague.—In an article read before the Grant College Medical Society of Bombay, Dr. R. Row recommends the treatment of plague by the method of inoculation with living pyogenic organisms. He does not enter into details of the character or mode of preparation of the material with which he claims to have produced useful results, but states, somewhat vaguely, that "the chief part of the matcrial consists of a species of *Staphylococcus pyogenes.*" This material is introduced by local scarification round about the plague bubo in six or eight points, and "allowed to remain there for eight to ten hours, so as to take root." Dr. Row enters into a lengthy discussion about the various physiological and pathological processes whereby these inoculations lead to a beneficial result, the gist of his argument being that the pyogenic organisms inoculated counteract the action of the plague bacilli.—*British Medicol Journal.*

Contribution to the Knowledge of the Function of the Hypophysis Cerebri.—A. Gemelli has studied the function of the hypophysis cerebri by ablation of the organ in animals. His conclusions are these: the organ is not indispensible to the life of the animal because animals survive indefinitely the removal of the organ without any untoward symptoms. In all probability other organs of similar structure and functions take the place of the removed organ. In young animals from whom it has been removed there are more effects noticed than in adult animals; there is an arrest of development, shown by lessened weight, length of the limbs, etc. The glandular lobe of the hypophysis has a marked antitoxic action. The other lobe is an ancillary organ of the kidney.—*La Riforma Medica.*

Obliteration of the Tubes After Resection.—I. Ronsse advocates the sterilization of women after laparotomy, when there are conditions present that render future conception dangerous to the patient by section of the Fallopian tubes between two ligatures. Some observers have stated that pregnancy has occurred after this procedure, and that the tubes do not remain permanently closed. The author has experimented on animals and has found that the tubes do remain closed. The tubes when examined histologically were seen to be closed by a mingling of cells of muscular, epithelial, and connective tissue character. The author has also examined three tubes that had been removed at a second operation after sterilization had been performed previously, and he finds that the closure of the tube was of a permanent nature.—*Bulletin de la Société Belge de Gynécologie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending May 14, 1909:

SMALLPOX—UNITED STATES

		CASES.	DEATHS.
California, Berkeley	Apr. 17–24	1	..

THE ETIOLOGY OF PAIN.*

By E. G. JANEWAY, M.D.,

NEW YORK.

The subject which has been chosen for this evening's consideration—the etiology of pain—though very broad, seemed possessed of the merit that it will enable each to add from his special fund somewhat of interest. I shall endeavor from my experience to draw attention to certain cases and conditions which have seemed somewhat unusual.

While the interpretation of a particular pain may be easy of solution, there occur, as we all know, pains whose correct understanding may need not only careful study but also the critical examination of coincident conditions. Idiosyncrasy, sex, defective ability of expression, a foreign language, the use of an interpreter, and also racial peculiarity may each add to our trouble. So, again, we may have malingering, the denial of habits which would, if known, be illuminating, the desire for drugs or intoxicants all stand in the way of successful search for the true cause.

The following illustration will show the fallacy of the hope entertained by a lady that an autopsy would reveal the cause for pains in the abdomen, which had anoyed her from time to time. As a result she had left an insistent request that, in the event of her death, a port-mortem examination should be held, as she hoped thus that her sufferings would prove of benefit to humanity. She died of pneumonia, which had no relationship to her previous troubles. A careful study of the viscera did not reveal any abnormality nor any such condition as would justify the opinion that this or that had been able to produce her sufferings. The condition of the gall-bladder, of the ducts of the pancreas, of the kidneys, etc., were studied. The possibility of hernia in usual and unusual positions was likewise investigated. In fact, the results of the autopsy were entirely negative. It did seem the irony of fate that where there existed so unusual a desire for a method of research, which is so generally avoided because of the prejudice against it, that it should not accomplish its end. I had only seen this lady during her attack of pneumonia. The exact character of her pains were not made very clear to me, though to her they had evidently been very real.

Early in my medical career, as a student visiting the wards of a hospital as member of a class, the professor in attendance showed us how to distinguish in a young woman, who had complained of abdominal pain, the hysterical nature of her complaint, peritonitis having been suggested as possible. Pressure under ordinary circumstances elicited signs of distress, but when the patient's attention was diverted fairly deep pressure was made without evidences of manifest discomfort. Two days later an autopsy disclosed peritonitis as the cause of her illness and death. Since then I have encountered other cases, denominated hysterical, which have terminated fatally from organic causes. For illustration, a patient entering a hospital for headache was on several occasions discharged as hysterical until she returned with severe attack followed by coma and death, whose cause was a tumor of the brain. Again, a woman at menopause had complained of severe precordial pain with which a heart murmur coexisted. The patient's physician and her husband were informed that this was hysterical, and that she was in no danger. Against this view I was obliged to take issue. A short time later the lady uttered a scream while her physician was in an adjoining room; he was barely able to keep her from falling to the floor, and lay her on a bed—she had died of angina pectoris.

It would be unwise to consider each severe pain in a female of organic origin, otherwise it might be that operations would be performed and normal parts removed, as has happened. These instances, among others, have taught me to be very cautious in labeling a severe pain as hysterical.

Pain dependent upon toxic influences may perhaps baffle us unless we make diligent inquiry even in spite of the patient's protestations. We are obliged at times to adopt devices such as a quiet inquiry of the friends, at the same time impressing upon them the necessity that we should know the truth for the patient's own benefit. More than once I have been enabled thus to rightly name a pain, or its causative pathology, as alcoholic neuritis. Each of us has no doubt been witness to the sad picture of the shattering of ideals, or idols, as you may choose to designate, the effect of knowledge by relatives of the injurious habits of their relations. But it is otherwise often when we look for the cause of vague aches and pains unless we are helped by the characteristic line on the gum in the case of lead, or unless we have the help of the associated paralysis.

Perhaps an illustration will serve best to set the matter a little more clearly. I was consulted in the office for pain in the abdomen by the proprietor of a saloon. The examination had not made me certain of the nature of the malady, when fortunately I examined the gums. These gave the indication, but I little felt that I had thus found that as in the case of Eve the woman was at fault, for upon a little cross-examination it came out that he had been drinking cider which was pumped through a lead pipe from the barrel in the cellar below. Then it was that the patient told his wife that it was her fault, as she had made him give up whiskey. The opportunity for a rejoinder was at hand, for it was not difficult to tell him that it served him right because of such unhygienic method of drawing cider.

*Read at a meeting of the Practitioners' Society of New York, February 5, 1909.

So all could, without doubt, enumerate instances of difficult detection of the method of entrance of poisons from hair dyes to galvanized tacks held in the mouth, or thread bitten by the teeth.

It behooves us, however, to be on our guard lest we be too zealous in our search and lay the blame on some condition which covers lack of diagnostic ability, as in the celebrated Boston case with which I take it you are all familiar. In this instance an autopsy made to show that the patient was a victim of arsenic inhaled from the material on the walls, showed that a carcinoma of the stomach was the true cause of the symptoms during life and of the fatal issue.

The diagnosis of sciatica seems and usually is simple enough, yet not infrequently pains taken to be those of simple neuralgia usher in a much more serious condition. Notwithstanding a careful examination, not alone of the bones of the pelvis inside and out at the inception of treatment of a case, yet a growth may gradually develop, and either the physician be surprised on a second investigation, or else a subsequent examiner discover a growth instead of simple neuralgia to the discomfiture of his predecessor. Hence it is a wise rule to make a critical reexamination after a moderate lapse of time of any patient whose history contained points of doubt. While the above remarks are the result of the review of several illustrative histories, yet I will draw attention to the salient points of one particularly. He came to me because he thought he had sciatica, and his impression had been confirmed by medical pronouncement. There was found on the posterior part of the ilium a small rounded portion tender to pressure. This was not removed, nor were the pains relieved by the employment of antisyphilitic measures, given with the bare hope that this swelling indicated that we had to deal with a specific development rather than a malignant growth. The patient was advised to obtain a surgical opinion as regards the possibility of operative interference. Two surgeons, both members of this society, advised that nothing could be hoped for from the employment of the knife. Later he was operated upon abroad by the removal of the affected bone, together with the whole lower limb. The operation was said to have been successful, though death happened shortly after (within 36 hours) according to my informant. This introduces as a subject the etiology of pain, especially nocturnal pain, when relieved by specific medication. In the above outlined case marked improvement apparently happened at first.

The following more marked illustration occurred in a male under 40 years of age. His main complaint was of pain in the region of the left fourth rib near the nipple and in the back, which occurred mainly at night. He made no complaint of gastric distress, nor was there any evidence of impaired digestion. The left fourth rib was somewhat prominent, but without the proof of a morbid condition. A trial was made of specific measures, and a marked improvement for a time resulted in complete absence of pain. Later the pain returned, and failed to be relieved as at first. Then a partial collapse occurred, with vomiting of a dark fluid in the street where it could not be had for examination. No doubt of its hemorrhagic nature was entertained, as he became quite anemic. Moreover, symptoms of perigastritis followed for a time. Examination of the stomach contents showed a normal state, and there was no retention of gastric contents. No tumor was manifest. On the development of these phenomena the etiology was transferred from possible specific disease to either gastric cancer or ulcer. Only when a nodule became evident in the left lobe of the liver could the positive diagnosis of cancer of the stomach be arrived at. The secondary spread was rapid, and an autopsy showed carcinoma of the lesser curvature of the stomach, not impeding the entrance nor the exit of food.

We can reconstruct this case in the light of the above. The pains occurred more at night because at this time the recumbent posture brought the stomach contents in contact with the lesion.

I have already made allusion to the lady who desired others to know the cause of her pains. So, we, as physicians, would be very glad at times if we could solve the problem of the source of pain in the abdomen. In not a few cases would the kidney be opened instead of the appendix removed. It requires very careful inquiry and search in order to be sure in certain instances which of the three parts, kidney, gall-bladder or appendix would be the right organ to be attacked. But I will not now mention these, nor the possibility of the duodenum or pancreas being at fault, but rather draw attention to the possibility of the pains of nervous disorder, especially of ataxia leading to laparotomy or even to the study of the ureter and kidney It is necessary to ascertain whether there are any such features present as would warrant a suspicion of ataxia or other cord disease before deciding. The etiology will be best understood if in the first place we find out whether there has been a preceding leutic infection. To me experience is very strong which connects these conditions. The crisis and at times, also, the desire for the relief afforded by medication intensify the expression of pain; as, on one occasion, the recurring pains were accompanied by extreme gastric irritability, and the more characteristic signs of ataxia were not in evidence, a surgeon in one hospital removed the appendix. After recovery from this, the patient, with the pains as severe as before, entered another hospital in a different city where the question came as to possibility of gastric ulcer. Again, as above stated, prior to the comprehension of the nervous condition as causative I have known the ureter and bladder to be explored and the question of nephrotomy to be raised.

If too much stress is laid upon the character and direction of the pain we may consider a case to be due to renal colic when in truth we have to deal with an aneurysm of the aorta, as in one case which came to autopsy under my observation, but those who had seen the patient during life considered the condition to be the former.

A still more interesting observation relates to a gentleman visiting in this city who was seized with a sudden pain in the left side of the abdomen in the kidney region. This was violent and led a physician because of the location and radiation of the pain to consider the condition one of renal colic. When I examined him the next day there was the history as above, and, in addition, a considerable swelling on the left side of abdomen could be observed which had an incomplete pulsation. The question came as regards renal distention or aneurysm. I decided upon aneurysm. By the next day the swelling had increased and towards the median line—pulsation continued. He died the day following, and at an autopsy it was found by Dr. Prudden that there was a rupture of the aorta and a very large subperitoneal extravasation of blood, and a rupture

through the peritoneum. He had as atheromatous an aorta as I had seen.

The possibility of mistaking pancreatic for biliary colic and the reverse happened in one instance which came under my observation at different times. In the first instance there had been very severe pains continued off and on for some time, and calculi had been obtained from the fecal evacuations. These, however, upon chemical examination, were of the nature of pancreatic calculi. So that in that attack we could only say that pains which seemed to be due to biliary calculi were dependent upon pancreatic. Upon the next occasion, about a year later, this lady was under the case of a different physician who made all preparations for a careful study of the fat digestion in the intestines which were carefully conducted. However, at this time, the lady passed biliary calculi, and not, as on the previous occasion, pancreatic. Neither I who had observed her on both occasions nor she herself could differentiate between the pain during these seizures. At the last seizure jaundice developed.

Angina Pectoris.—Pain in the chest particularly requires study of the coincidences. We all meet those lighter cases whose symptoms impose upon the patient and at times even upon the attending physician. When the attack is severe and characteristic, but little doubt can be entertained. Yet it is the coincidence of relief experienced by belching of gas which makes the invalid assume that his trouble is simply an indigestion and desire treatment to that end, while the physician looks for the coincidence of increased blood pressure or some demonstrable cardiac lesion to prove the heart-nature of the malady. But the absence of any marked cardiac trouble on examination should not impose upon us, for I presume we have all encountered cases which have succumbed to an attack and in whom no very marked cardiac change had been noted on examination. It has seemed to me that the development of an ashy gray hue of the lips, etc., has been a coincidence which was in a measure not only diagnostic in conjunction with the characteristic pain, but was also possessed of a serious prognostic import. How doubtful the nature of a case may be, the following will illustrate. This consisted in a postmortem examination of a man of 50 years. The history at first was that he had died suddenly in his room late in the evening. The peculiar feature was that only a housekeeper and he were in the house at the time. He had at first been said to have been previously well, though a more thorough inquiry resulted in developing the fact that three weeks prior to the fatal evening in walking across a field he was obliged to stop, lean against a fence for a time owing to severe pain in his chest. The preliminary examination did not disclose sufficient evidence of diseased change to account for death. The heart had been removed, but in the light (candle) no very evident changes were noted. It was put aside with the remark that later the coronary arteries would be examined. As the other viscera showed nothing of note it was feared that possibly the death might have been dependent upon toxic influences. Questions were asked in regard to the last meal, when he had partaken of it, and of what it consisted. The opening of the coronary arteries disclosed the cause of death as one contained a thrombus completely obstructing, and the other was three-quarters obstructed. The pain three weeks prior to death was thus explained, and the fatal issue as well. There was nothing in the appearance of the valves of the heart to indicate that in this case there would have been a murmur to assist the ante-mortem diagnosis. Moreover, the housekeeper was freed from such suspicion as sudden death under the circumstances might have implied.

In a previous portion I have alluded to a lady in whose case a very competent physician had, notwithstanding the presence of an aortic murmur, considered the condition as hysterical. Cases come to my mind where the ashy gray color has enabled me to consider the condition as angina in connection with the pain. On the other hand, I recall in particular two men who were relieved of the severe distress which they considered cardiac by the passage of a stomach tube and the removal of the stomach contents. One said that we must have removed a lizard or other reptile which had been gnawing at his vitals. In his case there were coincident circumstances which pointed to a nervous origin of his symptoms. The possibility of nausea which might produce a pallor should be carefully considered for occasionally its existence has prevented me from laying too great stress on this phenomenon as a determining factor in deciding on the etiology of precordial pain.

Continued pain in the back, if of considerable duration, will rarely be rightly designated by the term "lumbago" which is no uncommon term applied to it. Rightly to understand the nature of such distress requires close observation and study of coincidences. Much help has been afforded by the *x*-ray of late years, but it will only be by careful thought that the physician will be enabled to decide which of the three causes that are the usual is the particular one. These three are: Aneurysm of the aorta, Pott's disease of the spine, or tumor. My own experience could bring out many illustrations of the difficulties. For instance, I recall the case of a man transferred from a medical ward of a hospital, where he had been treated for lumbago, to a surgical ward, upon the discovery of an angular curvature of the spine, who died suddenly from rupture of an aneurysmal sac the day after he had served as the subject for a clinical lecture upon Pott's disease. So, again, allusion could be made to a case which required medico-legal notoriety because it related to the plaintiff in a law suit against the city, defended by expert witnesses who each testified differently from the other, while Prof. Lewis Sayre and the writer defended the etiology as being that of Pott's disease, which an autopsy later confirmed.

In no other instance do we so often witness the obtuseness of our surgical friends than when pain in the back follows the operation of tumor removal. There is a hesitation to consider the right cause. Yet physicians are liable to err at times on the tumor side too quickly. Where there has been no preceding tumor observed or removed, pain in the back may be inferred to be due to tumor development in the spine, but certainly, notwithstanding the employment of the *x*-ray, may only be reached by secondary developments as the appearances of growths in other bones discernable by the *x*-ray while the possible primary source cannot be disclosed. In the chest we have the added help of the recurrent nerve, whose paralysis may throw much light upon the investigation of cause. Yet even under these circumstances the *x*-ray picture may show an abnormal shadow which, not pulsating with the fluoroscope, may leave a contention between two

examiners, one taking the ground of aneurysm with clot, and the other of new growth which, as specific trouble had existed, should be called a gumma.

In a portion of this communication mention has been made of the supposition that neuralgia was present when in reality tumor development in bone existed; also of abdominal or intrathoracic aneurysm as the cause for severe pain in the back. At times an aneurysm of the intrathoracic aorta may give rise to severe cervicobrachial neuralgia, imposing itself thus on those in charge.

Perhaps mention might also be made of the vagaries of the pains which occur with herpes zoster. At times, if the pains are severe before the eruption, the physician may be unnecessarily alarmed at possible developments. Or, again, we may encounter a well-marked outbreak when we have the patient ready for examination, having from the history, given supposed that the malady was of internal origin.

The feet are so open to observation and palpation, as well as to other methods of examination, that it would seem as if pain in them would be rightly named. But no doubt to you, as has happened to me, cases have demonstrated the error of this opinion. Some years since a young man consulted me regarding his heart, about which he was apprehensive. A careful study revealed no proof of organic disease. Then he made the following statement: He had been treated at a prominent bath resort in Germany for heart disease following rheumatism, the proof of the existence of which was found in the pain in his feet. He did not improve, and consulted Prof. von Noorden, who had a radiograph of his feet made, a reproduction of which he brought to me. This showed that there was calcification in the plantar ligament. Thus was made manifest the non-rheumatic character of the pains in the feet, and with this the rheumatic character of the affection. The heart disease went by the board, as Prof. von Noorden told him, and I had done later, that he had no evidence of rheumatic endocarditis.

Particularly in elderly people, but a wise rule in others also, we should take the pulsations of the arteries of the feet. We are enabled to find thus those persons whose pains are dependent upon poor circulation. It has been a matter of surprise to me to discover the frequency with which this study has been omitted. The result has been that people have been treated for gout, or more often for gouty tendency when in reality defective circulation was proven by absence of the pulse in the dorsalis pedis and the posterior tibial arteries. These pains are the presage at times of gangrene. The very interesting study made of limbs amputated at Mt. Sinai Hospital by Dr. Leo Buerger gives details of the anatomical conditions found. The comment on the clinical condition by Dr. Sachs is to be considered with the pathological. The etiology of certain types, at least, of erythromelalgia and of Raynaud's disease is thus placed upon a pathological basis, though the inquiry may be justly promulgated, Why was the thrombosis started and what was the condition upon which it was dependent?

If my purpose to bring before you certain cases and suggestions as regards the etiology of pain has been successful, then a number of illustrations possibly more to the point will follow from those whose work in special fields may have led them to think that neglect was the lot on my part of their favorite study. Thus I have left out of account that fruitful source of pain, the female pelvis; as, also, some may think that headache did not receive its due of consideration. There are present those who can do justice to this portion of the field, though I will add one observation made to me once by a school girl—that hers was not a "school headache" on that particular occasion. I did not wish to annoy you with detailed histories, but rather to use the pith of the statements.

HAY FEVER AND OTHER RHINOLOGICAL CAUSES OF ASTHMA.*

By WILLIAM WESLEY CARTER, A.M., M.D.,
NEW YORK,
ASSISTANT SURGEON MANHATTAN EYE, EAR AND THROAT HOSPITAL.

When I responded to the request of the president to bring this subject before you to-night, I must say that it was with much trepidation and a feeling that there are among you many far better qualified for the undertaking. However, I have been encouraged by the hope that this effort may bring forth in the discussion suggestions that will throw additional light upon the subject and be of material help to us in the treatment of this extremely annoying affection.

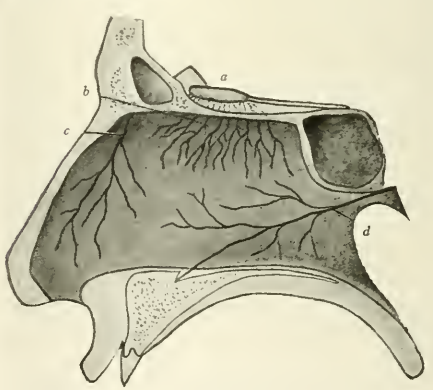

Fig. 1. *a*. Olfactory bulb; *b*. olfactory nerves; *c*. branches of nasal nerves; *d*. branches of nasopalatine nerve.

The season is almost upon us when the importunities of the hay fever sufferer will fill the air. The recently developed cases will come to us for diagnosis, advice, and treatment; while old sufferers, wise in the lore of their affliction, will drop in for post-graduate instruction or skeptically to inquire if there are any new experiments to be tried, and if we have yet caught the slightest glimmer of the light that will lead us out of the darkness. Among these there are some patients who may ask these questions with propriety, but there are others who would be greatly benefited or cured but for carelessness in following directions or a disinclination to consult the physician, preferably during the quiescent period, and submit to a proper course of treatment systemic and local.

Hay fever is an affection of comparatively recent date; there is no positive evidence that it had been recognized prior to 1819, when Bostock read

*Read at a meeting of the Society of Alumni of Bellevue Hospital April 7, 1909.

before the Royal Medico-Chirurgical Society of London a paper entitled "A Periodic Affection of the Eyes and Chest," in which he described his own affliction and attributed it to the sunshine and heat of summer.

In 1839 Elliotson associated the disease with the presence of pollen in the air. Blackley, whose painstaking experiments extended over several years, confirmed his views and added many new data to our knowledge of the affection.

Recently Dunbar proved beyond the shadow of a doubt that the disease is due to pollen of certain grasses and plants. Out of 130 plants examined by him he found that the pollen of twenty-five grasses and only seven other plants had a definite effect upon a susceptible subject.

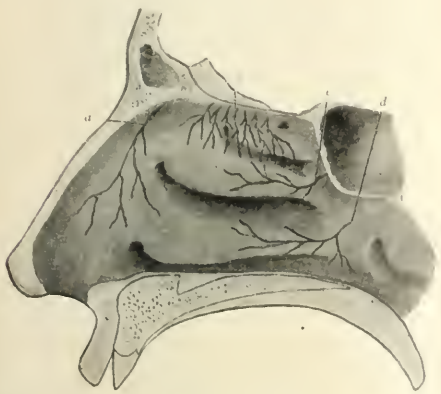

FIG. 2. *a*. Branches of nasal nerve; *b*. olfactory nerves; *c*. superior nasal nerve; *d*. inferior nasal nerve.

Beard of New York called attention to the marked neurotic tendency of hay fever subjects and disclosed much valuable information on the etiology. In his recent work Grayson classifies it as a neurosis, and this view is now generally conceded to be correct.

Hay fever is an affection having no pathology of its own, therefore it must be studied and discussed entirely from a clinical point of view. Its etiology is so inseparably linked with its treatment that a consideration of this is necessary to make clear the application of the various measures for its relief.

The remarkable increase of this malady during the past half century at once arrests our attention and we seek an explanation. This increase has been more marked in the United States than in any other country in the world; there are within our boundaries in the neighborhood of 100,000 hay fever subjects, and this number is being rapidly augmented. The explanation of this is self-evident when we consider the prominence of the neurotic element in the affection and how this is favored by the constantly increasing demands of modern civilization upon the nerve centers.

Hay fever like other reflex neuroses is preeminently an affection of civilized man, and is most common in our large cities where it is increasing *pari passu* with the increased demands for nerve energy. On the other hand, the farmer who comes in contact with more pollen than any one else is practically never affected. In this case the immunity may have been acquired by constant contact with the exciting cause of the disease; but what is more likely it comes as a compensation for his simple habits of life. He is early to bed and early to rise, he enjoys three plain meals a day and takes plenty of healthy exercise, while his mind is free from the strain endured by those who throng the marts of civilization. Among my own patients, all belong to the brain-working class. I do not remember ever having seen a case of hay fever among those who earn a livelihood by manual labor.

Hay fever is not a hospital disease. In the Manhattan Eye, Ear and Throat Hospital, among 384,901 out-of-door patients treated during the past eighteen years, there were only 205 cases, and these include intumescent rhinitis, sympathetic rhinitis, hpyeresthetic rhinitis, and vasomotor rhinitis. It is safe to say that a large proportion of these were not cases of true hay fever.

Heredity plays a most important part in this affection, and is recognized by various writers in from 40 to 50 per cent. of their cases. In my own practice in fully 75 per cent. of cases more than one member of the family is affected. In one New York family where the father and two uncles are affected, five out of seven children have hay fever and two of these have also asthma.

According to the statistics compiled by Blackley, Wyman, Lloyd, and others, the disease is more apt to occur for the first time between the ages of fifteen and forty-five years, the extreme limits according to these statistics being five and seventy years. I have recently heard of a patient three and one-half years old, the case occurring in the practice of one of our New York physicians; the child was the offspring of neurotic parents and had a typical attack of hay fever.

In regard to the predisposing causes of this affection, I have found in my studies that there is confusion in the minds of some writers. This I believe is due to the fact that these men have failed to observe that sufferers from hyperaesthetic rhinitis may be divided into two classes: those in whom there is a morbid susceptibility to the toxin of pollen, and those in whom there is some pathological condition in the nose or its accessory sinuses; here thermal and various chemical and mechanical irritants may act as exciting causes.

For the sake of making clear this important distinction the term hay fever should be applied to the former only, and *intumescent rhinitis* or *pseudo-hay fever* to the latter.

It is beyond the scope of this paper to enter into a discussion of the evidence bearing upon pollen as an essential etiological factor in this disease; suffice it to say that the experiments and clinical observations of a large number of reliable men have adduced what seems to be an incontrovertible fact, namely, that true hay fever and hay asthma are reflex neuroses always dependent upon the pollen of certain grasses and plants acting as the exciting cause upon the mucous and cutaneous end organs of the fifth nerve, chiefly in the nose, throat, conjunctiva, and on the face.

Pollen is a yellow powder thrown off from grasses and plants only during the flowering season. The pollen grains are round or oval, covered with spicules, and vary in size from .01 to .001 of an inch in diameter. Each grain consists of an envelope enclosing a granular substance which constitutes the toxic principle.

When the pollen grain comes in contact with the

mucous surface the envelope under the influence of the natural secretion bursts, the toxic material comes in contact with the nerve endings in the mucous membrane, and in the susceptible subject immediately exerts its characteristic effect, that of a vascular dilator, while in the normal individual its influence is merely mechanical like that of common dust.

This toxic substance is very powerful. Blackley found that he had symptoms of hay fever when as many as ten pollen grains fell in twenty-four hours on a cover-glass one centimeter square.

The first mild symptoms of the disease may be produced by inhaling in twenty-four hours 1/120,000 of a grain of the toxic substance, while 1/3,427 of a grain in twenty-four hours will keep up hay fever in its severest form.

Kammann of the Hygienic Institute of Hamburg states that 1/400,000 of a milligram, when placed on the conjunctiva of a susceptible subject, will cause itching and burning for several hours.

Why, in the hay fever subject, the vasomotor center is susceptible to the toxic effect of pollen acting on the end-organs of the trigeminus, whereas it is inert in the normal individual, is a problem still open for solution. It may be compared to the idiosyncrasy which some people exhibit for certain drugs, as iodine and quinine, and the violent reflex disturbances which some individuals experience after eating certain articles of food, such as shell-fish, strawberries, etc. I know of three hay fever subjects whose symptoms are made worse and who have urticaria after eating strawberries. There has been noted by many writers a close relationship between urticaria and hay fever.

The primary cause of this peculiar susceptibility in the hay fever subject may depend upon a faulty metabolism in the tissues causing a change from the normal in the body fluids, the latter affecting the physiological condition of the nerve centers.

In true hay fever, as we have observed, there is no distinctive pathological lesion. When the disease has lasted for some time the turbinate tissues are hypertrophied, but this is the result of repeated attacks of turgescence.

In some cases areas of hyperesthesia can be mapped out in the nose, but in the majority of cases I have found a uniform condition of hyperesthesia, certainly no definite, constant hyperesthetic area is known.

In this affection three conditions are necessary: (1) An irritable nerve center; (2) hypersensitive nerve endings in the mucous membrane; (3) an exciting cause. The absence of any one of these will prevent an attack.

Before this audience it is unnecessary to detail the symptoms of this well known malady. Suffice it to say that the itching and burning in the nose and eyes, the constant sneezing and running from the nose, the headache, the photophobia and lacrymation, and in some cases the asthma endured by the wretched sufferer for six weeks or longer every summer, should excite our deepest sympathy and call forth our best efforts for its relief.

The average hay fever sufferer is an extremely difficult patient to treat. He is nearly always a skeptic, having been told by his friends that his only chance of relief is to change his residence. Then again he seldom places himself under treatment until the attack has begun, when the conditions for successful treatment are not so favorable; he realizes also that the affection never results fatally and is careless in following directions and usually discontinues treatment as soon as the acute symptoms are relieved.

In considering all forms of treatment we must constantly bear in mind that we are dealing with a reflex neurosis, a condition resulting from perverted nerve impulses. As in all troubles of this kind our chances for effecting improvement, other things being equal, are in direct proportion to the time the affection has lasted, for once the nerve impulses to and from the center are established in perverted channels, in my opinion, our only recourse is to palliative measures. Therefore the slightest tendency to hay fever, and especially to asthma, should at once be given our serious consideration.

The benefit to be derived from a change of residence is usually thoroughly understood by the patient, who knows more about it than we do, for individuality in selecting a favorable locality is a peculiarity of the affection. The resorts in the White Mountains, Maine, and Nova Scotia are favorites in this country, but some of these are being spoiled by the cultivation of gardens.

A sea voyage offers the surest immunity, but the patient must not return until after the hay fever season.

In regard to the use of drugs, with a view to curing the affection, I must say that my own experiences have been most unsatisfactory, and I am inclined to think that those observers who have reported favorably on this or that drug have been misled by the normal variations in the severity of the affection due to the varying amount of pollen in the air, which in turn is dependent upon the season, atmospheric conditions, etc.

I have used quinine, belladonna, arsenic, and protiodide of mercury. From quinine I obtained no good results, and the discomfort was in some cases increased. Belladonna and Fowler's solution, given for two months before the attack, were not followed by the good results credited to this treatment by some writers. Protiodide of mercury administered for the same length of time before the expected attack seemed to modify it, but in this I may have been mistaken, for the number of cases treated was not large enough to yield positive conclusions.

On the supposition that the affection is based primarily upon a faulty metabolism, in addition to the drugs used, I paid particular attention to diet and elimination in the treatment of these cases.

Palliative Measures.—If the patient is unable to go to a hay fever immune district, there are some measures, both general and local, that will as a rule enable him to pass the critical period fairly comfortably.

He should avoid excitement and hurry. Exercise increases the number of respirations, consequently the amount of pollen inhaled. Then, too, the perspiration is a solvent for the pollen and in the susceptible subject causes the face to itch and burn.

Bright sunlight and dust aggravate the symptoms. When once the disease has become established and the catarrhal stage has been reached, ordinary dust from the street or from the railroad train will keep it up, though this dust may also contain pollen.

The skin, bowels, and kidneys should be kept active and the diet must be frugal. Well known reflex excitants, such as shell-fish and strawber-

ries, should be avoided and meat should be taken only sparingly.

Among the local applications, unfortunately, those that give the most relief at first are followed by a disagreeable reaction, and on being continued rapidly lose not only their beneficial effect, but actually favor the vasomotor paralysis, making it practically continuous and depriving the sufferer of those delightful periods of relief that should normally come to him during the course of the affection. This is especially true of adrenalin, atropine, and cocaine.

I have recently operated upon a patient for intumescent rhinitis whose symptoms were those of true hay fever. She had used cocaine and adrenalin excessively for six years to allay the disagreeable symptoms. Both drugs had lost completely their physiological effects and the blood vessels of the mucous membrane were relaxed and toneless.

Adrenalin, 1/10,000 in normal saline solution, is very grateful to the patient and does not lose its beneficial effect if used sparingly during the attack. According to Cohen suprarenalin in 1/20 grain tablets dissolved on the tongue, one every ten or fifteen minutes, is very satisfactory. Adrenalin taken internally is not effective.

I have found menthol, twenty grains to the ounce of albolene, almost as effective as adrenalin and preferable to it for general use. I have obtained good results also by cleansing the nose with warm Dobell's solution and then applying carbolic acid six grains to the ounce of albolene.

Dunbar's pollantin, a serotoxin prepared from the pollen of various grasses, can in no sense be considered curative; it merely acts locally by neutralizing the pollen toxin, and hence to control the affection would have to be applied to the susceptible mucous surfaces continuously during the critical period. My experiences with the preparation have been altogether unsatisfactory.

Hay asthma occurs according to various authors in from 25 to 50 per cent. of the cases of hay fever. Thost, in a report on 400 cases of hay fever, states that 266 suffered with asthma.

This complication comes on as a rule after the hay fever has been established for several years and develops during the later stages of the attack. It may be regarded as an extension of the nasal irritation into the lower respiratory tract. The reflex impulse in this case is conveyed to the trachea and bronchi through the thoracic branches of the vagus. After asthma has become established it may come on at any season and seems to lose its connection with the hay fever, which it sometimes appears to replace.

As to the local condition in the trachea and bronchi there are three views: (1) That the obstruction is due to the contraction of the muscular coats of the bronchi; (2) that it is due to vasomotor paralysis and turgescence of the blood vessels in the submucosa; (3) the theory of Curschmann that it is caused by a special form of inflammation in the smaller bronchioles.

I am inclined to the view that it is due to turgescence of the mucous membrane of the trachea and bronchi and is analogous to the condition in the nose of the hay fever subject, or in the larynx in urticaria of the larynx. The fact that when the attack is passing off there is an increase in the secretion, seems to support this view, for this phenomenon always accompanies deturgescence of a mucous membrane.

In the treatment of hay asthma I have obtained good results only from morphine and atropine by hypodermic injection, cocaine spray in the nose, and chloroform inhalations. A cup of strong coffee I have on several occasions found very effective in relieving the attack.

During the intervals potassium iodide and such nerve tonics as arsenic, phosphorus, iron, and valerianate of zinc should be given and the diet carefully regulated, for the attacks seem to be closely allied with digestive disturbances. If the attacks are brought on by the latter, the iodides should not be used.

I wish here to call attention to the frequency with which ordinary spasmodic asthma is associated with pathological conditions in the nose and nasopharynx; especially is this so in the case of polypi, ethmoiditis, hypertrophy of the inferior turbinates, and adenoids. These cases furnish some of the most brilliant results obtained in rhinological surgery, for many of these may be cured by a simple operation.

It has long been my belief that mouth-breathing, due to nasal obstruction, is an important factor in the development of asthma. The impact directly upon the walls of the trachea and bronchi, of air unfiltered and imperfectly warmed and moistened would certainly seem to be a strong predisposing factor. Especially would this be true in the case of hay-asthma, where a large amount of pollen would be carried direct to the bronchi. The fact that asthma seldom develops until several years after the hay fever has become established and the turbinates have become hypertrophied and obstructive to respiration, in my opinion lends considerable strength to this view.

We do not concede, however, that all cases of spasmodic asthma are due to nasal disturbances, for the large proportion of cases reported by some writers are not substantiated by the majority of operators.

Temporary relief from asthma frequently follows operations of any kind on the nose, but this is not sufficiently constant to warrant resort to indiscriminate operating and cauterizing as a routine measure in the absence of distinct pathological conditions.

Before considering further the local treatment of hay fever it is well to recall the nerve supply of the nose.

Special sensation is supplied by the olfactory nerve through its twenty or more branches distributed to the upper part of the nose. The chief nerve supply and that which concerns us in hay fever comes from the trigeminus. Indeed it is upon the extensive mucous and cutaneous distribution of this great nerve that hay fever depends.

The anterior portion of the nose is supplied by the nasal nerve, a branch of the ophthalmic, while the posterior portion, including the greater portion of the turbinates, is supplied by the superior and inferior nasal nerves and the nasopalatine, all branches of Meckle's ganglion. Where the nerves are very superficial and the end-organs are especially aggregated are located the sensitive spots, here the mucous membrane seems especially sensitive to the pollen toxin in hay fever subjects, however, we do not yet know of any constant irritable area. The extensive distribution of the trigeminus to the conjunctiva and to the skin of the face explains the eye symptoms and the irritation of the skin after excessive exercise during the critical period.

In hay fever the nerve impulse passes to the medulla and is transferred to the root of the vagus through association fibers. This connection is especially important in hay asthma, where, as we have seen, the vasomotor impulse is conveyed to the trachea and bronchi through the thoracic branches of the vagus which is in close relationship with the sympathetic system.

Intranasal procedures for the relief of hay fever have for their object either to destroy the sensitive end-organs or to disconnect these from the nerve center.

The intranasal conditions in hay fever present what I believe to be one of the few opportunities for the legitimate use of the electrocautery. To destroy the sensitive spots, the mucous membrane should first be sprayed with a solution of half and half cocaine 10 per cent. and adrenalin 1/1,000. The surface of the cautery at white heat should be gently touched to the anterior ends of the inferior turbinates and to the septal mucous membrane opposite the anterior end of the middle turbinate. The burn in these cases should be made very superficial. I never cauterize the middle turbinate nor do I care to attack the posterior end of the inferior turbinate for it is a step in the dark. I touch these areas with a solution of carbolic acid in albolene, six grains to the ounce.

Hypertrophied inferior turbinates may be reduced by applying the sharp edge of the cautery knife at cherry red heat and burning deeply to the bone. The cicatricial contraction following this certainly does diminish to a marked degree the disagreeable symptoms of the disease. An interval of ten days should be allowed to elapse before treating the opposite side. After the use of the cautery I always introduce narrow strips of sterile vaseline gauze; this modifies the inflammatory reaction and prevents adhesions. This treatment I have found fairly satisfactory as a palliative measure for both hay fever and hay asthma.

All operative procedures in the nose should be done if possible during the quiescent periods of the disease, though in hay fever this is not obligatory, for at least during the early stages we are dealing not with an inflammatory condition, but with a condition of complete vasomotor paralysis, due to the specific action of pollen. The nasal discharge at first may be considered a flux, and it is only later that it becomes catarrhal in character. The effect of the cautery at this stage, therefore, is stimulating as well as destructive. It is upon this principle that Grayson advises pin-point applications of chromic acid to the sensitive areas; he claims good results from this method of treatment.

There has recently been introduced by Stein of Chicago a method of procedure which theoretically at least promises to be a valuable addition to the palliative treatment of hay fever. I refer to the injection of alcohol into or near the principal nerves at the point where they enter the nose. Five drops of alcohol are introduced at these points by means of a hypodermic syringe having a long curved needle. This method depends for its efficiency upon the disorganization of the nerve elements at the point of injection, thus interrupting the passage of various stimuli from the point of irritation in the nose to the nerve center. While we know from experience that nerves in other parts of the body sooner or later resume their function after being treated with alcohol, yet we may reasonably assume that in the nose this will not occur until after the critical period of hay fever has passed. Stein has not made a final report on his cases, but the immediate results he assures us have been satisfactory.

There are some extremely radical operations that have been recommended which should be mentioned only to be condemned; such are: *Complete removal of the turbinates.* It is unnecessary to say that were this procedure entirely effective in securing comfort to the patient during the critical period of six weeks, we would be unwarranted in subjecting him during the balance of the year to the dangers and discomforts resulting from complete loss of turbinate tissue.

Resection of the Nasal Nerve.—Younge has recently advised resection of a portion of the nasal nerve in certain intractable cases. His method is to make an incision from the inner extremity of the eyebrow downward along the root of the nose. He then dissects up the tissues from the inner wall of the orbit until he reaches the nasal nerve where it enters the anterior ethmoid canal. He resects ¼ inch of the nerve at this point. A reference to the chart will show what a small portion of the nasal mucous membrane (only that portion anterior to the ends of the turbinates) is supplied by this nerve. To me it seems altogether improbable that anesthesia of this small area would give sufficient relief to warrant so formidable an operation.

It is necessary to consider in connection with hay fever the so-called pseudo-type of the disease, because of the very common mistake made in confounding the two. The symptoms are in many respects the same, but this affection may occur at any season of the year and is more common in the winter. The etiology is entirely different. True, hay fever is due to the specific action of pollen toxin upon the end-organs of the trigeminus in a person having an idiosyncrasy for this poison; pseudo-hay fever has on the other hand for its predisposing cause some abnormal condition in the nose or its accessory sinuses, and its exciting causes may be thermal, chemical, or mechanical and are too numerous and varied to mention. Among the conditions most frequently acting as predisposing causes are deflections and spurs of the septum when they are extensive enough to come in contact with the turbinates, polypi, hypertrophied turbinates, suppurative disease in the accessory sinuses, and adhesions caused by operations and the use of the galvanocautery.

In a great many of these cases where the proper measures are employed the prognosis is good, and yet I have learned never to risk offering a positive prognosis based upon intranasal appearances. For it has been my experience on several occasions for hyperesthetic rhinitis to persist in spite of the removal of what apparently was the exciting cause. Some of these failures occurring in the summer time I regarded as cases of true hay fever due to pollen, while in others I am satisfied that constitutional conditions were responsible for the continuance of the affection.

In a series of over three hundred cases in which I did the submucous operation for deflected septum, about 20 per cent. had hyperesthetic rhinitis attended by excessive sneezing and running at the nose; these symptoms disappeared after the operation. One patient, referred to me by an oculist, had suffered almost continuously for three months with violent attacks of sneezing and profuse lacrymation. She was being treated for detachment of the retina, which we thought had been caused by

the violence of her sneezing attacks. The latter were caused by a badly deflected septum coming in contact with the middle turbinate. The septum was straightened by a submucous operation and the attacks ceased.

In conclusion I wish to say that:

In every case of hyperesthetic rhinitis, hay asthma, and spasmodic asthma, all pathological conditions in the nose and its accessory sinuses should be corrected. In true hay fever this may prove to be only a palliative measure, while in the pseudo form in many cases it will be curative.

In cases of hay fever known palliative measures, if judiciously applied, will in the majority of cases carry the patient through the critical period in a state of comparative comfort.

I believe that true hay fever and hay asthma can be cured only by correcting the basic nutritive fault that is responsible for the susceptibility to the pollen toxin, and this can be accomplished only by a complete reform in the personal hygiene of the patient before the affection has reached the stage of chronicity.

69 West Fiftieth Street.

REPORT ON A CASE OF MYELOGENOUS LEUKEMIA.*

By CONDICT W. CUTLER, M.S., M.D.,

NEW YORK.

The patient, Mr. H., presented himself at my office in September, 1905, with the following family history: His father died of pneumonia at the age of 60 years, having been in previous good health; his mother died at the age of 75 years of pernicious anemia, having had anemic conditions for about ten years previous to her death, this being the only case in the family history of any so-called blood disease. His brothers and sisters are living and in good health. The patient himself was an active business man, a broker in Wall Street, 47 years of age, married with one child, a boy 17 years old, in good health.

He had never had syphilis or venereal disease of any kind, nor had he ever had any serious illness. He was a moderate drinker and smoker, never dissipated, and had always taken good care of his health. He was fond of out-door exercise and frequently played golf and rode horseback; his appetite and digestion had always been good; he slept well and his weight had kept about the same for a number of years; in fact, except for being nervous and easily worried, he considered himself perfectly well, until six months before consulting me.

His reason now for consulting a physician was the fact that for the past few months he had felt continually tired, lacked energy and ambition, and could no longer ride and play golf without physical effort and expenditure of so much nerve force as to produce great fatigue.

On inspection and examination, I found Mr. H. nearly 6 feet in height; weight about 151 lbs.; he was pale and had a sallow complexion. Nothing was found wrong with the heart, lungs, liver, or kidneys; the spleen was slightly enlarged, but there was no enlargement of the lymphatic glands or any tenderness or swelling of the bones or cartilages. In fact, all the physical and rational signs pointed toward an anemic condition, perhaps the result of malarial infection, although there was no previous history of chills and fever.

A blood examination taken at this time gave the following results: Red cells, 3,500,000; white cells, 85,000; hemaglobin, 78 per cent.; color index, 1 1/10 per cent.; Myelocytes, 31 per cent.; mast cells, 2 per cent.; neucleated red cells, few; no plasmodia of malaria found. From the result of this analysis, the diagnosis of myelogenous leukemia was made.

One month's treatment by rest and internal administration of iron and arsenic did little to improve the patient's condition. The iron given in various forms upset the digestion and produced headache, and was stopped at the end of this period.

At this time a second examination of the blood was made which showed a decided increase in the number of red cells, and hemaglobin. Also an increase in the number of white cells, but a decrease in the number of myelocytes. The spleen had in the meanwhile increased in size and the patient's weight had diminished. A consultation was now held with Drs. Delafield and Janeway, and it was decided to continue the rest for another month and give strychnine and cacodylate of sodium hypodermically. The blood test at the end of this month showed a decided improvement. The number of red cells had increased from 3,700,000 to 4,800,000; the white cells had decreased from 91,000 to 61,500, and the myelocytes from 26 per cent. to 11 per cent. The general condition of the patient, however, remained about the same, while the spleen had increased considerably in size. The hypodermics of strychnine and cacodylate of sodium were ordered continued for two months and a course of *x*-ray treatment given twice a week for the same period.

At the end of March, 1906, six weeks after beginning the *x*-ray treatment, 12 or 13 treatments in all having been given, owing to a superficial dermatitis over the splenic area, the treatment was discontinued. As a result of this *x*-ray treatment, the spleen had rapidly decreased in size so that it was nearly normal, when it was stopped. Also as a result of this treatment, the number of white blood cells had greatly diminished, being reduced from 61,500 to 26,000; otherwise the condition of the blood remained about the same. During this period the general health of the patient had not improved. He felt weaker, and although allowed to go out every day and take some exercise, he felt too prostrated to do so; he lacked ambition, and would not even go out for a drive, unless urged to do so. His appetite remained fairly good and he slept well.

In April, Mr. H. felt that he was losing ground and decided to stop all treatment and move to the country, which he did in May. At this time the spleen had greatly increased in size and a blood examination showed the white cells had increased from 26,000 to 44,000, which proved that the beneficial results of the *x*-ray treatment had only been temporary. In fact, as soon as the *x*-ray treatment was discontinued, the spleen began to increase rapidly in size, so that when the patient left the city in May, two months after the *x*-rays had been stopped, it was probably twice as large as it was before they had been used at all.

After stopping all treatment and going to the country, living out-of-doors all the time, his general health greatly improved, so that he was able to play golf in moderation without great exhaustion. Improvement continued until an attack of appendicitis with operation kept him in bed for several weeks. My examination in September, several weeks after

*Read before the Society of the Alumni of Bellevue Hospital, February 3, 1909.

the operation, showed that the spleen had increased in size since the previous examination in May. It was now extending about one inch beyond the median line and downward into the pelvis, making the abdomen decidedly prominent. He complained of some pain in the region of the spleen, but no tenderness on pressure. An examination of the blood at this time showed an increase in white cells from 44,000 to 81,000 and the myelocytes from 17 per cent. to 36 per cent. with hemoglobin at 54 per cent. The patient was now urged to resume the x-ray treatment and hypodermics of cacodylate of sodium, but refused. With my consent and approval, he decided to change his medical attendant and secure thereby a radical change of treatment. Homeopathy and Christian Science were seriously considered and afterwards Osteopathy, but at my suggestion and at my earnest request, in October he placed himself under the care of Dr. A. A. Smith, who treated him until he (the patient) went to Europe in February, 1907.

The patient's treatment through this period was principally, I understand, one of diet and rest, living mostly or exclusively on Kumys and beef. I have invited Dr. Smith to be present this evening to hear the reading of this report, and have extended to him an invitation to tell you more particularly of the patient's progress and treatment while under his management and care.

In February, Mr. H. went to Europe to consult the physicians on the Continent. While abroad, he consulted with physicians in Italy, France, and England, with great uniformity of opinion as to diagnosis and prognosis, but with varied opinion as to treatment. While in London, he had a bad attack of hemorrhoids and was operated upon successfully. In June his general condition became so alarming that after a consultation of physicians he was advised to return home as soon as possible, as he could not live more than one month.

He returned to this country in July and with Dr. Smith's approval again placed himself in my care. I found him very weak and emaciated. The spleen was painful and tender, extending well down into the pelvis, and two inches beyond the medium line. The abdomen was greatly distended by the enlargement of the spleen and by gas. His appetite and digestion were poor, the bowels were constipated, and there was great restlessness at night. It was with great effort that he could walk across the floor even with assistance.

The urine showed a small amount of albumin, but no casts. The blood examination gave 4,000,000 red cells, 318,000 white; 56 per cent. hemaglobin, and 68 per cent. myelocytes on differential count.

I advised his going into the country, living out of doors, taking inhalations of oxygen, colon irrigations of normal saline solution, and hypodermic injections of cacodylate of sodium, and although the treatment was not very conscientiously carried out, there was a decided improvement in his general health, and he was able to go to Southern California in November to spend the winter, although still unable to walk, except for a few steps and then only with assistance.

While in California, Mr. H. was practically confined to his bed, and suffered greatly from neuritis in both legs, more especially in his left, requiring the use of morphine for the relief of pain. He remained West until the latter part of February of last year, and then very much against the advice of his physicians, who told him he would probably die on the train, he returned to New York. His condition on his arrival here was very bad. He was exceedingly weak, not being able to sit up in bed, and was greatly emaciated. His spleen was very large, extending down into the cavity of the pelvis and the lower edge was below the crest of the pubis, the right border reaching the anterior superior spine of the ilium. The greatly distended abdomen now gave the appearance of a woman at about the seventh month of pregnancy. The liver was also found increased in size although difficult to map out owing to the great size of the spleen. The heart's action was rapid and weak; feet and ankles were edematous, and the urine contained considerable albumin and a few hyaline casts.

With assistance he could stand and walk a few steps, but the slightest exertion tired him and made him short of breath, although his lungs on examination were found normal. Lifting his arms or feeding himself was a great effort and to talk for a few minutes was distressing. He had no appetite, and was greatly distressed by gas distention. He complained of a great deal of pain running down both thighs; this had been diagnosed as neuritis, but was probably due to the pressure of the enlarged spleen on the nerve trunks. He also complained of some pain in the region of the spleen and of obstinate constipation, due undoubtedly to partial intestinal obstruction from splenic pressure. He had almost constant pain deep in the pelvis, especially on the left side, also probably a result of pressure. The temperature was normal. The patient was very much discouraged, prayed for death, and frequently talked of suicide. He refused at this time to have another blood examination or to take any form of treatment, except to relieve symptoms such as constipation and pain. Early in April, he had an acute attack of hemorrhoids causing much pain. He called in a surgeon, who without the consent or presence of either Dr. Smith or myself operated at once. The operation consisted simply of opening the pile, turning out the blood clot, packing the cavity with iodoform gauze, and applying pressure with a T-bandage. As might have been expected, there was a copious and continuous hemorrhage from the wound, which packing and pressure failed to keep in check. This continued for 48 hours, when I was sent for by the rectal surgeon, saying that the hemorrhage could not be checked and that the patient was dying. When I reached Mr. H. I found him nearly exsanguinated and the surgeon in charge seemingly unable to cope with the conditions present. At the request of the family he resigned from the case, and I called in consultation Dr. B. F. Curtis and assisted him in stopping the hemorrhage by means of a plastic operation which succeeded in closing the venous cavity. Neither of us expected the patient to survive the operation or to live longer than a few days, but from that moment he began rapidly to improve. Within a few days the spleen had been reduced in size to nearly one-half. It reminded me very much of a big wet sponge which had been squeezed and shrunken in size. His appetite and strength gradually returned, so that he was able to sit up in bed. The albumin disappeared from the urine, and no casts were found. The edema entirely disappeared from the lower extremities, the neuritis also disappeared, and the constipation was much less obstinate. In fact, all the symptoms due directly or indirectly to the splenic pressure were either relieved or entirely disappeared. Besides the improvement in the patient's general health, he was

much less despondent, slept better, and said that he felt better than he had at any time during the past two years. He believed that he was going to get well, and was very hopeful. A blood examination was now made with the following result: Red cells, 2,000,000; white cells, 528,000; hemaglobin, 62 per cent.; myelocytes, 30 per cent., and a large number of normoblasts. This improvement continued for some two or three weeks, and then the spleen began gradually to increase in size, and with this increase in size there was a return of the previous conditions and symptoms, except there was no return of the pain. The patient himself recognized the change in his condition and begged to be bled again, believing that was the only cure or at least the only help.

During my absence from the city this past summer, the patient was left in the care of Dr. Carlyle. No special plan of treatment was at this time being carried out, the symptoms alone being treated as they demanded attention. *X*-ray treatment was again urged but refused, the patient having no faith in their curative properties, and great fear of being burned. On my return in September, I found him in about the same condition as when I left. He had been practically bed-ridden during the whole summer. The latter part of this month he ran an irregular temperature with frequent sweats and slight chills. Accompanying this, was a bronchitis and a bronchial pneumonia. He looked and acted decidedly septic. There was an entire loss of appetite and much insomnia, with general aching and great despondency and melancholia, begging for an opportunity to take his own life.

It was at this time I began to give the patient without his knowledge, small tonic doses of morphine and large doses of glycerophosphate of lime, which resulted in a decided improvement in his condition, although he continued to run until the time of his death an even temperature of about 101°. The lungs cleared up, the appetite returned, sleep became natural and refreshing, and a general buoyancy of spirits replaced the depression. I have never known tonic doses of morphine to act to better advantage than in this case. From the time he began to take it regularly, he more than held his own in every way for over two months. His appetite continued good, his sleep was refreshing, his digestion improved, the bowels were less constipated; his strength returned so that he was able to sit up for an hour or more every day and walk around the room with assistance. The circulation improved and the edema of the legs and feet entirely disappeared. The size of the spleen, however, remained about the same, but it never quite reached the size it was before the hemorrhage. The size of the dose of morphine did not have to be increased, it ranging from 1-8 to 1-4 of a grain in divided doses during the day. An examination of the blood taken in December, two months after the beginning of the morphine, showed a decided improvement. The red cells had increased from 2,000,000 to 2,420,000; the number of white cells decreased from 528,000 to 397,000 per cubic millimeter, and the myelocytes from 30 per cent. to 22 per cent.; a large number of normoblasts were still present.

On Jan. 10 Mr. H. had an attack of grippe which greatly prostrated him. However, the active symptoms wielded to treatment kindly, and he was feeling very much better and able to sit up in bed and smoke on the 15th inst., although he complained of a catarrhal condition in the nose and throat with considerable deafness in the left ear, for which he called in Dr. Chas. H. May, who had previously treated him for ear trouble. Dr. May stated he could find no cause for the deafness in the ear itself. On the 16th he felt about as usual, although the deafness continued. He ate his noon dinner with relish and slept for three hours in the afternoon. When he awakened, he complained of great pain in the top and back of his head and in his neck. It was only partially relieved by hypodermics of morphine. He also complained of his sight being greatly impaired, seeing double all objects directly in front of him, with inability to see objects at all on the left side. With either eye covered, he could see objects singly, but only if placed directly in front of him. The pupils were even, but greatly contracted, and responded poorly to light. There was no sign of paralysis in either the facial muscles or those of the extremities. His speech was not affected in any way, and his mind was clear. He vomited freely, first partially digested food and about an hour afterwards a dark-colored fluid blood and bile. His temperature remained about normal, and his pulse which had previously been good, now became very weak, intermittent, and slow, beating about 50 per minute. His extremities were cold and clammy and he became semicomatose and vomited some fresh blood clots. From this time he gradually passed into a state of coma with slow, deep breathing, and died less than 12 hours from the time he awakened with the headache.

An autopsy was performed by Dr. J. E. Welch in the presence of Dr. Sondern and myself, and he has kindly consented to give you the result.

I have briefly recited the history of this case, not only on account of the general interest taken by the medical profession in all cases of splenic leukemia, but also to show: (1) the effects of *x*-ray treatment on this particular case in reducing the size of the spleen to nearly normal and considerably improving the condition of his blood without improving to any extent the general health of the patient. (2) The great temporary beneficial effects of the severe hemorrhages, not only on the size of the spleen, but also on the general condition of the patient, to such an extent that he frequently since then threatened to open the veins in his own arm, so as to produce bleeding, and thus get the good results before experienced. (3) The very slight, if any, beneficial results obtained by any course of therapy or diet on the general course of the disease, with the exception perhaps of the tonic doses of morphine which certainly seemed to hold the disease in check for some time and greatly to improve the mental and physical condition of the patient. Perhaps it was the combining it with the large doses of glycerophosphate of lime which increased its beneficial effects, for leaving off one and giving the other resulted in the patient's loss of apetite and general depression in health and spirits. However, this was decidedly more marked on the withdrawal of the morphine than it was when the glycerophosphate of lime was stopped. (4) The absence all through the disease of any spontaneous hemorrhage or diapedesis until a few hours before his death, when hemorrhage occurred, as shown by the postmortem, into the left occipital lobe of the cerebrum, into both lobes of the cerebellum, and into the stomach.

Lastly, through the whole course of the disease, up to the time of his death, it is interesting to note that the bones were not at any time either swollen or tender.

In connection with this case, it is of interest to contrast in a few words this history with that of another patient of splenic leukemia, who at the same time was under my care and for the first year was placed under the same plan of treatment, including rest, diet, iron, hypodermic injections of cacodylate of sodium, and *x*-rays. Both patients were nearly of the same age, had been in previous good health, were active business men, with about the same sized spleen, and with blood counts, made by Dr. Sondern, not very different. In both cases, treatment seemed to have very little effect on the general health of the patient, but the effects of the *x*-ray given by the same operator (Dr. Cole) had very different results both on the spleen and on the blood. The blood examination in Mr. H's case at the beginning of the *x*-ray treatment showed red corpuscles, 4,800,000; leucocytes, 61,500; myelocytes, 11 per cent., and at the end the same number of red corpuscles; leucocytes, 27,000; myelocytes, 14 per cent., with the spleen reduced in size to almost normal.

In the other case, at the beginning of the *x*-ray treatment, the blood examination gave red corpuscles, 4,250,000; leucocytes, 100,000; myelocytes, 30 per cent., and at the end, red corpuscles, 3,700,000; leucocytes, 210,000, and myelocytes, 20 per cent., with the spleen increased considerably in size. Both patients experienced slight *x*-ray dermatitis and neither felt his health had been at all improved by the treatment.

At the time one patient left me to place himself in the care of Dr. Smith, the other also left to take up Christian Science, but with different results. Dr. Smith kindly returned his patient to me in as good condition as could be expected considering the nature of the disease; but after the healers, both absent and present, had for a few months practised their Eddycisms on their patient, it was only left for the undertakers to fulfill their duties, for he in some unaccountable way had absorbed an error and passed on.

POSTMORTEM RECORD.

Body: Is medium build and well developed, but very much emaciated. The abdomen is very prominent. There is a very marked general pallor of the body surface and no postmortem hypostasis. Rigor mortis is very marked. The superficial veins of the arms and chest are engorged. There is an old cicatrix about two and a half inches long over the site of the appendix. The superficial lymph nodes are just palpable in the inguinal, epitrochlear and axillary regions, but are not in the cervical. The pupils are equal and slightly dilated.

Head: Scalp tissues are slightly congested. Skull cap is thin but normal in density. Dura mater shows slight congestion posteriorly but is not thickened or adherent. Pia mater shows general congestion but no thickening or adhesions. Microscopically are found slight edema and an exudate of leucocytes composed for the most part of mononuclear cells. The vessels are all very much engorged with leucocytes with very few red cells visible. The prevailing type of cell in the vessles is a large mononuclear, many of which contain eosinophile granules in their protoplasm. There are also a few polynuclear leucocytes and an occasional small lymphocyte present. The walls of the larger vessels show slight cloudy swelling.

Brain is symmetrical and well developed. The convolutions over both cerebral hemispheres are somewhat flattened but much more over the right than the left hemisphere. The right occipital lobe is extensively lacerated and occupied by a large mass of blood. The laceration and hemorrhage extend to the posterior part of the right parietal lobe and into the posterior part of the right lateral ventricle filling the lateral horns. There is some oozing of blood to the under surface of the right hemisphere through the hippocampal fissure. The blood of the hemorrhage is neither fluid nor coagulated but has a viscid mushy consistence and is brownish red in color. Section through the brain substance shows the vessels engorged with blood, which has the appearance of that found in the hemorrhage. Miscropically the contents of the vessels is found composed almost exclusively of leucocytes mainly of the mononuclear variety. Very few red cells can be seen in the vessels. The walls of the larger vessels show cloudy swelling and there is a slight perivascular edema about some but this is absent for the most part. The neuroglia appears very well preserved. The pyramidal cells of the cortex show cloudy protoplasm and in some there is an excess of brown pigment. The nuclei are well preserved. Sections through the corpus striatum, optic thalamus and pons all show marked vascular engorgement with leucocytes as above described. The large nerve cells in these regions show an excess of pigment and a diffuse clouding of their protoplasm. Through the right corpus striatum are scattered many large corpora amylacia. The epithlium lining the ventricle is intact.

Cerebellum is well developed. On the upper surface of the right hemisphere near the posterior part of the upper worm is a small deposit of blood which lies over a laceration. Section shows this laceration connected with a hemorrhage in the posterior part of the upper worm and adjacent part of the right cerebellar hemisphere. Microscopically the hemorrhage appears composed almost entirely of leucocytes mostly of the mononuclear variety. The vessels through the cerebellum are congested with leucocytes. The cells of Purkenji show clouding of their protoplasm.

Medulla oblongata shows engorgement of the vessels with leucocytes but no other change.

Pituitary body is normal in size. The vessels show engorgement with leucocytes. The epithelial elements are very granular.

Middle ear cavities are both normal. In the base of the cranium are about three drams of edema fluid.

One section of the body panniculus is very scant and brownish red in color. Muscle is scant and very pale. The striations of the muscle cells are fairly well preserved. Some show slight atrophy. There is a general very marked engorgement of the vessels and capillaries with leucocytes. In some places the capillary engorgement has caused pressure atrophy of the intervening muscle fibers.

Retrosternal cellular tissue is slightly adherent to the sternum. Retrosternal glands are not enlarged.

Pleural cavities both contain a few drams of straw-colored fluid and there are a few old adhesions at both apices which extend a short distance down the posterior borders of both lungs. There are no lymph nodes in the pleura.

Pericardium. The wall is thin and covered by a thin, imperfect layer of superficial fat. The cavity contains about two drams of clear serum.

Heart. The epicardium is slightly congested. All cavities are very much dilated and filled with blood which has the appearance of very soft splenic pulp, grayish pink in color. There is no fluid blood or clot present.

Endocardium is normal.

Valves are all normal except the large cusp of the mitral which shows a small amount of fatty degeneration at its base.

Myocardium is thin and pale. Microscopically the vessels show marked engorgement with leucocytes which fill the spaces between the muscle cells and cause a diminution in their size from pressure. There appears to be no extravasation of cells from the vessels. The striations of the muscle are indistinct. There is an excess of pigment about the nuclei and the nuclei show considerable irregularity.

Respiratory system. Trachea is slightly congested and the mucous membrane is coated with mucus.

Bronchi are slightly congested and contain a small amount of mucus.

Lungs are both slightly emphysematous and pigmented. The vessels and capillaries are engorged with leucocytes. There is extensive desquamation from the walls of the alveoli and air spaces. The air spaces contain edema fluid, large phagocytes filled with brown pigment and about some of the bronchi they are completely filled with leucocytes. The pleura at the apex of the right shows a thick cicatrix of dense fibrous tissue.

Abdomen. Peritoneal cavity contains about 500 c.c. of straw-colored fluid. There are firm old adhesions binding the caput coli to the anterior and lateral abdominal walls. There are no adhesions between the viscera.

Spleen is very much enlarged. The upper pole reaches the fourth intercostal space, the lower to the brim of the pelvis. The body occupies the left half of the abdomen and extends a little to the right of the median line. It weighs 4.6 kilograms. The resistance to pressure gives the sensation of a fluctuating tumor. Microscopically the capsule shows slight thickening but there is no thickening of the fibruos trabeculæ. The normal retiform arrangement of fibrous tissue through the pulp appears absent and in its place there is a rather uniform infiltration with leucocytes mostly of the large mononuclear variety many of which contain eosinophile granules in the protoplasm. The malphaghian bodies can not be distinguished from the general infiltration. There is a large amount of brown pigment scattered through the organ. Near the hilum is a small accessory spleen about three centimeters in diameter which has a structure like the larger spleen.

Pancreas is normal in size. Microscopically the glandular and connective tissues appear normal. The vessels show very marked congestion with leucocytes.

Liver is very much enlarged, especially the right lobe which occupies almost the entire right half of the abdominal cavity, extending downward as far as the brim of the pelvis and to the left almost to the median line where it lies in contact with the spleen. The capsule is smooth and glistening and free from adhesions. Section shows in the gross a uniformly pale appearance of the tissue. There are no nodular accumulations of lymphoid tissue visible. Microscopically the capsule is found not thickened. The lobular arrangement found in the normal liver is entirely absent. The portal areas with their vessels and the central veins cannot be identified. The cords of liver cells are disarranged and appear in irregular groups. This apparent disorganization is produced by extreme engorgement of the vessels and capillaries with leucocytes. The capillaries appear especially distended by leucocytes and the liver cells between them have suffered complete atrophy in many places which gives the appearance of large communicating blood spaces filled with leucocytes. The liver cells are granular and in places swollen. They show considerable vacuolation and in many there is a large amount of brownish-yellow pigment.

Gall-bladder is filled with dark-colored bile. The bile ducts are patent.

Adrenals are both normal in size, but very soft and friable. Microscopically they both show congestion of their entire vascular system with leucocytes. In the cortices the congestion pressure has caused considerable atrophy of the parenchyma.

Kidneys are both slightly increased in size and rather pale. The capsules strip easily. Microscopic section shows small areas of fibrous tissue through the cortex and slight thickening of some of the glomerular capsules. The vessels and capillaries throughout are much distended by leucocytes. The tubular epithelium in the cortex shows marked cloudy swelling. The glomeruli are congested with leucocytes and the spaces about some of them contain leucocytes. There are no nodular accumulations of lymphoid tissue in either organ.

Gastrointestinal tract. Esophagus show slight dilation of the veins in its lower part.

Stomach is about normal in size. The cavity contains three or four hundred cubic centimeters of coffee-colored liquid in which is mixed some mucus. Microscopically all coats show congestion with leucocytes. The glandular coat shows extensive desquamation of epithelium and the capillaries are much distended by leucocytes. There are many leucocytes found adheing to the inner surface of the mucosa.

Intestine shows the vessels of all coats congested with leucocytes. The epithelium of the mucosa shows marked degeneratiove change and desquamation.

Vermiform appendix has been removed by operation.

Colon shows congestion and extensive desquamation of epithelium.

Circulatory system. The right coronary artery shows a very small patch of fatty degeneration near its origin.

Aorta shows a few very small points of fatty degeneration in the ascending part of the arch. There were no changes found in any other part of the arterial or venous system. Through all organs and tissues of the body cross sections of the vessels give the appearance of small abscesses filled mostly with mononuclear cells some of which are eosinophiles. Only a few polynuclear leucocytes are found and an occasional small lymphocyte.

Lymphatic system. Bronchial nodes are slightly

enlarged and anthracotic. Their vessels are congested with leucocytes. The follicles do not show hyperplasia. A few giant cells are found in different places without any relation to any inflammatory process that is apparent.

Mesenteric nodes are very slightly enlarged. Their vessels are engorged with leucocytes and there are a few giant cells present.

Retroperitoneal nodes are considerably enlarged. The vessels show congestion with leucocytes. The follicles show hyperplasia and there are giant cells present. In all of the lymph nodes, in many of the blood-vessels and in the bone marrow mitoses in the leucocytes are found.

Osseous system. The bones are normal and regular in contour and size. The marrow as expressed from the sternum and ribs has a grayish-pink color and is semifluid. Microscopically sections of the sternum and ribs show the spaces enlarged and filled with large mononuclear cells among which are many eosinophiles. There are also a few polynuclear leucocytes, small lymphocytes, red cells, erethroblasts and giant cells present.

THE FUTURE OF THE ALCOHOL PROBLEM.*

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

SUPERINTENDENT WALNUT LODGE HOSPITAL.

PUBLIC opinion in 1860 was distracted and confused. There were signs of revolution and change, and everyone was reading these signs and predicting what they meant. The political horizon was a great tumultuous cloud bank of conflicting theories and opinions. To-day, in 1909, the political and social sky is overcast with doubts, theories, dogmatic predictions, and opinions of every sort concerning the meaning and direction of the great temperance movements, and a feeling of alarm is pervading all society concerning alcohol and the diseases associated with it.

The efforts of reformers have assumed startling prominence with revolutionary consequences, and the dealers in spirts are alarmed and read in these movements the doom of their business. Everywhere in the pulpit, press, and platforms are explantations, predictions and appeals concerning the alcoholic problem, but through all this there are unmistakable signs of the direction of the movement and the coming changes that are sure to follow.

In 1860 nothing was very clear and settled. There was a conflict ahead and no one could predict where it would end. To-day there are unmistakable indications, through the gloom and confusion of theories, that a new era is coming, and that the solution of the great problem with all its influences is not far away.

Every advance in scientific study of disease and degeneration shows that alcohol is one of the most prominent agents, and is very vitally concerned in the destruction of diseases of the human race. Statistical studies of the causes of accidents, injuries, diseases, and the great forces of hereditary which enter into our civilization bring out the same fact in greater prominence, that alcohol in some form is the most influential factor of these losses.

Medical, sociological, and economical studies all confirm these facts, and make prominent the conviction that alcohol in some way is a source of danger imperfectly recognized and yet powerful beyond measure in degeneration and increased mortality. These facts have created a sense of alarm in the public mind which is materializing in various ways and is apparent in very remarkable forms.

Thus in the legislatures now in session in thirty-four States of the Union there have been introduced 221 laws restricting and regulating the use of alcohol as a beverage. Sixteen of these laws urge the prohibition of both its manufacture and sale. Ninety-two laws concern the sale of spirits and the control of saloons, and others refer to punishment for various enactments concerning the alcohol question.

A second indication equally significant is the fact that over two-thirds of the territory of the United States have specifically voted to prevent the sale of alcohol as a beverage. Such sections are called "drys."

There are over one million men and women organized in societies and working through churches for the specific purpose of driving out the saloons and stopping the use of alcohol as a beverage. In addition to this there are over half a million voters who have expressed the same conviction in some form or other, although not in organized parties. From these facts alone it is evident that the movement toward total abstinence is not the enthusiasm of reformers or a matter of sentiment among hysterical men and women, or even a psychological craze, but a deep settled conviction of danger and a consciousness of the possibility of removing and destroying it.

It is becoming more and more evident every day that the theories which have come down from the past, and opinions and conclusions of our forefathers, however respectable and apparently based on wide experience, cannot be accepted unless they are able to pass the bar of scientific inquiry and be judged in the light of modern science.

Thus the great evils, diseases, and questions of mortality, losses, and obstacles which limit progression and development are to be measured by the same standard and tested by a critical examination of the facts and their meaning. The theory that alcohol as a beverage has tonic or stimulant properties, coming down through the ages to us with historical prestige, must be sustained by the laboratory research and clinical experience of this new century if it be accepted.

Within a half century research and experience have pointed out the errors of the past theories, and now it is proven beyond question that alcohol is simply a narcotic and depressant in its effects. That it has no stimulant or tonic properties, and that as a beverage it has no claim or reason for existence.

Consumption, insanity, epidemic diseases, and many of the great scourges of civilization are found to be the direct result of causes which are traceable and which move with a uniformity and certainty that cannot be mistaken. In the same way inebriety, marked by an insane-like impulse or craze for spirits with a full knowledge of the results, is traceable to causes and to physical conditions which can be understood, controlled, and prevented with the same certainty as any other disease. All questions of will-power, moderate drinking, culture, control have about the same meaning as dispensation of Providence so often used in explanation of the mysteries of life. A deep-seated conviction is growing in the public mind that the alcoholic problem is a physical

*Read at the Washington Meeting of the Society for the Study of Alcohol and Narcotics, March, 1909.

and not a moral one, and that the same laws which govern the slow development of human life work with equal exactness in tearing down and destroying the unfit and removing those who disobey the exact requirements of physical laws.

The realm of devolution and degeneration is as exact and clear as that of evolution and progression. Theories which urge that alcohol in some way favors evolution and progression, are really evidences of degeneration and revolution. Its warmest patrons and defenders are the most pronounced promoters of its destructive influence upon the race and civilization. Everywhere the accumulated facts concerning the saloon and its influence show that its doom is near and the cosmic consciousness of its evil and the tremendous opposition to it show that its disappearance is only a question of time.

The pecuniary powers bound up with the manufacture and sale of alcohol, while making tremendous efforts to conserve their interests and prevent the destruction of their business, are strangely oblivious to the great commercial revolution that is rapidly coming into prominence. The stupidity of carrying on an organized combat with these mighty forces of evolution and the money and energy spent beating the air and shouting to check the march of the race from the lower to the higher is startling.

Scientific research has pointed out beyond question that alcohol possesses tremendous powers for heat and light which can be made force producers equal to electricity. Every year new discoveries show that alcohol can be made from a great variety of substances, many of which are now regarded as waste products, and these can be produced very cheaply. Already this has become practical in Germany and other Continental countries where alcohol is manufactured from potatoes, beets, roots, and other substances, and used for power and light at a cost of 20 cents per gallon. As a fuel it is far superior to coal, wood, and oil, and in the manufacture of electricity it is cheaper than steam. The recent laws denaturing alcohol, rendering it poisonous as a beverage, have opened up a new realm and new uses in the arts and in other directions. As a competitor with gas and electricity it has already been demonstrated to have equal and greater capacity for power and work. Inventors have turned to this problem and have confirmed the wildest expectations and possibilities of its practical use in the world's work. They have shown beyond question that the only obstacles are the discovery of apparatus and means to utilize it. To-day a small army of experimenters are working to perfect boilers which will make available the tremendous power of alcohol lamps, and means for utilizing this new force and turn its vast powers of light and heat into commercial channels.

Already great progress has been made in this direction and the question is simply one of the means and methods of harnessing this great new power and turning it into practical uses. It can be made cheaply in great abundance on the farm, in the factory, and in every section of the country. It will do equally as great work as electricity, and with that force it will bring about a new and higher civilization, enabling us to use both these forces in ways undreamed of at present.

The great liquor interests with their millions of money will turn to the manufacture of this product with greater profit and will find an increasing demand for it, and this is a positive indication of its future. Alcohol as a fuel will take the place of coal; as a power it will supplant gasoline, and the great alcoholic problem will merge into the utiliation of this force for the benefit of mankind and the world. A number of different manufactories in the West have begun to change their products from refined liquors to crude alcohols for the trade. New inventions and new possible methods are growing in many directions.

Thus a tremendous revolution of industrial energies has already begun and promises to constitute a new era in the economies of the race. The extinction of the saloon will follow early, the change in the breweries and distilleries is bound to come, and the frantic efforts of the trade to obstruct progress will disappear. Far-seeing men recognize this already and refuse to take an active part in the great pro-alcoholic struggle. They realize the oncoming of a new force in the economics of the world. Alcohol, which has so long been regarded as a beverage and the destructive effects of which are now beginning to be realized, will be changed to a great motor power to propel machinery, heat buildings, and in many other ways contribute to the advancement of the human race.

With the extinction of the saloon and alcohol as a beverage many of the very active causes of criminality, pauperism, inebriety, and insanity will disappear. A new realm of cause and effect will come in and a new step forward will be made to lengthen life and avoid its present perils.

Another evident indication is that inebriates and alcoholic victims will be gathered into hospitals and treated as sick and diseased. In nine different States in the Union there are bills introduced for the organization of such hospitals and the appropriation of money to build them.

It is also evident that this great alcoholic problem, urged with such enthusiasm by laymen and philanthropists, is particularly a public health and hygienic question, and one in which physicians should be the leaders and teachers. They must tell the public what to do and how to avoid the causes of this and other diseases. These are some of the great facts rising higher and higher in the confused public opinion of to-day which indicate clearly the new dawn and the new solution along scientific lines of the great alcoholic problem.

THE ADMINISTRATION OF ANESTHETICS.*

By H. J. BOLDT, M.D.,

NEW YORK.

I BELIEVE it may be conceded that the competency of the anesthetizer is, in many cases, more important to the surgeon than the competency of the latter's first assistant.

As to the safest anesthetic, it has been demonstrated that of ether, chloroform, and the A. E. C mixture, ether is the least dangerous to life. This was shown in an investigation of about 380,000 anesthesias made by me for my paper in 1897. It would be misleading, however, to make this statement without modification. Some patients do not take ether well; fall, in fact, into a condition that renders a continuance of its administration very hazardous, but will tolerate chloroform with no untoward symptoms whatever during the anesthesia.

*Read at a meeting of the American Gynecological Society, April 20-22, 1909.

The belief that ether is more injurious to the kidneys than is chloroform, does not coincide with my experience. In nearly every instance of either ether or chloroform narcosis, there has been subsequent transitory albuminuria of mild degree, with renal elements in the urine. The casts were usually noted for periods of from three to fourteen days after the anesthetization.

To assert that any one anesthetic is devoid of risk, or that any one method of administering an anesthetic is entirely free from danger, is to assert a fallacy. I have been particularly unfortunate in having had several deaths from ether and from chloroform, and one even from the supposedly safe nitrous oxide gas. So, after long experience, I have become more often fearful of the effect of the anesthetic than of the result of the operation. I may say, however, that I believe nitrous oxide gas mixed with oxygen, is the safest anesthetic of any at our command; and the time for which it may be administered is almost unlimited. On one occasion I had a patient under this form of anesthesia for nearly three hours, Dr. S. Ormond Goldan being the anesthetizer. It was a Meyer-Halsey operation for carcinoma of both breasts in a woman of 70. She lived six years before any sign of recurrence showed itself. Then it was remote from the original site of the neoplasm; it was in the uterus.

During the past few years it has become customary with a number of surgeons to have the anesthetizer administer before operation, in three divided doses, $\frac{1}{4}$ of a grain of morphine with 1/50 of a grain of scopolamine. This idea of preliminary narcosis, first advised in Germany, has found many followers. While I was very favorably impressed with it in the beginning, I now believe there is a risk connected with it—a risk otherwise absent. I have had three deaths on the table that might possibly have been avoided had not the preliminary narcosis method been used. It has been asserted that with the substitution of hyoscine for scopolamine, and the addition of cactine, there is no risk. I have had one death with such combination; and I have seen two patients so close to death that it was a grave question as to their recovery. In hospital work, where unfortunately we may have inexperienced members of the house staff to administer the anesthetic, I have discontinued preliminary narcosis.

To consider in detail the methods of administering an anesthetic is not my purpose. This has been done so frequently that I believe it is understood, at least in theory, by every practising physician. I shall limit myself, therefore, to a few remarks as to how it should not be done.

Do not give an anesthetic on a full stomach. If an emergency present itself, always have thorough stomach lavage before the anesthetist starts with his work.

A patient who is very nervous and apprehensive as to the outcome of the anesthesia, should have a single preliminary dose of a narcotic. Twenty or thirty minutes before the anesthetic is given, an injection of morphine with atropine should be made. It is always preferable to start the anesthesia with nitrous oxide gas, rather than to begin directly with ether. If ether is used from the beginning, it should not be forced upon the patient; it should be administered gradually with reassuring words spoken by the anesthetizer. Minimize the quantity of ether to be inhaled so far as is consistent with retaining the patient under complete anesthesia.

This requires the abandonment of the almost universal custom of making the final preparation of the patient during the process of anesthesia. I regard such practice as entirely uncalled for. It is certainly bad practice. A patient can be fully prepared for operation before the beginning of the anesthesia. Surgeons alone are to blame if they omit this prior preparation.

Furthermore, the quantity of ether administered can be greatly reduced if the anesthetizer uses the "drop method," as he should do when giving chloroform. After a patient is fully under the anesthetic, complete relaxation may be continued by constantly adding fresh ether, drop by drop, on a chloroform mask. Or, if preferred, a closed inhaler may be used; then, a few drops of ether, occasionally added, will suffice to keep the patient quite under its influence.

Do not continually touch the cornea to ascertain whether the corneal reflex has subsided. It need not be touched at all. There is risk of causing conjunctivitis by such procedure.

Do not use alcoholic stimulation when a patient is suffering from the effects of excessive etherization.

Do not permit the anesthesia to begin until a careful physical examination has been made and the urine examined.

In nephritis, the choice of some other method than the inhalation of ether or chloroform should be considered, and, if at all possible, the method that has no injurious effect on the kidneys should have the preference. For instance, on two occasions I have found it possible to do major operations under the scopolamine-morphine narcosis. (If no ether or chloroform is used, this narcosis seems safe.) On several occasions I have used only nitrous oxide gas combined with oxygen; the abdominal parietes, however, were not so thoroughly relaxed for the satisfactory performance of the abdominal section, as would have been the case with ether or chloroform. A number of times I have used lumbar analgesia with perfect result in complicated abdominal operations.

Do not permit indiscriminate use of hypodermic injections of strychnine; a practice which is prevalent and against which I have repeatedly protested.

The anesthetist should never divert his attention for a moment from the patient; he should remember that he is scarcely less important than the surgeon. His finger must not be removed from the pulse of the patient, especially if chloroform is being used. He must be a thoroughly trained person, ready for any emergency, or the surgeon will be needlessly harassed.

I now come to a question which has given me much thought for many years, and on which I read a paper before the Society of Medical Jurisprudence of New York City in April, 1897 (*Medical Review of Reviews*, April, 1897) "Should Legislation Regulate the Administration of Anesthetics?" Dr. Baldy, in his address at the last meeting of this society, called attention to this subject, and suggested that nurses be trained for the giving of anesthetics. This undoubtedly would be the best solution of the problem in some localities, but not in all. For instance, in this State the surgeon would be liable in case of a fatal termination should the anesthetic be administered by any but a physician legally entitled to practise medicine. Yet who doubts that an intelligent non-medical person, who has been properly trained, would be as capable as

most of the internes of hospitals to whom this duty is assigned?

In very many localities it is legally permissible to have a non-medical person take charge of the administration of the anesthetic, and that, too, where the requirements for the practice of medicine are as strict as in the State of New York. If the statute cannot be so amended that a non-medical person may administer the anesthetic without the surgeon being held responsible, then a law should be passed which will compel all institutions where anesthetics are used to employ a thoroughly qualified anesthetizer, whose duty it shall be to be present and to give instruction at every anesthetization (for not less than 100 consecutive anesthesias) to every interne who is assigned to such duty. This would mean extra expense to the respective hospitals; yet in justice alike to the patient and to the surgeon, there should be such a law.

39 East Sixty-first Street.

Feeding of the Sick Infant.—Séverin Lachapelle believes that we do not consider the nourishment of the sick infant as of enough importance. We cannot successfully combat infections without a resisting power in the organism that can only be sustained by thorough nourishment. The well child also must have enough food to cause his growth, and this condition is present in the sick child as well. All children would be able to pass through their sieges of infectious disease if they were sufficiently fed and nourished. Complications appearing after the infection is spent require nourishment to resist them and the infectious agents must be destroyed so that they may never be able to renew their ravages in the organisms. Owing to the loss of appetite due to fever, the stomach rejects nourishment. We must then make use of the rectum by injecting eggs and broths, and by the use of suppositories of peptones in powder. We must add the glycerophosphates, and lecithin to reconstitute the precious nervous energies of the patient.—*Le Journal de Médecine et de Chirurgie.*

Contribution to the Study of Pararenal Tumors.—E. T. Pietrabissa distinguishes between pararenal and renal tumors and refers to an illustrative case observed by him. He concludes from his studies that, while these tumors are easily differentiated anatomically, clinically they cannot be diagnosed in life, since their symptomatology is in no way peculiar. The opening of the abdomen for operation alone will make the diagnosis certain. The indication for treatment is the ablation of the tumor by the abdominal route. Prognosis should be reserved even in case of benign tumors, on account of the high mortality from this growth. —*La Riforma Medica.*

Painful Abdominal Paroxysms in the Course of Infantile Purpura.—M. L. Ginnon describes a form of purpura characterized by its sudden onset, with intense abdominal pain, meteorism, retraction of the abdomen, vomiting and diarrhea, both streaked with blood. Fever is slight. The hemorrhages may be severe internally while there is only a moderate or no purpura externally. The autopsies show intestinal hemorrhages and ulcerations. The prognosis is relatively benign. This form of purpura is frequent in infants and young children, and an exploratory laparotomy may be necessary to make the diagnosis. It is probably of toxi infectious origin, the poison having a selective action on the nervous centers, especially the medulla.—*Revue Mensuelle des Maladies de l'Enfant.*

Treatment of Some Acute Pulmonary Affections of Infancy.—Delearde gives revulsion as the primary indication in the treatment of bronchopneumonia and capillary bronchitis in children. It should be applied energetically four times every twenty-four hours throughout the diseases until the fall of temperature and the disappearance of the principal signs. The methods recommended are sinapisms and hydrotherapeutics. The mustard leaf may be made use of, but a much more effective application is made by wringing out a napkin in a thin mustard paste and enveloping the chest in it. The child is then wrapped in flannels and left for fifteen minutes. After this he is unwrapped and bathed in warm water to remove the loose mustard, and dressed and put to bed, when he usually goes to sleep comfortably. This should be repeated two or three times in twenty-four hours. The rubefacient effect lasts several hours. The mustard bath also produces a good revulsive effect. This form of application is appropriate when the extension of the lesion gives us a bad prognosis, rather than degree of the infection. Two sinapisms and four hot baths at 38° may be given daily. When the involvement is small in area and the infection severe the prostration would be increased by hot, while cold baths will lessen it and stimulate the child, lessen pulse tension and increase diuresis. Cold packs have the same effect. Another application that the author finds useful is the fixed abscess, which is produced by the injection of turpentine subcutaneously over the seat of the lesion. An aseptic abscess is produced which heals up rapidly and has an excellent counterirritant effect. The child is treated with expectorants and heart stimulants as indicated, and is allowed to sit up in bed to relieve passive congestions of the lungs.—*Revue Française de Médecine et de Chirurgie.*

Diphtheritic Paralyses.—M. H. Chêne admits the toxin of diphtheria bacillus as the cause of the paralyses that occur in the course of diphtheria. The poison probably ascends from the peripheral nerves to the brain centers, especially the bulbs. Constant myocardial lesions are found at autopsies and few nerve lesions, which favors the idea that the paralyses are of cardiac origin, resulting from emboli. The prognosis depends on the extent of the paralysis and the time of its appearance. When the paralysis is confined to the soft palate the prognosis is generally good. If it is extensive and comes on slowly and late, the prognosis is good again. But an extensive paralysis coming on suddenly and early is unfavorable, especially when the symptoms show the heart to be involved. Treatment consists of antidiphtheritic serum administered even when it was given early in the diseases, in doses sufficient to counteract the toxins. Cardiac stimulants and faradism to the pneumogastric nerve may be of use in cases of urgent heart symptoms.—*Gazette des Hôpitaux.*

Toxicity of Mother's Milk.—Raymond François believes that he has seen cases in which the milk of its own mother has been an evident poison to an infant, while it would thrive on the milk of a wet nurse or on artificial feeding. He believes that there are conditions in which the human milk has a toxic effect on the infant. This poison is evidently in the milk, and is due in general to some form of intoxication in the mother, the poison of which is carried over into the milk. It has been shown that coloring and other matters, diphtheria antitoxin, etc., are carried over into the milk. Menstruation, dyspepsia, constipation, and similar conditions may produce this poison.—*Journal de Médecine de Paris.*

Syphilitic Myelitis.—Jh. Ferrux gives the etiology of myelitis as in general some infectious disease which determines an acute infection of the spinal cord. Traumatism and cold act as predisposing causes. Anemia favors its occurrence. The tubercle bacillus, gonococcus, and malarial organism all act as causes of such disease. The spirochetes of syphilis produce very active effects on the spinal cord; their virulence exalted by traumatism, cold, or intercurrent affections creates an especial toxemia and insufficiency of the nervous system and the spinal medulla especially. The symptoms are proteiform, and difficult of diagnosis. Granular tissue formed of round cells covers the outside of the cord. The alterations of the dura involve especially its external surface. A granular exudate separates it from the cord. An obliterating arteritis and phlebitis are frequent. The spinal nerve roots are affected by gummatous deposits. Any region of the cord from the medulla to the lower lumbar region may be affected. In hereditary syphilis the cerebral syndrome dominates. Premonitory symptoms consist of weariness, difficulty in walking, pains, hyperesthesia rigidity and paralyses. The prognosis should be reserved.—*Gazzetta Medici di Roma.*

Arterial Hypertension and Eclamptic Seizures.—J. J. Chérie finds as a result of his observations and experiments on animals that the high tension to be observed in puerperal eclampsia has no causal relation to the eclampsia. It is rather dependent on the condition of the kidneys. In normal pregnancy arterial tension is normal. Also in some cases of albuminuria there is a normal temperature. There seems to be no constant relation between this rise of tension and the amount of albumin found in the urine. The high tension is of prognostic value in these cases. When a seizure is imminent there will be found a rise of blood pressure, and, conversely, when we have no rise of tension we need not fear eclampsia. There is a definite relation between the tension and the capillary hemorrhages which occur in eclampsia in the internal organs. The walls of the capillaries are weakened by the poison and yield to the high blood pressure, and hemorrhage occurs. Venesection is of value to relieve this tension.—*Annales de Gynécologie et d'Obstetrique.*

SOME NONTUBERCULOUS THROAT COMPLICATIONS OF PHTHISIS.

Whatever field of medicine a man may eventually follow, he has at some time or other under his care cases of pulmonary tuberculosis, and though their progress may be steadily downward he feels it is his duty to make his patients as comfortable as possible. It is therefore also his duty to consider the various complications which may arise and to have clearly in mind the measures of relief which may properly be employed.

The great throat complication is tubercle in the larynx, but Harold Barwell reminds us in the *Lancet* of May 1, 1909, that this is by no means the only condition requiring our care. He repudiates the existence of a "pretuberculous" condition in the sense that there is any distinctive state of the larynx which is always or frequently followed by tuberculosis. Pallor of the larynx is but a local manifestation of the general pallor so common in these patients. In fact, it is probably true that there are in tuberculous patients quite as many reddened and hyperemic as pale larynges. Swollen arytenoids are often pale and the margins of ulcers markedly anemic, but tuberculous infiltration is decidedly red and congested, especially on the cords, ventricular bands, and epiglottis. But Barwell notes that simple chronic pharyngitis and laryngitis are extremely common and that not every pulmonary case with hoarseness and throat discomfort has actual local tubercle. The constant coughing of untrained patients and the constant irritation of sputa with pus organisms as well as the specific bacillus inflame the larynx. In the absence of other objective signs a uniform redness of both cords should not be regarded as tuberculous in nature, though there may be a strong suspicion if one side is markedly reddened over the other. The author notes that the subjects of active phthisis have much dryness and discomfort in the throat at night and this he attributes to the pyrexia and the consequent rapid respiration which makes nasal breathing insufficient. A drink of hot milk or some demulcent troche will often relieve this discomfort. Pain in the larynx in the absence of any apparent cause should always lead to a careful examination of the chest.

Another condition frequently found in tuberculosis cases is a laryngeal pachydermia, but the firm, white, almost cornified appearance in a typical case is very different from the soft, semitranslucent granulations of laryngeal tubercle. This pachydermatous thickening may be removed from the posterior commissure and no tuberculous manifestations whatever be found on microscopical examination. Functional aphonia also is very common among consumptives. Every intractable case of functional aphonia calls for chest examination. Occasionally, says Barwell, true paralysis of one of the vocal bands may occur. It is generally on the left side and due to the pressure on the recurrent nerve, being of the abductor type; but right-sided paralysis due to pleuritic thickening on that side near the apex is by no means unknown. Perhaps, says the author, this is the most frequent cause of right-sided paralysis, and therefore calls always for chest examination.

USE AND ABUSE OF ANESTHETICS IN GREAT BRITAIN.

Most persons competent to judge are of the opinion, according to medical and lay papers, that there is need for reform in Great Britain in the mode of administration of anesthetics. A committee of the English Home Office has held several sittings devoted to the subject and some remarkable facts and figures have been forthcoming. Further, the Home Office is considering the question of issuing an interim report dealing with these facts. A bill has been prepared to be presented to the British House of Commons, consisting of two substantive clauses. According to the first clause, it will be a penal offence for any person not medically qualified to administer a drug for the purpose of producing a state of unconsciousness during any medical or surgical operation or during childbirth. For the first offence a maximum penalty of $50 is imposed, and for the second a maximum penalty of $100. Two exemptions are allowed. Such an anesthetic may be administered under the immediate direction and supervision of a legally qualified medical practitioner, or when the person administering it has reasonable grounds for actually believing that delay caused by calling in a medical man would endanger life. The second clause provides that the law is not to apply to those already registered under the Dentists' Acts.

The opposition to a continuation of the existing state of affairs in brief, is as follows: General anesthetics are, for the most part, powerful poisons, they are being used upon a vast and constantly increasing scale throughout the country, and an increasing and considerable number of fatalities are taking place annually in connection with their administration. The main arguments in favor of a revision of the present system are that the numerous deaths which have occurred during recent years as the results of the administration of anesthetics could be prevented only by a careful study of the circumstances of such fatalities, and safety could be secured only by restricting the administration to men who had received a general medical education. In order to bring about this object, the curriculum of the medical student must include a thorough training in the administration of anesthetics. Other points in support of a change in the existing conduct

of affairs are that in England under present conditions only the rich and the hospital poor enjoy the services of medical men for anesthetics. The middle classes ought to have the same privileges. Furthermore, the passage of such a bill would deal a crushing blow to the quack. He would be able neither to give an anesthetic himself, nor to have it administered for him by a medical man. The status of the registered dentist would be improved, and the particularly dangerous procedure of the man who both operates and administers the anesthetic would be avoided. It goes without saying, that there is widespread opposition to the proposed bill, and naturally the dentists of nearly all grades are most prominent in this movement. Most medical men aver, and it would seem with justice, that a very large proportion of the fatalities which follow the administration of anesthetics is the outcome of the use of these drugs by dentists who are presumably more or less unskilful and lacking in medical knowledge as to the condition of the patient. The dentists themselves contend that the number of fatal cases from dental operations is extremely low, more especially when compared with the accidents in non-dental surgical cases, and that there appears to be no call for legislation in that direction. The situation, then, as regards the matter in Great Britain, is that the majority of physicians are in favor of rendering the administration of anesthetics less easy, that is, to place such administration in the hands of thoroughly trained and otherwise competent individuals. The dentists assert that anesthetics are now administered in a satisfactory manner, and that to alter the present modes of giving the drugs as suggested would be doing them as a body an injustice and material harm, and they hint that the agitation is aroused for the benefit of the doctors.

Regarding the question from an impartial standpoint, it certainly seems that the medical profession in England has a very strong case against the way in which anesthetics are generally administered. It might be said without much exaggeration that the methods now in vogue are unscientific in a high degree, and even slipshod. At least in matters of life and death extraordinary care should be used, and although the enactment of severe restrictive laws respecting the administration of anesthetics might press hard on a portion of the population, a revision of this nature would be for the public good. At any rate, one point is perfectly plain, so plain, indeed, as to be palpably obvious, that every medical student should receive as a necessary part of his medical education, a sufficiently thorough training in the administration of anesthetics. In this country also, as a whole, the administration of anesthetics is susceptible of great improvement. Here, as in England, we have a lengthy annual list of fatalities from the employment of anesthetics by untrained individuals, and, in fact, the arguments adduced in Great Britain in support of placing this service in the hands of avowedly competent persons apply with almost as much force to parts of America. It may be laid down as an axiom that every medical school should teach its students how to administer anesthetics properly. It is true that the medical course is already full, but the question of anesthetics is so important, and the neglect of it may be so deadly in its consequences that it can no longer be evaded.

THE ORIGIN OF THE RECENT EPIDEMIC OF FOOT-AND-MOUTH DISEASE.

That the recent epidemic of foot-and-mouth disease in New York, Pennsylvania, Maryland, and Michigan started from calves used in the preparation of vaccine which had been contaminated with the virus of foot-and-mouth disease, and that the contaminated strain of vaccine came originally from a foreign country, are the conclusions reached as the result of an investigation by the Bureau of Animal Industry in conjunction with the Public Health and Marine Hospital Service. The investigation was conducted by Dr. John R. Mohler of the former bureau, and by Dr. M. J. Rosenau of the latter. The disease first appeared among the cattle in Pennsylvania on November 10, 1908, and a few days later was reported from the other States named. A strict quarantine was immediately enforced, and as the result of active measures the last of the infected territory was freed from quarantine on April 24.

Early investigation resulted in tracing the disease to calves that had been used for vaccine by one firm, and it was suspected that the vaccine used had been contaminated. Further investigation showed that another company had imported certain vaccine virus which was contaminated with the virus of foot-and-mouth disease; that some of this vaccine was obtained by the first firm in May, 1908; that calves used by the latter in propagating vaccine were sent on October 16 to the stockyards and thence to a farm near Detroit; that four days later three carloads of cattle reached the stockyards and were put into the pens occupied previously by the vaccine calves, and that some of these cattle were shipped to New York and to Pennsylvania, where the disease soon after appeared. Three series of experiments showed that the vaccine virus obtained from both of these firms was capable of producing foot-and-mouth disease, while other strains of vaccine were negative. The fact that the infection was present in the vaccine virus of the first company for so long without being transmitted to outside cattle, the investigators explain, was due to this firm's practice of killing its calves after taking the virus, a practice not followed by the second company. As soon as the contamination of the vaccine virus became evident, the licenses of the two firms were suspended, all the suspected vaccine virus was withdrawn from the market and destroyed, and other measures were taken, in all of which the Government had the hearty cooperation of both firms.

The report dwells upon the fact that foot-and-mouth disease is primarily a disease of cattle, and only secondarily of man. Children are sometimes infected through milk, as are also persons coming in contact with diseased animals, though the affection in man is usually very slight. No instance of the transmission of the disease to man through vaccine virus is on record, and it is doubtful whether it could be produced by cutaneous inoculation.

Cardiac Massage in Apparent Death.

It is now some four or five years since the direct application to the heart of manual massage in persons apparently dead was first described. Since then this method of resuscitation has been tried in forty-five recorded cases, and something like a definite tabulation of results becomes possible. M. von Cackovic, in an article in the *Archiv für klinische Chirurgie*, Vol. LXXXVIII, No. 4, 1909, devotes nearly seventy pages to an analysis of details and results. His attention was first drawn to this subject by a case of sudden death in a boy aged nine upon whom he was operating for harelip. At autopsy an enlarged thymus was discovered, hence little could be expected of the direct massage so persistently carried out in this case. Of the forty-five cases in the literature seventeen patients were resuscitated, nine with complete recovery. The remaining eight died after a short time. It is worthy of note that forty cases demanding this extreme measure are said to have been due to the anesthetic administered, which, if true, is of itself sufficient admonition to those who are inclined to look upon the giving of anesthetics as a matter of small moment, inasmuch as it seems so uniformly safe. Causes other than anesthetics were embolism in the pulmonary artery, strangling from attempted suicide by hanging, and asphyxia in the new-born from some obstruction in the larynx or trachea. If the heart stops, and ordinary measures do not suffice to renew the beat within one minute, especially if the patient is lapsing into "white" syncope, the author says the direct method is indicated. Massage through precordial incision usually fails, the best incision being in the mid line above the umbilicus and just large enough to admit the hand. The heart is grasped and pushed toward the anterior thoracic wall, and the ventricles are squeezed rhythmically at about the normal rate of heart beat. Sometimes fully fifteen minutes elapse before any response is obtained. During all this time assistants should be busy with artificial respiration, saline and adrenalin infusions, tongue traction, intubation or tracheotomy, and elevation of pelvis and legs. Inasmuch as life has been saved in about 20 per cent. of all cases in which direct massage of the heart has been applied, it would be well for the surgeon to be perfectly familiar with the technique in order that his patient may have the very last opportunity for recovery from suspension of respiration or circulation. Of course, the latter condition offers most encouragement, since paralysis of the respiratory center may fairly be said to be always permanent. Heart massage must, it is claimed, be begun within five minutes from the cessation of the pulse. One must never lose sight of the fact that one cannot be sure, absolutely sure, that any person is dead because the vital functions can no longer be detected by our necessarily crude methods of examination. Surprises sometimes occur in which a patient seems to "come back to life," as the newspapers phrase it, after suspension of vital function has existed for some moments. Since the dividing line between life and death is of such extreme narrowness as to defy all human attempts at determination and definition, one may well be glad to make use of such a measure as direct cardiac massage in those cases especially where we have no reason to suspect disintegration of indispensable organs through disease.

The Diet in Typhoid Fever.

In addition to the ever present possibility of acute hemorrhage or of perforation during the course of a typhoid fever, the patient is in constant danger because of the weakening effect which the prolonged fever has upon his organism. While the continuous high temperature results in great increase of his protein metabolism with consequent increase in his tissue waste, the intestinal lesions are such as to demand great care in the selection of a proper diet to make up for the waste. Milk was once considered the ideal food for typhoid patients, but Seibert has long contended against its use in typhoid fever, and more recently others have opposed it through a realization of the fact that it is impossible to provide from two to three thousand calories in a milk diet without producing serious intestinal disturbance. It is this phase of the question which is very practically considered by S. Strouse in the *American Journal of the Medical Sciences* for May, 1909. The author presents a series of figures showing the comparative results in a great number of typhoid fever patients fed on milk and others supplied with a more liberal diet. Some figures gathered by Kinnicutt show in the percentage of hemorrhages, of perforations, and finally of deaths, results that speak distinctly though slightly in favor of the more liberal diet. Later figures gathered by Strouse himself are still more convincing in this respect. He concludes that the course of typhoid fever is a long-drawn battle between the patient and the disease and the result depends a great deal upon the preservation of the strength of the former. He must be supplied in one way or another with about the same amount of energy as a healthy resting man, and this amount cannot be well furnished by a pure milk diet.

News of the Week.

Major Carroll's Widow.—Efforts are being made to complete the sum of $7,800 needed to pay off a mortgage on the house owned by the widow of Dr. James Carroll, to whom Congress has granted only a small pension. The American Association of Pathologists and Bacteriologists, of which Dr. Carroll was a member at the time of his death, has directed the treasurer to call the attention of its members to this fund, and to request that contributions be sent to Major M. W. Ireland, Surgeon-General's Office, Washington, D. C. The Medical Society of the County of New York has voted $150 from the general funds of the Society to be given to the Carroll fund, and further contributions will be received by the President of the Society, Dr. H. Seymour Houghton.

Civil Service Examination.—The State Civil Service Commission will hold an examination on June 19, 1909, for the purpose of filling the position of Director of the Pathological Institute of the State Commission in Lunacy, at a salary of $6,500 per annum. Applications must be filed before June 14, and further information and application blanks may be secured by addressing (preferably on a postal card) the State Civil Service Commission, Albany, N. Y.

Medical Colleges Give Degrees.—Commencement exercises of the St. Louis College of Physicians and Surgeons were held on May 7, when eighty-seven students, of whom four were women,

received the degree of M.D. The diplomas were presented by Prof. Waldo Briggs, Dean of the college.

A class of twenty-one men was graduated from the Cooper Medical College of San Francisco on May 6, J. F. Walsh, of Eureka, Cal., taking the highest honors. The degrees were conferred by Dr. Henry Gibbons.

The Medical Department of the University of Oregon bestowed degrees on fifteen graduates on May 3. The annual address was delivered by Prof. Samuel E. Eliot, and the diplomas were presented by the President of the university.

Nurses Graduate.—The commencement exercises of the Training School for Nurses of St. Vincent's Hospital were held on May 19, when twenty-one nurses received diplomas. The address to the graduates was made by Dr. Francis J. Quinlan, and diplomas were presented by Mgr. Lavelle, of St. Patrick's Cathedral.

Another Nurses' Home.—The new home for nurses connected with the Metropolitan Hospital on Blackwell's Island, New York, was formally opened on May 17. The building is four stories high, and will accommodate 125 nurses. It cost about $315,000.

The Brooklyn Hospital.—The first night clinic and dispensary exclusively for women in Brooklyn has recently been opened at the Brooklyn Hospital. The hours are from 7 to 9 on Thursday evenings.

Ambulance Bill Signed.—Governor Hughes on May 20 signed the bill passed at the recent session of the Legislature, establishing a Board of Ambulance Service, to be composed of the Commissioner of Police, the Commissioner of Charities, and the President of the Board of Trustees of Bellevue and Allied Hospitals. The board is to have control over all ambulance service in New York except that maintained by the Department of Health.

Railway Accidents.—The report of the Public Service Commission shows a slight reduction in the number of accidents on the traction lines in New York City. Twenty-eight persons were killed as against 30 in April, 1908, and there were 177 serious accidents, against 191 in April, 1908. The total number of accidents was 4,170 last month and 4,710 in 1908 during the same month.

The report of the Pennsylvania Railroad for 1908 shows that during the year 141,659,453 passengers were carried over its various lines, and that not one passenger was killed as the result of an accident to a train. The total number of passengers receiving injuries of any sort requiring medical attention as the result of a train accident was only 102, 452 less than in 1907.

Vital Statistics.—In the State of California during the month of March, 1909, there were 2,707 deaths, of which 475, or 17 per cent., were due to some form of tuberculosis. Deaths from diseases of the circulatory system were next in the list. Those from epidemic diseases numbered 126, of which typhoid fever claimed the largest part. The State Board of Health calls attention to the fact that all the laws relating to tuberculosis and its control were defeated in the Legislature, with the exception of one appropriating $2,000 "for the dissemination of knowledge concerning the disease." This amounts to about one mill for each inhabitant of the State.

Charitable Bequests.—The will of the late Mrs. Jane G. Phelps, of Tarrytown, N. Y., provides for bequests of $5,000 to the Tarrytown Hospital and to the Lincoln Hospital, New York, and of $10,000 to the Presbyterian Hospital of New York.

Red Cross Stamp.—The award of prizes for designs for the Red Cross Christmas stamp to be used in raising funds for the tuberculosis work, has been made. The first prize, $500, goes to a New Yorker, Mr. Carl Wyngate. Nearly a thousand designs were submitted.

Bubonic Plague Active.—A severe epidemic of bubonic plague is reported from China, official estimates placing the number of cases in Amoy at about forty a week. After an absence of six months the plague has reappeared at Caracas. One case is officially under examination. The rats of Caracas show infection. No case has been found at La Guayra, or elsewhere in the Republic. The Government authorities have announced that they will make no secret of the existing conditions, and that they purpose to adopt strong measures of sanitation in fulfillment of the Washington convention. A surgeon of the U. S. Marine Hospital Service is expected to reach La Guayra shortly, where he will be attached to the U. S. Consulate.

State to Educate Blind Girl.—A special appropriation of $2,000 has been made by the Legislature of Pennsylvania, and approved by the Governor, to be used for educating a nine-year-old girl of Harrisburg, who is deaf, dumb, and blind. This is the first time that the State has undertaken the individual instruction of a person.

Osteopath Bill Defeated.—Senate Bill, No. 214, of the Illinois Legislature, known as the osteopath bill, came up May 19 for final vote in the House. A roll-call was demanded. Total number of votes cast was 117. Of these there were 45 for the bill and 72 against it. It is believed that this bill will never again be brought before the Legislature.

Dr. Otto T. Freer of Chicago has been elected a corresponding member of the Danish Oto-Laryngological Society, in recognition of his work in rhinology and laryngology, and in appreciation of his operative demonstrations in Copenhagen last summer.

Tuberculin in Certain Diseases of the Skin.—Dr. A. Schuyler Clark writes that, in the discussion of this subject at the Academy of Medicine, reported in the issue of May 8, he was quoted as saying that "the administration of tuberculin was dangerous and unjustifiable," but what he did say was that "its administration, under the old method with the production of reactions, was dangerous and unjustifiable."

Illinois State Medical Society.—At the fifty-ninth annual meeting of this society, held at Quincy, May 18, 19 and 20, the following officers were elected: *President*, Dr. J. L. Wiggins, East St. Louis; *First Vice-President*, Dr. Clifford U. Collins, Peoria; *Second Vice-President*, Dr. James E. Stubbs, Chicago; *Treasurer*, Dr. E. J. Brown, Decatur; *Secretary*, Dr. E. W. Weis, Ottawa. Danville was selected as the place for holding the next annual meeting.

Sixteenth International Congress of Medicine.—This congress will meet in Budapest, Hungary, from August 29 to September 4, 1909. The membership fee is twenty-five crowns (about five dollars), which will entitle a member to attend any of the twenty-one sections into which the congress

will be divided. These sections will be as follows: (1) Anatomy, (2) Physiology, (3) Pathology, (4) Microbiology (including bacteriology), (5) Therapeutics, (6) Internal Medicine, (7) Surgery, (8) Obstetrics and Gynecology, (9) Ophthalmology, (10) Pediatrics, (11) Neurology, (12) Psychology, (13) Dermatology and Venereal Diseases, (14) Urology, (15) Laryngology, etc., (16) Otology, (17) Stomatology, (18) Hygienics and the Study of Immunity, (19) Forensic Medicine, (20) Military and Naval Sanitation, (21) Tropical Medicine and Marine Surgery. Dr. John H. Musser of Philadelphia is the President of the National Committee of the United States; Prof. Alexander MacPhedran of Toronto is the President of the Canadian Committee, and Dr. F. W. Pavy of London of the English Committee.

The International American Congress of Medicine and Hygiene will meet in Buenos Aires in May, 1910, in commemoration of the first centenary of the May Revolution of 1810. The congress will be divided into the following sections: Bacteriology, Pathology, Physiology, etc.; Medicine, Surgery, Public Hygiene, Pharmacology and Chemistry, Sanitation, Veterinary Medicine, Dentistry. Papers for the congress or titles and abstracts of papers will be received until January 1, 1910, and may be written in Spanish, French, Portuguese, or English. Further particulars may be secured from the secretary of the congress, Faculty of Medical Sciences, Buenos Aires, Argentina.

Kansas State Medical Society.—At the annual meeting of this society held in Emporia during the first week of May, the following officers were elected for the ensuing year: *President,* Dr. O. J. Furst of Peabody; *Vice-Presidents,* Dr. T. F. Foncannon of Emporia, Dr. Walthall of Parsons, Dr. J. P. Kaster of Topeka; *Secretary,* Dr. C. S. Huffman of Columbus; *Treasurer,* Dr. L. H. Munn of Topeka. Dr. C. C. Goddard of Leavenworth, Dr. L. L. Uhls of Osawatomie, and Dr. J. E. Sawtell of Kansas City were elected delegates to the meeting of the American Medical Association, to be held in Atlantic City in June. Topeka was chosen as the next meeting place.

The Nebraska State Medical Association closed its annual session in Omaha on May 6 with the election of the following officers for the ensuing year: *President,* Dr. P. H. Salter, Norfolk; *Vice-presidents,* Dr. W. J. Berkhofer, Gothenburg, and Dr. S. S. Wilson; *Secretary,* Dr. A. D. Wilkinson, Lincoln; *Treasurer,* Dr. A. S. von Mansfelde, Ashland; *Corresponding Secretary,* Dr. H. W. Orr, Lincoln; *Delegate to the American Association,* Dr. L. M. Shaw, Osceola; *Alternate,* Dr. T. P. Livingston, Plattsmouth.

The New Hampshire State Medical Society held its 118th annual meeting in Concord on May 13 and 14. The following officers were elected for the ensuing year: *President,* Dr. Frank S. Blaisdell of Goffstown; *Vice-President,* Dr. A. S. Wallace of Nashua; *Business Councilors,* Dr. H. H. Faulkner of Keene, Dr. E. M. Fitts of Claremont, and Dr. Fred von Tobel of Lebanon; *Member of the Board of Trustees,* Dr. S. M. Dinsmore of Keene.

American Therapeutic Society.—The tenth annual meeting of this society was held in New Haven on May 6, 7, and 8, under the auspices of Yale University. Officers for the ensuing year were elected as follows: *President,* Dr. James C. Wilson, Philadelphia; *Vice-Presidents,* Dr. Alexander D. Blackader, Montreal, Dr. Howard Van Rensselaer, Albany, Dr. Robert T. Morris, New York; *Secretary,* Dr. Noble P. Barnes, Washington, D. C.; *Treasurer,* Dr. A. Ernest Gallant, New York; *Members of the Council,* Dr. Thomas E. Satterthwaite, New York; Dr. J. Blake White, New York; Dr. Frederic H. Gerrish, Portland, Me., and Dr. Clarence J. Blake, Boston; *Members of the Standing Committee on Therapeutic Research,* Dr. Spencer L. Dawes, Albany, and Dr. Harvey W. Wiley, Washington. The next annual meeting of the society will be held at Washington, D. C., in May, 1910.

The Worcester District (Mass.) Medical Society held its annual meeting on May 12 and elected the following officers for the ensuing year: *President,* Dr. L. F. Woodward, Worcester; *Vice-President,* Dr. A. C. Getchell, Worcester; *Secretary,* Dr. G. E. Emery, Worcester; *Treasurer,* Dr. G. O. Ward, Worcester; *Orator,* Dr. L. T. Newhall, Brookfield; *Censors,* Dr. R. W. Greene, Worcester; Dr. F. H. Baker, Worcester; Dr. R. P. Watkins, Worcester, Dr. A. G. Hurd, Millbury; Dr. J. J. Goodwin, Clinton.

The Franklin District (Mass.) Medical Society held its annual meeting at Greenfield on May 11, when the following officers were elected: *President,* Dr. C. L. Upton, Shelburne Falls; *Vice-President,* Dr. L. A. Newton; *Secretary and Treasurer,* Dr. Harry N. Howe.

The American Society for the Study of Alcohol and Other Narcotics will hold its thirty-ninth annual meeting in Atlantic City, N. J., June 7, 8, and 9, 1909. Sessions will be held from 9 to 11 A.M. A temperance lunch will be served at 1 P.M. on Wednesday at Young's Hotel.

Obituary Notes.—Dr. Isaac F. Galloupe of Lynn, Mass., a surgeon of the Civil War and a survivor of Libby Prison, died at his home on May 17, aged 86 years. Dr. Galloupe was graduated from Harvard Medical College in 1849, and in 1861 entered the service as surgeon of the Seventeenth Massachusetts Volunteers. Later he was made a brigade surgeon and was highly commended for his conduct of the hospital at Newbern, N. C. At the close of the war he resumed practice in Lynn, retiring about fifteen years ago. Dr. Galloupe was one of the group of medical men who witnessed the first use of ether as an anesthetic by Dr. T. G. Morton at Harvard in 1846. He was a member of the Massachusetts Medical Society, the Essex South District Medical Society, and the Lynn Medical Society.

Dr. John M. Boyd of Knoxville, Tenn., died at his home on May 16, aged 75 years. Dr. Boyd was graduated from the medical department of the University of Pennsylvania in 1855, and had practised continuously for over fifty years.

Dr. J. E. Payton of Redlands, Cal., died at Monrovia on May 10, after a long illness. He was a graduate of the medical department of Willamette University, Salem, Oregon, receiving his degree in 1877.

Dr. Gerardus H. Wynkoop of New York died at his home on May 16, after an operation for appendicitis. Dr. Wynkoop was born in Wilmington, Del., in 1843. He was graduated from Yale University in 1864, and from the College of Physicians and Surgeons, New York, in 1866. He was for some years on the staffs of St. Luke's and the Roosevelt hospitals, and was a member of the State and county medical societies.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RHEUMATIC FEVER (ENDOCARDITIS), SYNONYMS, PROPOSED HEART FEVER—CARDIAC TONICS—OVERLAPPING OF HOSPITALS AND POOR LAW—AMBULANCE BILL—COLLEGE OF PHYSICIANS ADMITS WOMEN—OBITUARY.

LONDON, May 7, 1909.

THE Lumleian Lectures at the Royal College of Physicians this year have been delivered by Dr. Norman Moore, senior censor, who, with his well-known taste for early literary information, said that the learned person after whom the lectureship is named inherited his estate from a grandfather who fought at Flodden Field, was educated at Cambridge, entering at Queen's College in May, 1540, and retained a taste for learning throughout a long life, in which, as Lord Lumley, he took an active part in the dangerous politics of the time. His wife, a daughter of the twelfth Earl of Arundel, was as well read as her husband, and among their learned friends was Dr. Richard Caldwell, an Oxonian, some time President of the College, who, with Lord Lumley, founded this lectureship in 1581. The course entrusted to Dr. Moore he devoted to the subject of "Rheumatic Fever," a name which takes us back to a pathology long anterior to the revival of learning, while acute rheumatism, the commonest synonym indicates a pathological confusion not yet dispelled from medical thought. Dr. Moore gave references to early writers, who more or less distinctly mentioned the disease or the conditions allied to it. He proceeded to state the grounds of diagnosis as endocarditis, multiple transient arthritis and a-temperature chart showing an initial rise followed after a fall by occasional rises with normal intervals. These three factors he declared essential to the diagnosis. The term subacute rheumatism should never be used, as it suggests absence of the importance of every case, however slight. Whether the pains are slight or severe made no difference. The essential and invariable feature of the disease was not a complication—that feature was the endocarditis, and "heart fever" would be an appropriate name. Dr. Moore would like to extricate absolutely the serious disease now termed rheumatic fever or acute rheumatism from the confusion involved in the word "rheumatism." But he found medical terms, inconstant in meaning, indeed, but surviving from century to century. Dr. Charles Badham's name "bronchitis," given a century ago, owed, he said, its firm place to the dislike of patients to think they have lung disease, from which they know people die. Were it not for the fear which men and women have of diseases associated with the lungs or heart the term "heart fever," he held, might "with advantage be adopted for that morbid condition in which endocarditis, transient arthritis, and raised temperature are always present."

The great service sometimes rendered by cardiac tonics is not to be denied; nor, on the other hand, is the risk which attends their administration. Yet very different estimates of either the value or the risk seem to prevail, for while with some physicians digitalis is such a favorite as to be constantly prescribed and becomes in small doses almost a routine prescription, others distrust it so much that they only order it when the indications are absolutely clear and the case urgent. No doubt insufficient power of the left ventricle may occur from mere weakness, as in convalescence, anemia, malnutrition, etc., and this whether any valvular lesion be present or not. The tendency to dilatation in these and some other conditions seems very well met by small doses of digitalis or its congeners. So also when compensation becomes insufficient in mitral regurgitation we turn to cardiac tonics and find them useful, but not too early. The risk of syncope whenever full doses are required must never be forgotten and the patient must keep in bed. Cases of sudden death on getting up have been numerous enough to make us insist on the recumbent position. Some persons, too, seem to exhibit a degree of idiosyncrasy to digitalis, shown in a minor degree by stomach derangement provoked with more than usual facility. When patients are not under constant observation, if only small doses are being given it is desirable, on account of the cumulative property of digitalis, to interrupt the treatment for a time—a hint for out-patient physicians.

Digitalin, although in use for some time, does not seem with the majority of practitioners to have displaced to any extent the cruder preparations. Perhaps this is due to its great power, the 1-100th of gram being an efficient dose; perhaps also to the fear of variation in its quality, for it is the amorphous glucoside which has been generally used here, though the crystalline product has been tried by some. Of course, the pure crystals are much more potent, so that the dose is only 1-130th of a grain. Crystallized digitalin has been admitted to the French codex and it is more used in France than here, especially since the Orfila prize, 1871, was awarded to M. Nativelle for his work in first obtaining crystals. It has been tried hypodermically, but as far as I gather from various observers it does not inspire more confidence by this method. In fact, most of them, as already said, are satisfied with the pharmaceutical preparations of the plant.

Strophanthus has so frequently been proposed as a substitute for digitalis that it may interest you in connection with the foregoing to refer to Fleischmann's recent report on the use of the active principle, strophanthin, by intravenous injection. This method of introducing so powerful a remedy does not seem likely to commend itself to English practitioners. I have not at present met one who has tried it, although Fleischmann reports excellent results, especially in failure of compensation. If a single injection proved ineffective in such cases, much less digitalis should afterward be employed—a quarter or half the dose. In renal cases the treatment was effective.

In a recent paper at the Royal Society of Medicine Dr. Gordon Sharp read a paper on heart tonics, in which he described some experiments, "pharmacological and clinical." He had bought specimens of tinct. digitalis which were inert when tested on a frog's heart. The leaves of the plant might be mixed by collectors, but more important was the proper drying, as, if allowed to steam, the contained ferment would break up the glucosides. He found the action of digitalis differed from that of strophanthus and squill. He strongly emphasized the importance of these drugs being standardized. He thought digitalis acted more quickly than was generally supposed, especially when given in full doses. It seemed to him the only real cardiac tonic The tincture was the handiest preparation, and when that was not tolerated the drug could be given in pill form. Strophanthus preparations had often been found inert, but in the last three years the value of standardization had been recognized and reliable products were available. This drug acted with certainty on the frog's heart and in full dose stopped it simultaneously in all its anatomical parts. In main its diuretic action seemed to be a direct one on the secretory tubules in contradistinction to the indirect diuretic effect of digitalis and to some extent of squill, through the circulation. He admitted, however, that it might by stimulating the kidneys produce a certain amount of diuresis. In dose of 20 or 30 minims the tincture had in many cases of cardiac dropsy produced a state of general analgesia and so given comfort to the patient, though without any effect on the dropsy. Squill preparations were not so often inert as strophanthus or digitalis. They acted energetically on the frog's heart, so energetically, in fact, as to appear to wear it out by excessive action. In medical practice their chief value was as adjuncts to digitalis, for though they acted well up to a certain point they were apt then to fail suddenly In the course of his paper Dr. Sharp said almost the only way of estimating the effects of heart tonics was an indirect one, viz., whether it would remove cardiac dropsy after rest in bed had failed. To improve the pulse, lessen the area of precordial dullness, and relieve palpitation would not be sufficient evidence that a drug was a true heart tonic.

Yesterday a bluebook was circulated containing details of an investigation as to overlapping of voluntary hospitals and Poor Law medical relief The result so far as three large London hospitals are concerned shows that 11 per cent. of out-patients are receiving Poor Law relief The proportion of hospital patients who may be said to be of the class for parish relief was 38 per cent. It is suggested that hospitals should adopt a precise registration in all departments and that the relations between the two agencies for relief should be authoritatively defined.

Sir William Collins has again introduced a bill to give the County Council power to establish an ambulance service for London. The former bill was lost on the question whether the County Council would be the best authority With the present state of the parliamentary work the bill has a poor prospect.

The Royal College of Physicians has decided to admit women to the examinations for the license, the membership, and diploma in public health on the same terms as men, provided always that women shall not be eligible for election as Fellows or entitled to take any part in the government, management, or proceedings of the college.

The death is announced of Gerald Francis Yeo, F.R.S., Emeritus Professor of Physiology at King's College, London. Born in 1845 he was educated at Trinity College, Dublin, graduating M.B. 1867, M.D. 1871, adding the diploma in State medicine. He subsequently studied physiology in Paris, Berlin, and Vienna and in 1874 was appointed to the professorship of the subject in King's College. He acted for about fifteen years as honorable secretary to our Physiological Society. He wrote a manual of physiology which had a good run, an essay on diseases of the kidney which won the Gold Medal of the Dublin Pathological Society. He also contributed to the *Jarb. d. Gesell. d. Aerzte* of Vienna, the *Proceedings of the Royal Society*, the *Journal of Physiology*, etc.

Dr. James Limont, formerly physician to the Royal Infirmary at Newcastle-on-Tyne, where he practised for many years, died on the 1st of the month. He had been in feeble health for two years or more. He graduated at Edinburgh, M.A., M.B., and after good work in subordinate positions at the Infirmary became physician and took M.R.C.P. In North England he was a highly esteemed, scientific consultant.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

CLOSING SESSION OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION—PHILIPPINE MEDICAL SCHOOL—COMMISSION FOR THE STUDY OF TROPICAL DISEASES—PLAGUE RATS IN SHANGHAI—FINDINGS OF THE OPIUM CONGRESS—PERSONAL.

MANILA, P. I., March 25, 1909.

At the last session of the fifth annual meeting of the Philippine Islands Medical Association, held February 20, a number of resolutions were considered. Among others, the recommendations made by the Philippine delegates to the International Congress on Tuberculosis at Washington were unanimously approved and the Government asked to put them into effect. The following officers were elected for the ensuing year: Dr. Benito Valdes, *President;* Dr. R. E. L. Newberne, *Vice-President;* Dr. Ariston Bautista y Lin, *Councilor* for five years.

Preliminary arrangements were also discussed for the first meeting of the Far Eastern Medical Association, which is to be held in Manila next February, and a permanent committee appointed to prepare a programme. The Philippine Government has promised to make an appropriation to aid in meeting the expenses, so that, on account of the convention being practically under Government auspices, it is expected that many foreign delegates will be present from every Oriental country.

The Philippine Medical School has just closed its second annual session, and at the commencement exercises, which were held on February 27 at the Zorilla Theater, five Filipinos received their diplomas. This is the first class that has been graduated from the new medical school, and even though only the last two years of the course were taken in this institution, it is probably safe to say that these men are better prepared than any that have heretofore been graduated in the Philippine Islands.

After numerous efforts made during the past year for the establishing of a commission for the study of certain tropical diseases, and after overcoming many obstacles and discouragements, such a commission has finally been put into the field under the general auspices of the Bureau of Health, the Bureau of Science, and the Philippine Medical School, the plan being to make a complete sanitary study of a native town of the Philippines. The main idea, of course, is to ascertain just what the incidence of the various diseases is among Filipinos who live amidst primitive conditions. For this purpose the town of Taytay, in the Province of Rizal, has been chosen. It has a population of about 6,000 persons, and is a town that in the past has suffered severely from outbreaks of dangerous, communicable diseases. In order to give an idea of the thoroughness with which this work is to be carried out, it may not be out of place to mention that a geologist will report upon the contour and formation of the country, a chemist is analyzing the water, and a biologist is examining it for animal and vegetable forms. Clinical microscopists are making blood examinations; zoologists are looking for intestinal parasites. Several clinical men are making physical examinations; medical men are treating all persons that require it. As practically all natives have intestinal parasites, it will be seen that to relieve 6,000 persons of worms is a task of no small magnitude in itself. An entomologist is studying the mosquitos and other insects. So far the work has not met with any opposition, and the prospects seem to be fair to carry it on to a successful conclusion.

Since the month of December plague infected rats have been found in Shanghai, and since that date the infection has spread among those rodents throughout the entire city. So far, however, no authentic cases of human plague have been encountered. The presence of this disease among rats in an Oriental city is being watched with considerable interest by sanitarians in order to observe whether it will eventually spread to human beings. It is presumed that the infection reached Shanghai by the so-called back door, viz., that the disease spread from Canton along the line of the new Canton-Hankow road, being carried by the laborers who are engaged in its construction, and after the disease once reached Hankow it was only a short time before it spread down the Yangtse River to Shanghai. A number of steamers are in daily communication between these two ports, and it would be almost impossible to regulate these river steamers so as to guard against the introduction of rats. After having been menaced for over ten years by vessels from nearby plague infected ports, which constantly make Shanghai a port of call, it seems hard that the good work of the port sanitary authorities should ultimately be defeated.

Following are the resolutions of the International Opium Congress, which has just concluded its sessions at Shanghai: It recognizes China's unswerving sincerity and real but unequal progress (in anti-opium campaign). It recommends measures for the gradual suppression of the opium traffic by other countries. It urges the governments (interested in the opium trade) to reexamine their systems regulating the use of opium other than for medical purposes. It urges the duty upon all nations to prevent the shipment of opium to countries forbidding the importation thereof. It dwells on the grave dangers of morphine. It recommends the scientific investigation of anti-opium remedies. It urges the governments having settlements or concessions in China to take steps toward the closing of divans. It recommends that effective measures for the prevention of the sale in such settlements and concessions of anti-opium remedies containing opium. It recommends each government to apply its pharmacy laws to its subjects in China.

Dr. S. Spencer Hough, who has been on duty as quarantine officer for the U. S. P. H. and M. H. S. at Hongkong during the past eight years, has returned to the United States on account of illness.

Passed Assistant Surgeon Thomas B. McClintic, who has been on duty at the port of Manila as quarantine officer of the U. S. P. H. and M. H. S., has been relieved from duty, and after spending several months' leave of absence in Europe, will return to the United States.

Colonel Louis M. Maus, Chief Surgeon, Division of the Philippines, has been relieved from duty in this division, and sailed March 23 for the United States via Europe.

Congenital Human Tuberculosis.—Maurice Pehu and Joseph Chalier, after a most careful study of the tuberculous cases denominated congenital that have been published, find only thirty-five that they consider undoubtedly congenital. Hence tuberculosis that is hereditary is exceedingly rare, and it is necessary to protect the infant against tuberculous surroundings. In judging of these cases every possible method of investigation must be used. The condition of mother and father must be known, the genitals and placenta examined carefully, and the organs of the infant and the umbilical cord examined. The differential diagnosis involves syphilis, early acquired tuberculosis, pulmonary milliary abscess, and lobular bronchopneumonia. Maternal tuberculosis is easily ascertained. That of the placenta is frequent. Contagion in utero occurs only after the placental circulation has been established, and involves the liver and the viscera, rarely the lungs of the child. A child more than a month old has probably acquired the tuberculosis.—*Archives de Médecine des Enfants.*

Progress of Medical Science.

Boston Medical and Surgical Journal, May 13, 1909.

Breast Abscesses.—R. L. De Normandie reports seven cases treated by Bier's suction method, and describes the special apparatus for its application to the mammary region. Six of the cases did well and one was a failure. In Case 1 the entire right breast was in very bad condition and had received no treatment. It was healed without induration in 38 days. In Case 2 the author says he did not carry out the treatment often enough or long enough, and failure resulted. Case 3 was a perfect result, with a minimum destruction of tissue, very small scar, and no induration thirty days from the time the breast was first seen. Case 4 did equally well, though the induration did not disappear quite as quickly. Case 5 was a small abscess before delivery, and healed well and the baby was able to nurse on the breast with but slight difficulty. Case 6 the author regards as his best result, for in this case even though there was no attempt to nurse for many days from the breast the milk finally returned and was given to the baby. In Case 7 both breasts were affected. One was treated by the usual open surgical method and the other by the Bier. The former was much the more serious virulent infection, but when opened it did well and healed without delay, but there was much destruction of tissue and there was still induration at the end of two months. The latter was smaller and less virulent, but there was no destruction of tissue, and the breast was left perfectly normal. In a possible future pregnancy it would undoubtedly be available for nursing, while the other would probably not.

Coffee as a Beverage: Its Use and Abuse.—R. Amory commends the use of coffee prepared by cold water instead of the usual infusion with boiling water. It may be prepared by passing the cold water through finely ground coffee in a porcelain or china percolator. This extracts only one-ninth of the caffein and one-fifth of the tannin contained in the bean, and it preserves the aroma of all the volatile oils in the bean. Consequently the wakefulness, excitability, and digestive disturbances are much less with the cold water coffee. The author has found from personal experience that coffee thus prepared may be carried for two or three weeks without any loss of color, aroma, or strength if it is kept in a cool place, carefully corked. This infusion is made strong and just as it is used hot water or milk are added. This sets free the volatile oils and fragrant coffee results. Full details are given for all the necessary manipulations.

New York Medical Journal, May 15, 1909.

Deafness Following Febrile Diseases and Its Prevention.—J. A. Pratt says that the majority of ear diseases are caused by adenoids and enlarged tonsils. These conditions are in the greater proportion caused by mechanical obstructions of the Eustachian tubes. The microorganisms found in the secretions are present in the normal middle ear as they are in the nasopharynx and sinuses. While varying in different parts of the country, from 25 to 30 per cent. of the children have adenoids or enlarged tonsils. All hypertrophied lymphatic tissues of the nasopharynx should be early and completely removed, so that mechanical obstruction of the Eustachian tube will not occur during congestion of the nasopharynx, thus interfering with the drainage and ventilation of the middle ear. A collective investigation among his colleagues shows that all agree that a very large proportion of the cases of incurable deafness or intractable suppuration in the ears have been caused by the various febrile diseases, and that a very large per centage of these had or had had adenoids.

The Individual as a Surgical Factor.—A. M. Crispin discusses the effects on surgical operations of such conditions as renal insufficiency, asthma, autointoxication, hepatic insufficiency, glycosuria, cardiac insufficiency, anemia, malaria, syphilis, and the mental condition. The paper is an earnest plea for a more extended recognition of the heterogeneity of the individual and a fuller appreciation of the constitutional conditions underlying or associated with surgical diseases, which emphasizes the advisability of an extended preparatory treatment before undertaking surgical operations. It is a dangerous error, says the author, to undervalue the constitutional disturbances which underlie many surgical diseases, and it is a useless nicety to establish a distinction between a diathesis and the lesion which it produces; it is a well known fact that wounds are very dangerous in persons who are suffering certain general diseases, such as diabetes, malaria, syphilis, general intoxications, either from internal or external sources, as those from the intestines, alcoholism, saturnism, etc., conditions all which may eventually cause alterations of the liver, heart, or kidneys. Alcoholism has only to be mentioned to evoke that dreaded postoperative sequel, delirium tremens, and the general alterations of the organism, for it is a truism that chronic alcoholism profoundly modifies the recuperative process. These morbid conditions have a decided influence on all surgical operations, even before the lesions they produce become appreciable.

Ophthalmia Neonatorum.—F. Krauss thus outlines curative treatment: (1) Thorough cleansing is best obtained by the use of a proper soft rubber syringe and the free use of a boric acid or weak potassium permanganate solution. This solution should be used not less than every hour, day and night. (2) Silver nitrate should be applied by the physician himself once or twice daily, according to the amount of the discharge. As the discharge lessens it can be done every second day, but early cessation of the silver solution will bring a recrudescence in many cases. To apply the silver solution properly the lids are everted, which is easily accomplished by traction along the lid margins with the finger tips. A ten grain to the ounce solution of silver nitrate is applied to the everted lids by means of a cotton swab, being careful to apply the same thoroughly in the conjunctival fornix. Have a second swab wet with normal salt solution conveniently ready and apply the same at once to the everted lids. (3) The question of hot or cold compresses is rather confusing. Formerly ice compresses were used freely, with the result that if applied too zealously the cornea would be deprived of its vitality and develop opacity. Intermittent ice compresses are of great service in the early stages, but judgment should be used by the physician. Hot compresses in the later stages applied for a short time daily seem to assist in clearing corneal opacities. The applications of compresses are of value also because they keep the lids from adhering to some extent by their moisture, thus allowing of the exit of the pus. (4) Constant bathing of the eyes with a 20 to 25 per cent. solution of organic silver solutions seems to be of some value, and should be used in every case. One drop instilled after every cleansing of the eye is most satisfactory. In this way the eye is constantly bathed in a solution that is mildly antiseptic, and has sufficient color to allow us to watch its diffusion. (5) Should the cornea become hazy, atropine (gr. ii to ℥i) should be dropped into the affected eye two to three times daily and every bright light excluded from the room.

The Clefts of the Axis Cylinder, the Cable of the Nervous System.—Basing his observations on facts observed by Foster, Sir James Grant says that the clefts of the axis cylinder are the factors in the production of an imperfect nervous impulse, amply demonstrated by defective transmission, of the electric current and such current reestablished brings to light the idea that the internal solution of conductivity, the highest order, in the transmission of nerve power, in the axis cylinder, depends as to electrical phenomena, on the organic salts, which it contains, and the change propagated by electricity, is the result of a dislocation of preexisting discrete particles, thus restoring the continuity, and conductivity, of the medulla of the axis cylinder. Nerve action to be of service must be normal in its distribution, so clefts in the axis cylinder are productive of constitutional troubles, occupying a wide range in the general system. The marked change for the better in the following cases in digestive power points to some latent irregularity, such as defined, far reaching in its influence, and corrected by a clearing up process of electrolysis, in the nervous system, concerned in the elaboration of chyme, from food products, and subsequent formation of blood. The histogenetic action of the abdominal ganglionic nerve centers is a complex problem, and so the part nerve tissue plays, in the most remarkable transformation from food to blood, the very pabulum of life. The clinical histories of four cases are given in detail and then the author gives the following directions for electrical treatment: (1st) Moisten the skin of the abdomen with warm water and a sponge before applying the electrical current to the space midway between the hip crest and the last rib, about three inches to the right of the navel; this application to continue about ten minutes. Afterward pass the current mildly over the entire abdomen for five minutes and dry the surface carefully after each application. (2d) Moisten each leg from the knee to the ankle and apply the

current freely for five minutes to each leg and dry carefully. The object in view in the application of the current to the extremities is to arouse increased nervous activity in the terminals of the sciatic and saphenous nerves and their varied communications, in the pelvic and abdominal regions, accessories, to the remarkable histogenetic spaces, where is produced the very papulum of life. These applications will be repeated each day, at bed time, for two weeks, and repeated once or twice afterwards each week for three or four weeks should any evidence of the weakness continue. No application of the treatment should be made less than two hours after a meal. Before the application of the electrical current drop fifteen or twenty drops of liquid antiseptic soap over the navel and use vigorous massage for ten minutes over the entire abdomen, with open hand placed in warm water, and then dry carefully. This massage is to take place before each application to the abdomen of the current.

Journal of the American Medical Association, May 15, 1909.

Congenital False Diaphragmatic Hernia.—H. S. Martland reports the clinical history and autopsy findings in a man, aged 70, who died as a result of a congenital deficiency in the central tendon of the diaphragm, the opening connected directly with the pericardial cavity, the heart at autopsy being surrounded by the entire transverse colon and the great omentum. The patient had never been confined to his bed by sickness before, and on his admission to the hospital he presented the clinical picture of an acute right heart dilatation, being markedly cyanotic and dyspneic, with a rapid, irregular, and feeble pulse. Aside from this there was little in the physical examination of much interest. In spite of treatment with cardiac stimulants, his condition did not improve, and he died seventeen hours after admission. The autopsy showed the conditions above described, together with evidences of irritation and inflammation, in places, in the small intestine, with contiguous reddened and thickened peritoneum. There was no hernial sac, and the hernial opening presented rounded borders, and the peritoneum of the under surface of the diaphragm was continuous with the parietal pericardium. Death was attributed to cardiac embarrassment, due either to slipping of too large a portion of intestine, or gaseous dilatation through the defect in the diaphragm. The author discusses diaphragmatic hernia generally, in explaining the embryologic mechanism of such a defect. He reports the case on account of its rarity, not finding any similar one in the literature. The age of the patient is also a point of interest. The evidence of irritation in the small intestine seemed to indicate that it also had been injured in former times, by forming part of the hernia.

Inoculation Accident in Manila in 1906.—W. M. Haffkine reviews this accident by which a number of persons were inoculated with plague bacilli during some anticholera vaccinations which were being made at that time, and a number of them died. He gives a history of the cholera vaccination in India, as originated and carried out by himself, the safety of which has been demonstrated. It is essential to note that in the accident at Manila the cholera vaccine did not become spontaneously contaminated by plague. Such a happening may be considered impossible. In that instance a plague culture, presumably pure, was mixed by some person with a watery suspension of cholera culture, also pure. The accident became possible by the nonobservance of two rules prescribed in the anticholera inoculation, namely, the contents of the culture should not have been mixed; and each tube immediately before being used should have been, apart from any other examination, submitted to an examination by the microscope. Under such circumstances a plague culture would never pass for one of cholera. The accident was of the same nature as would have followed a pharmacist mixing a poisonous substance while preparing a prescription. While using a strain for preventive inoculation in man of the cholera germ, prepared and maintained in the way in which this is done in India, instead of operating with that substance itself, they have in Manila adopted the plan of leaving it to digest in water and using the resulting soluble extract, which they are under the impression is free from the possibility of such misadventure as they have had with the vaccine. The same department of the Manila Institute which prepares the extraction of the cholera vaccine prepares soluble products of other microbes, such as the toxins of diphtheria and tetanus and probably solutions of snake venoms for the preparation of antivenene, etc. If these toxins and solutions are so kept as to permit of their being inadvertently mixed with one another, if before using them under such circumstances the inscriptions on the receptacles are not ascertained, and the physical difference of the contents is overlooked, the extraction from the cholera vaccine would still be liable to produce the same unfortunate results as before. It is not suggested for a moment, Haffkine says, that the above is the normal prevailing condition in the Manila laboratory, which has deservedly taken a place among the first-class institutions of its kind in the world. It is only noticed now, he says, to make clear that their accident has not been conditioned by the peculiarities of the anticholera vaccination method, as they believe it has.

Submucous Perineorraphy.—W. W. Babcock criticises the modern methods of perineorraphy and describes the technique which he has adopted since 1902. The principles on which it is based are the following: "First, no tissue is removed or extensive denudation made. Second, buried, absorbable, layer sutures are used exclusively, none of which penetrates the skin or mucous membrane. Third, the operation is done from the outside of the vagina, rendering the introduction of sutures easier and the exposure of tissues better than with those operations done from within the vagina. Fourth, each structure is sutured with precision under the guidance of the eye; there is no blind groping with the needle for tissues not seen and perhaps not felt. Fifth, each of the layers of the perineal floor—vaginal wall, submucosa, muscular supports, facial planes, and skin—are united seriatim, in layers after the plan of the better types of herniotomy. Sixth, the vagina is not separated from the rectum and therefore there is no danger of wounding the bowel." He claims for this method the advantages of restoring and increasing the length of the vagina instead of shortening its posterior wall; better supporting the anterior one; restoring the normal H-shaped section instead of destroying the lower lateral sulci; requiring no removal of sutures or use of foreign bodies like shot, and the avoiding of all seton action of fluid through sutures. The technique is described in detail, but does not lend itself to abstracting without reproducing the illustrations. All the sutures being buried and the layers bound together compactly, there are practically no dead spaces.

Treatment of Scoliosis.—A. Steindler remarks that while a number of good and practical corsets have been made which give approximately satisfactory results, it is somewhat difficult to meet the two most important requirements, the one of giving a reliable and uniform support to a deformed spine the position of which has been improved by mechanical or gymnastic treatment, and the other of exerting a correcting influence on certain parts of the body by means of the corset itself. In cases in which there is considerable shifting of the body to one side, for instance in which the lumbar part of the spine is primarily involved in the curvature, not enough hold may be gained for correction and the maintenance of the corrected portion. He has devised an apparatus which he describes here and illustrates. "The sideward shifting of the body will always result in a lifting of the pelvic belt of the corset from the iliac crest of the opposite side, unless its position there is otherwise secured. In order to obtain this advantage, and, on the other hand, to exert some correction on the costal prominence, I attached to the pelvic belt on the healthy side a thigh-piece connected with a hinge and embracing the leg by means of a padded ring right above the knee. On the side of the scoliosis a pad corresponding to the costal prominence articulates by means of a hinged steel piece with the pelvic belt, a similar pad being attached on the corresponding anterior costal prominence of the opposite side. On both pads a considerable amount of elastic pressure is secured by a couple of springs. It is easily to be seen that, if the attachment to the leg is given, bent decidedly outward, and then fastened closely above the knee, an opposite movement of the pad will result in bringing the sideward shifted body over the median line to the other side. Two uprights in the back on both sides of the spinous processes give the body rest and allow the shoulders to be pulled back by shoulder straps." The patients had been given mechanical treatment, gymnastic and otherwise, which was continued after the application of the apparatus. Steindler had to a great extent given up mere extension as a method of correcting curvature, because the extension of the spine thus obtained led to the formation of flail intervertebral joints and increased flabbiness of the spine. Similar results occur with the use of plaster casts and the discomfort which these cause is sometimes found to prove an insurmountable obstacle in a certain class of nervous and delicate patients. The principle of using the hip joint and the motion of the leg for correction of deformities of the body might prove useful in conditions other than lateral curvature.

The Lancet, May 8, 1909.

Bilharzia Hæmatobia and Circumcision.—J. F. Allen, who has practised for years in Natal, Africa, is convinced that in his territory the bilharzia is not taken into the stomach, but enters the body through the urethra while the patient is bathing. It may perhaps enter through the rectum and anus, and it may enter the lungs by the sniffing of infected water while the patient is bathing, although he has never seen such a case. There can be no doubt that the parasite does at times enter the stomach in drinking water, but it is destroyed by the gastric juice and does not penetrate the tissues of that organ. In the countries where it is prevalent its invasion is confined for the most part to those who acquired it when children, and it is almost altogether found among males. Those affected are almost always those who bathe in streams. If it were possible to divide the population into bathers and non-bathers it would be found that the latter escaped while the former were infected. The sex difference would be due apparently to the fact that boys are far less liable to use towels than are girls and bathe far more often in open streams. The nonuse of towels leads to the clinging of the parasite to those parts of the body, which facilitate invasion. The author enters at length into the question of the behavior of the parasite in the body, and advises circumcision as the best method of prevention of infection.

Sudden Death from Unsuspected Cardiac Lesion.—H. Galt's first case was that of a baker of 66 years admitted to hospital with anorexia and emaciation for eighteen months, epigastric pain and vomiting for ten months, and very recent swelling of the abdomen. There was a marked alcoholic history, and the urine contained albumin and casts. Autopsy showed the pericardium full of clot, brown atrophy of the myocardium, moderate hypertrophy of the left ventricle, mitral and tricuspid valves normal, dilated coronary arteries with free lumen, and, just above the right coronary, a tear one and a quarter inches long, no fatty or calcareous deposits, nephritis, and a soft carcinoma of the stomach. The blood from the right coronary had dissected the adventitia, and finally burst through it near the origin of the left coronary. The second patient was a storeman of 65 years, with alcoholic history, epigastric pain, and occasional attacks of vomiting (the vomitus containing a little blood). These symptoms had lasted two years. The man died in collapse a few hours after the onset of an attack of epigastric pain. Autopsy showed normal heart valves, aortic atheroma, thrombus in right auricular appendage, healthy myocardium externally, recent ecchymosis over the middle part of the left coronary artery surrounded by softened tissue, and a thrombus in this vessel which also showed advanced calcareous change. A rent was found over the interventricular septum. There was extensive necrosis of the myocardium, in the center of which was a large gaping orifice which led directly into the right ventricle, the opening being much larger on the left ventricular aspect. The pericardium was healthy, and there were no adhesions. There was a shallow ulcer in the stomach involving only the mucosa. Other organs were healthy.

A Simple Operation for the Complete Removal of the Tonsils.—G. F. Waugh describes a procedure he has followed in 900 cases. Immediately external to the internal surface of the anterior pillar, just where it blends with the surface of the tonsil, an incision is made with fine-toothed forceps parallel to and extending the whole length of the free margin of the pillar. The capsule of the tonsil is thus exposed, but it must not be penetrated. The tonsil is firmly grasped with ring forceps and the pillar drawn out with the fine-toothed forceps. The tonsil is then dislocated from it bed and a pair of smooth, blunt-ended scissors slipped behind it. The tonsillar vessels are thereby torn across and are able to retract within the muscular wall of the pharynx, and there is practically no bleeding. Average time required for removal of tonsils and adenoids is three minutes. Chloroform anesthesia is employed deep for a brief period, so as to abolish cough, which tends to increase the bleeding, and the blood may be easily drawn into the air passages. There have been in the author's large number of cases no sepsis or hemorrhages. He very aptly remarks that it is not the size of the tonsil which determines the necessity of operation, but its septicity, which may be very high in comparatively small organs. The danger of swallowing septic material from the mouth has not been sufficiently emphasized, and the author makes the practical point that no attempt should be made to remove tonsils until all carious teeth have been extracted or properly filled.

The Alcohol Injection Treatment of Neuralgia and Spasm.—W. Harris gives histories of several patients on whom he has operated by this method. He regards it as a certain relief for trigeminal neuralgia, and although recurrence of the pain is likely after an interval varying from four or five to eighteen months, it is perfectly simple to repeat the injection when necessary. The operation is preferable to the more formidable one of extirpating the Gasserian ganglion and should certainly be tried first. The method is practically one of resection of the nerve. The technical details are given in full. In addition to trigeminal neuralgia the method is of great service in controlling facial spasm and also other forms of neuralgia, such as postinfluenza supraorbital neuralgia, the facial pain of inoperable carcinoma of tongue or jaw, and in chronic sciatica. Tabetic neuralgia affecting the lower limbs and other causes of severe persistent neuralgia below the middorsal region may possibly be relieved by this method by injecting the spinal nerves at their point of emergence at the intervertebral foramina. These foramina the author has found it comparatively easy to reach for the lower dorsal, lumbar, and upper sacral roots.

British Medical Journal, May 8, 1909.

Spirochæta Pallida.—A. G. Coles discusses methods of examination and detection, especially by means of the dark ground illumination. The material may be taken from the primary sore, condylomata, and mucous patches, the indurated glands and the various eruptions, especially the papular and vesicular forms, more rarely the roseola. The various staining preparations are given, together with much information of a purely technical character. The author's conclusions are thus expressed. The easiest, quickest, and by far the most certain method of detecting the organism is in a serum cover glass by means of dark ground illumination. The taking of the material is the most important stage in the entire proceeding. It is not essential to examine fresh films (which have been surrounded with vaseline) at once, as the organism may be recognized some days later. The serum of irritation may be taken conveniently in capillary tubes or blood capsules provided the ends are sealed and cover glass preparations made from or at pleasure. A negative finding is, as regards the diagnosis of syphilis, of little value. The spirocheta fades somewhat in anilin stained preparations. A mounting medium in which the staining would persist is a thing greatly to be desired.

The Etiology of Beri-Beri.—H. H. Weir suggests that there develops on rice an epiphyte which develops a nerve toxin. The active principle of a certain fungoid on rice has been called arsin. The Chinese cook rice with the dust on it and suffer from beriberi, while the Koreans are very careful about washing their rice, rinsing it in several waters before they cook it. They do not have beriberi. The author therefore attaches much value to washing in removing this fungoid material, which, in his judgment, is the cause of the malady in question.

Treatment of Rheumatoid Arthritis by Cataphoresis.—W. F. Somerville surrounds the affected joint with a large pad of lint ten layers thick, and soaked in the particular solution to be used, and around this pad a metal gauze electrode is tightly bound to the limb and connected with the negative pole. By this means salicylic acid is introduced from a solution of solicylate of soda, iodin from potassium iodide and chlorine from sodium chlorate. The positive electrode laid on a large pad of lint soaked in an ordinary salt solution may be placed on another part of the body. The author testifies from personal experience to the value of this treatment in reducing swelling, alleviating pain, and lessening rigidity of the tendons in cases of rheumatoid arthritis.

Acute Addison's Disease.—The patient of A. F. Shoyer was seen on account of increasing weakness and anorexia of three weeks' duration. There was a history of chronic bladder and kidney trouble for five years. The urine was alkaline, and contained considerable mucopus, but apart from these facts the woman, aged 33 years, did not complain. On the second day of treatment she began to vomit and she grew weaker, being relieved temporarily by 5-grain doses of suprarenal extract, but she gradually sank, and died on the sixteenth day. Autopsy showed the kidneys in a condition of advanced tuberculosis. They were enlarged and riddled with pus cavities. Their capsules were studded with tubercles. The walls of the bladder were thickened and covered with mucous ulcers. The suprarenals were covered and permeated by miliary tubercles. Other organs were normal.

On the Use of Certain New Chemical Tests in the Diagnosis of General Paralysis and Tabes.—G. W. Ross

and E. Jones refer to recent studies on the behavior of the cerebrospinal fluid in the general paralysis of the insane. A preceding discovery of value was that lymphocytosis in the fluid was one of the most constant accompaniments of both general paralysis and tabes. A second discovery was that the fluid contains considerable quantities of protein in paresis and to a less extent in tabes. The third discovery was that of Wassermann that the fluid in paresis contained substances which, combined with the syphilitic virus, had the power of inhibiting hemolysis. Wassermann's interpretation of his own discovery has met with serious criticism, but its value as a certain sign of general paralysis is generally admitted. It is too complex for general clinical use. A later discovery is the increase in globulin in the fluid in general paralysis. Two methods of estimating this increase are referred to by the writers. The first is that described some months ago by Noguchi of New York and its features are set forth. The second is here published for the first time. Two c.c. of a saturated solution of ammonium sulphate are placed in a test tube and 1 c.c. of the cerebrospinal fluid is gently run on to the surface in the way done in the Heller cold acid test for albuminuria. The formation of a ring at the junction of the two fluids constitutes a positive reaction. The ring is thin, clear-cut, grayish white, and as thick as a thin piece of paper. It should form within three minutes, and in half an hour it may be observed that the surface of the ring shows a delicate mesh appearance resembling a fine cobweb. Indirect illumination must be used or it may escape detection. This is best accomplished by a black-lined box in which the test tube can be inserted and viewed at right angles to an electric bulb which is fixed in the box a few inches away. In applying the test it is essential to see, first, that the ammonium sulphate is pure so that the solution is neutral and not acid, and, second, that the solution is quite saturated, which is best insured by the use of heat in its manufacture.

Berliner klinische Wochenschrift, May 3, 1909.

Experimental Pulmonary Tuberculosis with Formation of Cavities.—Römer accepts the statement of Behring that pulmonary tuberculosis of adults occurs in the great majority of cases after a previous infection of the organism in infancy with tubercle bacilli. According to Behring, the so-called predisposition to tuberculosis is nothing but the existence of such a previous infection, which has produced certain changes in the tissues of the lungs, making them especially susceptible to the action of the bacilli. To clear up this point, Römer has studied experimentally the reaction of animals already suffering from tuberculosis to new infections with the bacilli. His earlier studies have shown that such animals show increased resistance to the new infection. The fact, then, that not all men become equally tuberculous on being exposed to almost universal presence of the bacilli, may be explained by the supposition of an earlier infection which has resulted in a partial immunity of some individuals. The opposite fact, that of the great frequency of pulmonary tuberculosis in human beings, Römer explains not by supposing an increased predisposition of the pulmonary tissues, but rather an increased resistance of other organs, leaving the lungs infected through the air to bear the brunt of the attack. Experimentally he has succeeded in producing typical pulmonary tuberculosis with formation of cavities in tuberculous guinea pigs by reinfecting them with large numbers of bacilli. The appearance of a pulmonary tuberculosis then is, according to Römer, a phenomenon of partial immunity; in the absence of such immunity acquired by light tuberculous infection in infancy, adults would more often show the picture seen in general tuberculosis of children and of laboratory animals not previously immunized.

Etiology of Yellow Fever.—Seidelin has had the opportunity of studying the blood of several patients suffering from yellow fever. He found numerous structures within the red cells which were apparently protozoan in character and which he considers as the excitants of the disease. They seemed to consist of a protoplasm taking the blue color in such a stain as that of Wright or Giemsa, and a centrosome that took the red stain. Most of the structures were ring-like in type. Seidelin excludes malarial parasites, malarial symptoms not being present in the patients he examined, quinine having no effect upon the disease, and pigment granules so often found in riper malarial organisms being absent from all types of the protozoa observed by him. The article is accompanied by pictures of the parasites.

French and Italian Journals.

Treatment of Hemoptysis by Galvanization of the Thorax.—P. Galante reminds us that at the positive galvanic pole an acid is formed, and at the negative a base. At the positive pole is formed a firm clot which organizes and becomes fibrous. This fact may be utilized in the treatment of pulmonary hemorrhage. The author gives two illustrative cases treated by himself. The effect on the hemorrhage is immediate and permanent. The technique is very simple. It requires only an ordinary portable apparatus of thirty cells, with a galvanometer. A large electrode of zinc covered with absorbant cotton and wet in sterilized water is applied over the anterior thoracic region, connected with the positive pole of the battery. The negative pole is placed on the back. The author used 15 to 50 milliampéres of current, for ten to twenty minutes. He concludes that positive galvanization of the thorax is a good remedy for cough, the respiration becoming freer and calmer, and the patient feels better. The irritating cough of tuberculosis is benefited. The blood in the sputum diminishes with the cough, and the sputum becomes loose and thinner. The treatment should be continued for some time.—*Annali de Elettricità Medica Terapia Fisica*, March-April, 1909.

The Use of Soap in Surgical Therapeutics.—L. Delrez describes the use of soap plasters and soap injections in the treatment of surgical tuberculosis. It is applied in form of a thick plaster underneath the immobilizing apparatus. No bad symptoms have ever been observed from this treatment. On the contrary the general condition improves rapidly. In case of tuberculosis of the soft parts or of bone fistulæ the same treatment may be used, after careful curettage of the fistula and hemostasis. The author has injected soap tinctures into softened inflammatory cavities without any bad effects. It causes pain and acts as a cauterant for a few moments, when all pain disappears. After from eight days to two weeks a new injection is made. Its action is not due to a marked bactericidal action, which it does not possess. At the same time it causes healthy repair of tissues. It does not prevent the union of a wound by first intention, but, on the contrary, facilitates it. After opening a tuberculous focus, curetting it, and removing the pyogenic membrane, it may be filled with soap solution, and we may suture the edges of the wound. Its action is to cauterize the entire surface that is tubercular, and destroy necrosis, and giant cells, but does not produce an acute inflammation. It acts directly on the tubercular tissue, destroys the pyogenic membrane, and increases the vital activity of the tissues.—*Archives Provinciales de Chirurgie*, February, 1909.

Electrization of the Stomach Studied with Radioscopy.—F. P. Sgobbo has made a study of the value of applications of electricity to the stomach, watching the picture as it appeared by radioscopic examinations made while the electric current was in action. He used faradism, galvanism, and static electricity, and applied them within the stomach, and outside on the abdomen. The experiments were made upon dogs. Of the three forms of electricity used, the faradic current was most effective in producing contractions of the stomach walls. Internal application gives no greater and even less effect than that of external applications, and they have the best effect when applied transversely or anteroposteriorly. The monopolar method is also effective. Contractions of the abdominal muscles or diaphragm produce no stomach contractions. Static electricity gave no good results. The galvanic current is somewhat less effective than faradism. Applications made directly over the stomach are less effective than transverse ones. The galvanic current should be interrupted or the poles changed, in order to get contractions of the stomach.—*Giornale di Elettricità Medica*, January-February, 1909.

Angina Pectoris and Its Treatment.—Marchiafava notes that angina pectoris is a more frequent malady than is generally supposed. In the light of his personal experience he treats of its etiology, symptomatology, course, pathogenesis, and treatment. The important part that the sclerosis of the coronary arteries plays in its causation is especially dwelt upon, above all the sclerosis of the descending branch of the left coronary artery. Aortic insufficiency frequently accompanies it. It is quite often of syphilitic origin. Rheumatism is another frequent cause of it, and a third is the use of tobacco to excess. As to pathogenesis, the most frequent element is arterial degeneration combined with relative ischemia of the myocardial area. In the treatment Marchiafava says that small doses of iodides are often of considerable value; he discusses at some length the advantages and disadvantages of nitrite of amyl and nitroglycerin. He has obtained excellent results from theobroma, of which he has made use for the past eight years.—*La Riforma Medica*, March 8, 1909.

Book Reviews.

Surgery of the Upper Abdomen. In two Volumes. By John Deaver, M.D., LL.D., Surgeon-in-Chief to the German Hospital, Philadelphia, and Astley Paston Cooper Ashhurst, M.D., Surgeon to the Out-Patient Department of the Episcopal Hospital, Philadelphia. Volume I, Surgery of the Stomach and Duodenum. With 76 illustrations. Philadelphia: P. Blakiston's Son & Co., 1909.

It is a matter of interest that the attention which was centered during the last decade on the surgery of the contents of the lower portion of the abdominal cavity, has gradually become transferred to the organs in the upper portion of the same cavity. The center of the stage has long been occupied by the appendix but this position is being steadily usurped by the liver and the pancreas. Many valuable original contributions to the knowledge of the subject have appeared in the journals and in special monographs and these publications have reached such numbers that the need for a review of this material in text-book form, is evident. The task has been undertaken and well done by Drs. Deaver and Ashhurst, than whom there are few men in America better fitted for this work. Their own contributions constitute an equally important element, as they themselves have had an extended experience in the operative treatment of the surgical diseases of the stomach and adjacent organs. It is intended to issue the work under consideration in two parts, the first of which is now at hand, and deals with the surgery of the stomach and duodenum. The second volume will take up that of the liver and bile passages, the pancreas and spleen.

The book is more than a review, the authors' personal opinions and practices are explicitly presented as well as their assent or dissent with those of the writers whom they mention. A feature of interest after the preliminary chapter on the anatomy of the stomach and duodenum, is another on the physiology of digestion in its practical application to the surgery of these organs. Gastric ulcer is the first lesion to be discussed and this is done in a very thorough manner. The writers do not look with favor upon persistence of medical treatment even in the simple hemorrhagic type where there is no imminent danger of perforation, and believe that gastro-jejunostomy is usually indicated and fulfills all the indications without subjecting the patient to undue risk. Excision of the ulcer is not advised except for undoubted malignancy. In perforation, abdominal section is urged at the earliest possible moment, not waiting for the subsidence of shock if present, for it has often been observed that this shock is apparently due to the presence of air in the cavity and when the latter is opened it almost immediately disappears. Drainage is advised invariably. The treatment of the section on malignant disease of the stomach is very complete and satisfactory. The authors agree with the opinion which is lately gaining ground that chronic gastric dyspepsia is the chief predisposing cause of cancer of the stomach. The remaining sections of the book are devoted to the discussion of the benign lesions of the stomach and duodenum, to miscellaneous affections, such as tuberculosis, syphilis, phlegmonous gastritis, etc., and to the technique of operations. The latter is a very important feature of the work. The methods in vogue at the German Hospital of Philadelphia are particularly described and we are glad to note among other things, that the patients are not allowed to get up out of bed until after the tenth day, in contrast to the idea of "early rising" so emphatically urged recently in other quarters. The well-tried operative procedures indicated for the various lesions are carefully described, together with personal comments based on the writers' clinical experiences. The text throughout is clear and concise and a feature worthy of comment is the use of only essential illustrations, which are diagrammatic and clear cut and serve to elucidate rather than burden the reading matter. They are, moreover, free from all artistic (?) embellishments such as we have become accustomed to see in recent medical publications. The appearance of the second volume of this work will be awaited with interest.

Medical Gynecology. By Samuel Wyllis Bandler, M.D., Fellow of the American Association of Obstetricians and Gynecologists; Adjunct Professor of Diseases of Women, New York Post Graduate Medical School and Hospital; Associate Attending Gynecologist to the Beth Israel Hospital, New York City. With original illustrations. Philadelphia and London: W. B. Saunders Company, 1908.

There has been no lack of books on gynecology during the last few years; most of them, however, deal with the subject, either chiefly or entirely, from the standpoint of the operating surgeon. But there are many conditions which can be treated by less radical measures, and the general practitioner (to say nothing of his patients) will gain much from this volume. Naturally it deals principally with the troubles that the family physician sees first, and which he will be glad to treat, and if possible save from the hands of the operating specialist. Thus such conditions as amenorrhea, dysmenorrhea, menopause, uterine hemorrhages, pruritus, gonorrhea, sterility, inflammations and constipation are discussed in detail, and are thoroughly well handled; and in spite of the title of the book, the author fairly and fully faces the fact that often operative measures are necessary, and in such cases he urges that the same be undertaken. The chapter on constipation is by Dr. Mannheimer, and is a very thorough and satisfactory exposition of the subject. There is much valuable material in the volume, particularly on diagnosis and treatment; unfortunately some of it suffers from poor arrangement, a few of the prescriptions are in need of critical revision, and the author uses the terms onanie and onanism when he means masturbation. But these are small points in a book which meets a distinct demand, which as a whole is exceedingly well done, and which is deserving of a hearty welcome from the general practitioner.

Introduction a l'Étude clinique et a la Pratique des Accouchements. Anatomie—Présentations et Positions—Mécanisme — Toucher — Manœuvres — Extraction du Siége—Version—Forceps. Principes fondamentaux d'Obstétrique, vérifiés, rectifiés ou établis a l'aide de l'expérimentation sur le mannequin naturel, et de l'observation sur la parturiente. Par le Professeur L. H. Farabeuf, et le Docteur Henri Varnier. Preface du Professeur A. Pinard. Dessins démonstratifs de L.-H. F., donnant avec les répétitions nécessaires 375 figures dont plusieurs nouvelles. Nouvelle edition revue et augmentée. Paris: Georges Steinheil, Editeur.

For many years this work has been out of print, hence the appearance of this new edition will be welcomed by those who have appreciated the earlier editions, as well as by many who will now form its acquaintance for the first time. It is not a complete textbook on obstetrics; only certain parts of the subject are dealt with, and these are sufficiently indicated on the title page. But what is does give is of the highest order of merit, and represents much original work on the part of the distinguished authors. They tell us that they experimented on dead bodies preserved in glycerin to keep them supple; and when possible on the dead bodies of eclamptic patients who were in labor. These they call their "natural mannekins." It will readily be seen that this book owes much of its well earned popularity to its origin in work in the classroom, in the laboratory, and at the bedside. The illustrations are quite the best we have seen, and many of them will be familiar to every reader, for the reason that they have been borrowed again and again by subsequent writers, "generally with acknowledgment of their origin, which is good, but not always, which is bad." There is no other work on lines similar to this one, and it would be difficult to say how it could be improved.

Manual of Operative Surgery. By John Fairbairn Binnie, A.M. C.M. (Aberdeen), Professor of Surgery, Kansas State University; Kansas City Fellow of the American Surgical Association; Membre de la Société Internationale de Chirurgie. Vol. I. Operations on the Head, Neck, Nerves, Trunk, Genito-Urinary System. Fourth edition, revised and enlarged, with 713 illustrations, a number of which are printed in colors. Philadelphia: P. Blackiston's Son & Co., 1909.

Although the chapters on orthopedic surgery and on the veins, contained in former editions, have been omitted from this, and although it still can be, as its author says, slipped into a coat pocket, the book is nevertheless larger by some two hundred pages than the first edition. The chief changes are in the chapters on the kidneys and on the nerves, the latter of which has been entirely rewritten and much enlarged. The various methods of nerve suture and of nerve anastomosis (sic) are described and illustrated in a most lucid manner, as are also the operations for Erb's palsy. Operations for stretching the peripheral nerves close the chapter. The chapter on renal surgery, while eminently practical, does not sacrifice clearness to brevity, and that on goiter has been much amplified and contains a résumé of recent writings on the subject. Many new illustrations have been added to this edition. It is an excellent book, and the fact that it has been through four editions since 1905 speaks well for its usefulness. It tells the reader not only what to do but how to do it

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Twenty-fourth Annual Meeting, Held in Washington, D. C., May 11 and 12, 1909.

DR. VICTOR C. VAUGHAN OF ANN ARBOR, MICH., IN THE CHAIR.

Tuesday, May 11—First Day.

President's Address.—DR. VICTOR C. VAUGHAN of Ann Arbor, Mich., took for the subject of his address "The Physical Basis of Life." He said that it had frequently been stated that the cell was the unit of life. The cell might be regarded as a morphological form of life. When matter was endowed with life, it did not cease to be matter; in studying the organized cell of living things it should always be borne in mind that it might be peculiar in composition but was subjected to the fundamental laws regarding matter. It was the molecule, and not the cell, that was the unit of life; so long as the molecule was the seat of excretion and secretion, it lived. The one phenomenon about living matter, not a part of nonliving matter, was metabolism. Molecules were not stable. The physical function of living matter seemed to be the absorption of energy to be expended in kinetic or an active form. Life was a function; it was a molecular function. Molecules fed, regenerated, supplied themselves with energy and new material. After speaking of two kinds of metabolism which occurred, one throwing out small amounts of carbon and hydrogen, the other the nitrogenous metabolism in which urea was eliminated and replaced by fresh material, he called attention to the fact that all forms of life, even those in which there was no trace of any nervous tissue, behaved in a purposeful manner; they had apparently learned by experience to choose between what was good and what was bad for them. Dr. Vaughan said that they had heard much of late concerning the influence of the mind upon the body, and many who spoke upon this subject seemed to assume that there was some entity, called mind, which controlled the body, to which it was superior, and apart from which it might exist. This dualistic doctrine was as old as the philosophy of Plato. It always had been and remained to-day a dogma without scientific support, and as an hypothesis it had led to the discovery of no scientific fact. Every attempt to apply it to the treatment of disease had led to the development of conscious or unconscious charlatanism, and had resulted in more or less marked atavism. The term functional disease was now being used by those who knew but little concerning the functions of the body in either normal or abnormal states. It seemed to be inferred or assumed by those using this expression that a mysterious power had been given to some to set the mechanism of a disordered body aright, although those supposed to be possessed of this gift had no knowledge, or but imperfect and superficial acquaintance, with the functions of the various organs and their interrelations. In truth, they had no evidence of the existence of a functional disease as thus understood. In health the several organs of the body functioned harmoniously, and they knew of no disease in which they did not act inharmoniously. He said they might not always be able to find where the basic fault lay. But should they for this reason stop looking for it, shut their eyes, give over the search, and ask some individuals, quite ignorant of the body and its functions, to undertake the task of inducing harmonious activities? Of mind apart from the body they knew nothing. Of the brain as one of the correlated organs they knew nothing, and by continued and patient research they hoped to learn much more. They did know that the cell molecules of the brain were the most complex and the most susceptible to external influences of any of the structures that constituted that community of organs which made up the individual. Medical observation and study had shown that healthy cerebral function was to be found only when the activity of the brain was properly influenced by normal function of all the correlated organs. They knew equally well of the influence of the brain on the other organs of the body. They were fully aware of the fact that impulses might be started in the brain through any of the five senses that might favorably or unfavorably influence the activities of the correlated organs. And for centuries the medical profession had employed this physiological principle in the treatment of disease.

Three Unique Cases of Amaurotic Idiocy, with an Anatomical Study of One.—Drs. HARLOW BROOKS and HENRY WANDLESS of New York presented this communication. They gave a brief outline of the disease. It was generally fatal, the patients dying before the second year of life. The clinical aspects of the disease were briefly passed over. In the juvenile type of the disease, as described by Sachs, the onset began in about the sixteenth year and progressed much slower. With regard to the pathological anatomy, there was a tremendous regeneration of ganglionic cells; this one type of cell, the swollen ganglion cell, was seen in no other disease. Cell regeneration here was a very complex process. Among the theories regarding this disease was that it was toxic in origin; if that was so, how about so many cases occurring in one family, and why should there appear different types of the disease in the same family? Three unique cases were reported; they occurred in a family of seven children. The parents were living and well. The children were brought up in an absolutely irreproachable way. Until the disease appeared the children were as bright as others of their age. A brief report of these three cases followed, with a protocol and anatomical study of one case. The changes in the brain and spinal cord were precisely like those described by Sachs.

Dr. B. SACHS of New York said that the cases described by Dr. Brooks were a form of disease very closely allied to amaurotic family idiocy, and were on a line with the cases Volk had designated as the juvenile form of amaurotic family idiocy. Changes in the macula lutea were not present in the cases described by Dr. Brooks, and the cases were more rapidly progressive; yet the two forms were so closely allied that it was very hard to separate them. It was very interesting to compare the anatomical findings in the two groups of cases. Dr. Sachs now had a typical case of amaurotic family idiocy, of which he showed photographs and drawings. Especial interest was attached to this disease, not merely because it represented a clinical entity, but that it would possibly lead to further studies, especially in heredity. The changes in the ganglion cells and other pathological findings in the disease showed that there was a change in the entire gray matter of the central nervous system; there was not a normal ganglionic cell left in any part of the central nervous system. The changes in the cells were most marked, and represented a swollen cell body, an unusual swelling of the dendrites. The primary change was evidently one in the plasma of the cell body. There were two theories regarding this disease. One was that it was a congenital affair; the defect in the nervous system was such that the children were equipped only for certain and limited function: in other words, at the start in life they could perform their functions properly only for a number of months, and then these nerve elements would give out, or undergo degeneration. The other theory was that the disease was toxic in origin, but Dr. Sachs could not conceive of this form of disease being due to toxic causes and not to anything else.

Visceral Angioneuroses.—Dr. Solomon Solis Cohen of Philadelphia read this paper, which recalled attention to his previous communications on the subject of vasomotor ataxia. The condition was by no means rare, and was marked in certain families, especially in those exhibiting hereditary tendency to disorders of metabolism, gout, diabetes, etc. It existed in some persons without causing any inconvenience. When, however, disease of any kind or from any cause arose in such persons, their constitutional peculiarities modified the symptomatology. An incautious observer, or one who did not recognize the significance of the vasomotor phenomena, might easily be led astray. This was especially the case in maladies attended with hemorrhage, whether slight or profuse, with cardiac disturbance, with headache, with painful crises, or with serous discharges. The dependence of certain asthmatic paroxysms upon what might be termed bronchial urticaria was emphasized in the author's previous communications, and was well known before that. Less familiar were the angioneurotic edemas of the base of the tongue and of the larynx, which caused suffocative paroxysms and might threaten death. Still rarer in the literature and in practice was the recognition of angioneurotic conditions of the gastrointestinal tract, the liver, and the kidney. Certain uteroovarian symptoms might, by analogy, be ascribed to similar processes, and there was no reason for excluding any viscus or tissue supplied with vessels. Considerable doubt and difficulty arose when cerebral symptoms were manifested. Dr. Cohen had seen two cases in which operations for appendicitis had been performed by reason of painful abdominal crises of angioneurotic origin, and normal appendices had been found. The operation was nevertheless justifiable in both instances by reason of the doubt always attending the diagnosis of visceral angioneuroses. The evidence from morbid anatomy supporting the disagnosis of viscreal angioneurosis was, from the nature of the process, practically unattainable, except negatively in the rare instances of surgery and the still rarer instances which could be followed throughout life and after death. Organic disease or deformity might coexist with angioneurotic disorder, as exemplified by one of the author's cases, in which malposition of the kidney was responsible for some of the symptoms, and these, together with general nutrition, were relieved by successful operation. Furthermore, it was Dr. Cohen's conviction, from the cases observed over prolonged periods, that actual disease of the vessels (angiosclerosis) might eventually be set up, pseudoangina, for example, becoming veritable angina. A number of cases were seen in which Graves' syndrome developed under observation from a basis of slight vasomotor ataxia, and one in which an incomplete Raynaud's syndrome similarly developed. A notable case was one which began with uremic symptoms, including suppression, and in which the patient exhibited no evidence of nephritis, but had passed through and recovered from the full Graves' syndrome.

Dr. William Osler of Oxford University, England, said that the subject under discussion led to much theoretical consideration, and he had never seen much beyond what his eyes had seen. The association of angioneurotic edema with certain skin disease was of the greatest practical moment, as was it with lesions of the abdominal organs, particularly the stomach and intestines; here angioneurotic edema might occur with symptoms of nausea, vomiting, pain, etc., and changes might be found in the walls of the stomach or intestines, or both, which were the counterpart of those occurring in the skin. These were an interesting group of cases and might or might not be associated with skin lesions; in children such changes might appear years and years before the skin lesions occurred. It should be borne in mind that hemophilia might be associated with very severe attacks of angioneurotic edema. Another group of cases was associated with arteriosclerosis and spasm of the blood vessels. It was certain that these cases of "angina abdominalis" had symptoms like those of angina pectoris and were due to spasm of the visceral blood-vessels. There certainly seemed to be a great perplexity on this subject of angioneurotic edema, but there was too much theory about it.

Clinical Experiments with Homologous Vaccines.—Dr. W. Gilman Thompson of New York recorded some of his failures as well as successes with these experiments. There were four out of eight cases which recovered, and three of them were subjects of endocarditis. The dosage was between fifty and two hundred million, given at intervals of two, three, or four days. The effect upon the temperature and other phenomena was very striking, and he showed charts of one particularly interesting case of recovery from a streptococcus endocarditis, and also one of pyemia. In each case the streptococci appeared to have been driven from the blood by means of the vaccination. The cases of malignant endocarditis of streptococcus origin and of pyemia were treated by the Wright method. In conclusion, Dr. Thompson referred to the importance of proper technique and the possibility of cure in some cases and of amelioration in others.

Dr. Blumer of New Haven, Conn., called attention to the fact that perhaps streptococcus infections were not so serious as they were imagined to be, and on more than one occasion he had been able to obtain streptococci from the circulating blood in individuals who were very ill, and before the days of vaccine therapy, and they got well spontaneously. In the last two years he saw a man who presented the typical signs of a malignant endocarditis get well, although he had remaining a valvular lesion. While vaccines in these cases might have something to do with the recovery of the patients, he believed they should be more conservative in their interpretation until the cases were numerically larger than they were at present, and had been more thoroughly investigated.

A Study of Achylia Gastrica.—Dr. Charles G. Stockton of Buffalo gave an analysis of 132 cases he had studied—62 males and 70 females, with ages running from 21 to 72 years, there being but five cases under 30 and but one over 70. There were 44 occupations of different natures, showing that apparently this had no bearing upon this disease. The previous histories were not as completely recorded as he wished they had been, but 25 per cent. of this number had complained of long-continued stomach trouble, 14 per cent. of some mental strain and worry, and 10 per cent. had had typhoid fever; 10 per cent. had had pneumonia; 30 per cent. had marked eye strain. In 23 cases there had been pernicious anemia, and in 8 arteriosclerosis. Anemia was a very frequent complaint. Diarrhea usually followed a condition of constipation. Occasionally the stomach would empty itself before the test meal could be utilized; there seemed to be some unusual motor activity. Albuminuria was present in 23 cases, something that was quite remarkable. Vomiting occurred in 20 cases, nausea in 10, and pain in 19. There was gastrointestinal distress in 30 cases. There was a very profound mental attitude in those patients who knew they were sufferers from this condition. The general symptoms were rather vague; there was headache, fatigue, disturbed sleep, loss of weight, and they complained about their intestines and liver. There was general weakness and depression in 33 cases, loss of weight in 24, arteriosclerosis in 24. Dr. Stockton closed his remarks with a discussion of the gastric chemistry.

Dr. Theodore C. Janeway of New York said that an examination of the stomach histologically after death was attended by difficulties which could never be remedied in the future, because of the post mortem degeneration which

occurred before the autopsies were obtained; therefore they could not hope to obtain any accurate information regarding the mucous membrane of this organ. Pernicious anemia was associated especially with those persistent types of diarrhea, and a number of persons, especially those coming from Cuba and South America, on careful examination, would be found to have achylia gastrica, and these were the cases that would readily respond to the administration of hydrochloric acid and pepsin after meals. The condition seemed in these patients to be due to a lack of stimulation of secretion formation. The cases associated with pernicious anemia and diarrhea seemed to give a little hint at therapeusis.

Chronic Cholecystitis as a Cause of Myocardial Incompetence, with Reports of Illustrative Cases.—Dr. Robert H. Babcock of Chicago gave a brief discussion of the frequency and symptomatology of gall-bladder disease, as this latter bore upon cases of the kind under consideration. Thirteen cases were considered, and they were divided into four groups: (1) Those displaying pronounced myocardial inadequacy, with dilatation and murmurs; (2) cases with pain, either of an anginal character or mistaken for angina, together with dilatation and incompetence; (3) cases showing persistent intermittence of the pulse or irregularity without marked symptoms of inadequacy and relieved by operation; (4) cases of valvular disease, in which compensation was destroyed and recovery prevented by attacks of hepatic colic or allied symptoms. Ten of the thirteen cases were operated upon, three resulting fatally. In four of the cases, as the result of operation, a very marked and gratifying improvement in the cardiac condition was noted. There seemed to be some predisposing factor in some diseases of the myocardium. He insisted upon the necessity of an early diagnosis of gall-bladder disease and the wisdom of operating to prevent loss of myocardial inadequacy. Operations in such cases were less serious, even in cases of myocardial inadequacy, than temporizing and leaving the patients unoperated upon. His concluding remarks were upon the possible mechanism of the effects on the heart and the literature of the subject, so far as this had been ascertained.

Dr. Edward G. Janeway of New York said that, no doubt, all present had seen cases of heart weakness in which there was some inflammation of the gall-bladder, or gallstones, or hepatic colic, but their cases had not been brought together in such a way that the question could be asked, how far the irritation of the gall-bladder, etc., and the weakness that was induced brought about myocardial incompetency. He believed that too often they were afraid to advise operation because of the heart condition, and it was surprising how the heart would stand operations if they were done without a general anesthetic: operations should be quickly done, and under local anesthesia in such cases, and it was remarkable how the heart would stand them.

Locomotor Ataxia and Paralysis Agitans in the Same Patient.—Dr. Augustus A. Eshner of Philadelphia said that locomotor ataxia and paralysis agitans had little or nothing in common—etiologically, anatomicopathologically, or symptomatologically. Their associated occurrence in a given patient must, therefore, be looked upon as a mere coincidence. While by no means rare, neither disease was common, and their association was correspondingly infrequent. Only a small number of cases had been placed on record in which both diseases had been present in the same patient. In Dr. Eshner's case, which occurred in an elderly man, the symptoms of paralysis agitans were observed while the patient was under treatment for locomotor ataxia, although members of his family had noted some shaking of the hands for many years.

Further Observations on the Third Heart Sound.—Dr. William S. Thayer of Baltimore reported the results of examinations on 231 normal individuals; 65 per cent. showed the characteristic third heart sound, a sound he had described at the last meeting of the association. In the first three decades of life this sound was heard as a rule, and it was caused by a slight tension of the mitral valve associated with the first inrush of the blood from the auricle. It was not *per se* an abnormal condition.

Dr. James L. Wilson of Philadelphia said he had heard the sound described, but that it was normal had never occurred to him.

Normal Auscultatory Differences Between the Sides of the Chest: (a) At the Bases Behind; (b) in the Lateral Recumbent Position.—Dr. Richard C. Cabot of Boston examined 250 chests that, so far as he could find out, were normal, and in 64 per cent. there were differences between the two bases: at the left base behind the breathing in 64 per cent. of the cases was harsher, rougher, and slightly louder than at the other base. All of them knew that for a long time it was believed to be unwise to examine patients when in the lateral recumbent position, because it was supposed to modify the sounds. Because of a difference of opinion on this point he asked his colleagues what the difference was, but they were unable to tell him. In fifty chests examined they seemed to be practically identical in regard to this point. Lying upon the side seemed to diminish the excussion of that side of the chest.

Orthodiagraphy in the Study of the Heart and of the Great Vessels.—Drs. Thomas A. Claytor and Walter H. Merrill of Washington described this method for demonstrating the exact size and position of the heart and great vessels, and charts were presented showing the size and location of the hearts of forty-two males and fifty-four females, showing the effects of bodily positions upon the location of the heart, showing a comparison of the percussion boundaries of the heart and those obtained by the orthodiagraph, and showing the heart in diseased conditions.

Dr. L. A. Conner of New York said that percussion of the right side of the heart was very satisfactory in its results and would correspond with the orthodiagraphic findings, provided the percussion was made heavily, with the finger pressed deeply and during deep inspiration.

Dr. Francis H. Williams of Boston said they should not deceive themselves into believing that any special method of percussion was going to give an accurate outline of the heart in all cases, although it might do so in a certain proportion of the cases.

Sensitization in Tuberculosis.—Dr. V. C. Vaughan, Jr., of Detroit discussed the nature of sensitization, the phenomena of general sensitization, local sensitization and its significance, and the possible value of the split products of the tubercle bacillus in the treatment of pulmonary tuberculosis.. The ophthalmic reaction which resulted from the instillation of tuberculin into the eye, if it was a positive reaction at the first instance, was a valuable and confirmatory evidence regarding the existence of tuberculosis; failure of the reaction, however, was of no value in diagnosis. By means of chemical agents, Vaughan had been able to split tubercle bacilli into poisonous and nonpoisonous portions; that was, he had been able to remove the poisonous group from the protein of the tubercle bacillus, and attempts had been made to ascertain what would be the result if the patients suffering from tuberculosis were treated with the nontoxic tubercle protein. Whether this protein was the same as would be obtained from tuberculin with the poisonous group removed was a question he was unable to answer, for they were not sure of the real nature of tuberculin. If the nontoxic portion of the tubercle bacillus had any thera-

peutic value, the action would be against the bacillus itself. What Dr. Vaughan offered was in the nature of a preliminary report.

Some Studies with the Cutaneous Tuberculin Test.—Dr. Lawrason Brown of Saranac Lake, N. Y., made this preliminary report and offered the following conclusions: (1) Much work must be done with the cutaneous test. (2) The test should not be pronounced negative until at least four, or, better, seven, days have elapsed. (3) The old tuberculin should be used, and a 25 per cent. solution was probably as effective as stronger solutions, but if the test was negative with a 25 per cent. solution, the full strength should be used for the second inoculation. (4) Failure to react to the cutaneous test did not absolutely exclude reaction to the subcutaneous test, nor did reaction to the cutaneous indicate that reaction to the subcutaneous test would always occur. (5) The degree of severity of the reactions to the cutaneous and subcutaneous tests did not go hand in hand. (6) It was difficult at present to judge of the prognosis from the cutaneous test. (7) Some sera, especially those from patients treated with higher doses of tuberculin, or from animals with higher agglutinative powers, when mixed with weak dilutions of tuberculin, tended to retard the cutaneous test.

Observations on the Cutaneous Tuberculin Reaction.—Drs. George Dock and Randolf Lyons of New Orleans reported a series of cases which indicated that the reaction was not present in as large a proportion of adults as might be imagined from the large number of adults with latent foci; the reaction could be obtained in many plainly tuberculous cases in a striking manner, but not so well or not at all in some others; the importance of gaining a wider knowledge of the reaction by carefully conducted tests with standard tuberculin before the results could be used with success in general practice was emphasized.

Types of Tubercle Bacilli Found in Human Tuberculosis.—Dr. William H. Park of New York said that he decided to take up and study consecutively a large number of cases of tuberculosis, testing with the usual culture material on rabbits and a few cats. There were 17 cases, two hospitals in New York City furnishing 8 apiece; in 12 cases human type was found, and in 5 cases the bovine type. In 8 cases from the Babies' Hospital only one showed the bovine type. In 10 cases of tuberculous meningitis in infants all were due to the human type; autopsy was performed on 5, and in all a general tuberculosis, well developed, was found. In these cases with the meninges markedly involved the human type of infection was probable. Dr. Park wished to report two histories, one of bovine and the other of human general tuberculosis, showing how much alike they were, but time would not permit. In two cases of bovine infection of the peritoneum, one mild case recovered after operation; the other, a severe case, died after operation. In 29 cases the lymphoid glands were examined; in 9 there was found the bovine type of infection. The bovine type of infection, as a rule, occurred earlier in life than the human. In his series there were only 5 cases of infection of joints and bones, and all were of the human type. In pulmonary tuberculosis there were 220 cases, and all were of the human type. In conclusion, he said that in children there occurred a considerable number of cases of bovine tuberculosis, whereas adults were seldom infected with the bovine type.

The Effect of the Ingestion of Dead Tubercle Bacilli.—Drs. M. J. Rosenau and John F. Anderson of Washington made this preliminary report of their work. The feeding of dead bacilli to guinea pigs did not alter their susceptibility to tuberculosis. It seemed to have no evident effect upon the subsequent course of the disease. It was not safe to conclude from this, however, that the ingestion of dead bacilli under all circumstances was harmless, though this was perhaps indicated. None of the 100 guinea pigs fed with dead bacilli lost weight during the sixty days this process continued. It was also evident that if a guinea pig was given a sufficient amount it might be infected by ingestion, for all animals, with one exception, became infected. In one instance the lesions of ingestion tuberculosis were all above the diaphragm. They hoped to be able to present more knowledge on this subject when their experiments were completed.

Dr. William H. Welch of Baltimore believed that Dr. Park's contribution was of great importance, especially in regard to the large number of cases of pulmonary tuberculosis in which no bovine bacilli were found; this confirmed Koch's well known contention. He asked Dr. Park if all these cases occurred in adults.

Dr. Park replied that there were but four cases between the ages of ten and sixteen.

Dr. Welch said that cases of pulmonary phthisis in the young were uncommon, but that they did occur.

Dr. Solomon Solis Cohen of Philadelphia thought a very important point was the fact that they might be enabled to determine what the minimum dose of tuberculin was. Formerly he had been afraid to use this test, but recently he had been using it in cases of pulmonary tuberculosis with good results, but not always with recoveries.

Dr. A. Jacobi of New York described the method he used, following the teachings of von Pirquet. He used only a very small part of a drop; one drop furnished material to suffice for twenty or twenty-five vaccinations. After scarifying, he inoculated, and placed on a shield. The patients were never allowed to go without the shield; even when they reacted, the shield was left on four or five days before thrown away.

(To be continued.)

THE PRACTITIONERS' SOCIETY OF NEW YORK.

231st Regular Meeting, held Friday, February 5, 1909.

Dr. E. G. Janeway in the Chair.

Pulsating Tumor of the Forehead.—Dr. Walter B. James again demonstrated the patient shown by him at a previous meeting of the Practitioners' Society. The case was that of a young man who presented a curious pulsating swelling upon the forehead, the swelling being supplied by several vessels, one of them probably continuous with vessels within the cranial cavity. The young man's life had been made miserable by the symptoms produced by the swelling, consisting of headache, vertigo, roaring in the ears, etc. Dr. James said that he has turned the patient over to Dr. Robert Abbe for operation since the last meeting of the society. Dr. Abbe ligated the two temporal vessels that were supplying the tumor, and then tied the pulsating mass by means of several ligatures. The result of this was that the humming sound heard over the mass disappeared; the tumor itself diminished in size very markedly, and, finally, the symptoms complained of by the patient were relieved completely. Indeed, the latter said that he has felt better since the operation than ever before since the beginning of the growth upon his forehead.

Radium in the Treatment of Tumors.—Dr. Robert Abbe showed a patient suffering from a mixed tumor of the parotid gland. He began treating the patient one month ago by making incisions into the tumor and slipping a tube of radium into the wound thus made. The tumor has decreased to one-fifth of its former size as a consequence of this procedure, and the speaker hoped that the cure may be accomplished with persevering in the use of the radium, as had apparently been done in the man recently shown,

who remains well after two years. The second case was that of a girl suffering from a sarcoma of the jaw of two years' standing. The tumor was very large, filling out the mouth and completely occupying the place normally taken up by the tongue. The tumor was of the spidle-celled variety, and this fact made it especially interesting in connection with the treatment of tumors by means of radium. Dr. Abbe has found that giant-celled tumors are favorably affected by being exposed to the action of radium, while sarcomata composed of cells of other varieties are much more difficult to treat in this fashion. He promised to show the patient at a future meeting of the society, after radium treatment has been carried out for some time. Even at the present moment, after a very brief duration of treatment, favorable changes could be noted. The tumor tissue had grown much firmer since treatment was begun, though previously it consisted of a very soft mass such as rapidly growing tumors usually showed. Now it seemed to have begun to ossify. The next case was that of a young girl who presented on auscultation at the root of the neck a curious humming sound, to interpret which was quite difficult. It suggested the possibility of an aneurism, yet a very similar bruit could be heard in cases of goiter, with very much dilated vessels supplying the thyroid gland. Another case was likewise shown in whom the same sound could be heard on auscultation, and the reason for the production of the sound in this instance was the probable existence of an arteriovenous communication in the vessels of the neck. Still another patient, suffering from an exophthalmic goiter, presented a like feature, such humming sound being, of course, quite frequently observed in cases of this disease. Finally, Dr. Abbe showed still another patient who was suffering from a large pulsating goiter. This patient was seen three years previously by Dr. Walter B. James, who sent him to Baltimore for operation. The operation was begun, but not carried out, because the growth, after being exposed, appeared to have a character quite different from a simple pulsating goiter. It seemed, namely, that the growth had all the microscopic appearances of a malignant tumor. A small piece was removed for microscopical examination. The specimen obtained was examined by a pathologist, who pronounced it to be an adenocarcinoma arising in an old goiter. This operation was performed in December, 1905. Since then the tumor has gradually increased in size, and now presented a typical pulsating mass. Over this tumor a humming sound such as was present in previous patients could also be heard. The speaker had been treating this growth with radium, using for the purpose open gold cages, into which the radium tube could be introduced. A cylindrical punch was devised by him, by means of which a piece of tissue could be punched out just large enough to admit the radium tube with its case. This method of using radium, the insertion method, was original with Dr. Abbe, and bade fair to become an important addition to the technique of its use, for with it the action of the salt could be tried on deep portions of tumors. Dr. Abbe expected to show the patient again at some future meeting. Three cylinders of this dense goiter had been carefully studied by Dr. F. C. Wood at St. Luke's Hospital, and, though taken from central parts of the growth, showed only hypertrophic thyroid tissue, which corroborated the clinical evidence that its long existence spoke against the probability of a malignant character.

Dr. James thought that the sound heard over the vessels of the neck in the girl patient presented by Dr. Abbe was a *bruit de diable*, which is quite a common physical sign in young girls suffering from anemia. It had a systolic exacerbation, however, which made it more similar to the aneurysmal bruit than is usually the case. The sound could be stopped by compressing the jugular vein low in the neck. Further proof of the nature of the sound was given by the increase in its intensity with inspiration, a phenomenon easily explained by the effects of deep inspiration upon the venous circulation in the veins of the thorax and neck.

Dr. E. G. Janeway agreed with Dr. James in calling the sound a *bruit de diable* produced in the veins.

Remarks on and Cases Illustrative of the Etiology of Pain.—Dr. E. G. Janeway read this paper. (See page 917.)

Dr. G. L. Peabody said that the paper read by Dr. Janeway called to his mind many instances of sudden death following attacks of pain of apparently innocent character. Frequently, too, though pain had existed before any serious features of the case developed, the history of it was not communicated to the physician. He vividly remembered the case of a well known physician who dropped dead while walking on a New York street. The autopsy showed only a moderate lesion in the coronary arteries, and as the family of the dead man could not recall any complaints of pain the diagnosis of angina pectoris, which of course suggested itself, could not be made. Only later Dr. Peabody happened to talk to a servant of the dead man and was told that the latter had often suffered from attacks of pain which were accompanied by profuse perspiration, dyspnea, etc. The servant was, however, enjoined not to mention anything of these attacks to the other members of the household. Dr. Peabody said that the coronary lesions in this case were very slight, yet proved fatal; he had seen before and since many hearts showing much more extensive lesions of the coronary arteries, yet no history of angina pectoris could be obtained in many of these cases. Not only, therefore, can the clinical picture lead to undervaluation of the severity of a case, but even the findings at the autopsy do not allow a certain diagnosis to be made of the character of the symptoms during the life of the patient. Dr. Janeway's paper was welcome, as it called attention to the necessity of care in basing absolute conclusions on such a deceptive symptom as pain.

Dr. Bryant said that the warning contained in Dr. Janeway's paper in regard to the danger of making light of the complaint of pain when no physical signs are present is very timely. Yet one must not forget the other side of the question and take care not to put too much faith in the statements of the patients and their subjective complaints. He was once called in a case as a consultant, another surgeon having advised amputation of the thigh because of severe pain in the knee of long duration, which no remedies could control. The physical changes in the knee were, however, so slight, and even uncertain, that Dr. Bryant refused absolutely to concur in the advice of the other surgeon, and the amputation was not done. The patient continued to have the same symptoms for some time, but finally was completely relieved by simple measures. Dr. Bryant had no doubt that most of the symptoms in this case were due to a coexistent hysteria, and not to any serious joint disease. Of course, just the opposite turn of affairs happens in other instances; he remembered one patient who complained of sudden obstinate pain in the instep. He was treated for rheumatism, little attention being paid to the changes in the physical signs about the involved area. The development of gangrene, involving much of the foot, soon showed, however, that the case was not that of rheumatism, and an early amputation of the toe could have saved the patient's foot.

Dr. Starr said that one variety of pain was not mentioned in Dr. Janeway's paper, and he would like to call attention to it because of the frequency with which surgical operations are performed for its relief. He had in mind the pain felt in the tip of the spine, the socalled coccydynia, which is frequently met with in nervous women. Dr. Starr was sure that hysteria had much more to do with this pain than any lesions of the coccyx. Surgical interference was certainly not called for in the great majority

of cases; indeed, if any operation was performed the usual consequence was that the symptoms returned as soon as the early psychic effects of the operation were gone. Dr Starr would warn practitioners against advising operation in these cases except in very rare instances, when anatomical changes could be surely demonstrated. Most of the patients of this type belong to the class of neurotic women whose nervous system must be strengthened by proper treatment.

Ulcer of the Stomach Cured by Simple Medication and Diet.—Dr. Beverley Robinson said that last summer he saw a lady affected with ulcer of the stomach. She had had very good expert advice, but was no better. Dr. Robinson counseled her as to diet, which was already careful and judicious, and gave her medicinally milk of bismuth (hydrate and subcarbonate of bismuth suspended in water) and lactic acid bacillus tablets. The result of treatment could be appreciated after listening to her husband's letter to Dr. Robinson on November 24, 1908, from which the following extract was read: "Unquestionably, the last bacilline tablets have been most efficacious; the disagreeable symptoms of her case, from which she has suffered for years without relief, have almost completely disappeared. She seldom has now acute attacks, and these are invariably relieved by the bismuth preparation," etc. "Under the advice of her physician, Dr. G., she is drinking daily much prepared milk with the tablets." On December 15, 1908, the husband wrote: "You will be gratified to know that she is enjoying good health." On December 31, 1908, the husband wrote: "Her health steadily improves, life is a joy to her, and we all pour benedictions on your head." Dr. Robinson then read the following extract from a letter received from Dr. L. H. Neuman of Albany, N. Y., on December 30, 1908, in regard to the foregoing case: "An examination of the stomach contents showed a marked hyperchlorhydria, with some blood and considerable epithelial desquamation. There was considerable localized tenderness and muscular spasm over the epigastrium. I looked upon the condition as one of chronic ulcer." A second case reported by Dr. Robinson was that of a single woman, thirty-three years of age, who did general housework. She had been treated with milk of bismuth. The result was shown in a letter of December 14, 1908, of which the following was an extract: "Since beginning to take the treatment I felt myself getting better each day. I have continued to take the treatment, as you told me, and have felt very well until the last few days, when I could not get the medicine. If I do not take it I feel somewhat bad. So far as I can remember, I took sick early in June, 1908. I was taken with a fainting spell, and afterward vomited up over a quart of blood at once, in very large chunks, so to speak, but that was all. I do not eat very much, as my appetite seems to be satisfied with the arrowroot, gelatine, etc. I must say I feel like a new person." Dr. Robinson said that these two cases appeared to him worthy of mention. He had seen and treated a great many cases of ulcer of the stomach, but failed to recall any two in which he had had such satisfactory results, apparently, as those which he reported this evening. He had come to the conclusion, in view of many cases of different kinds seen and treated by him, that milk of bismuth was the best bismuth preparation; further, that it was serviceable in more instances of gastrointestinal disturbances (dyspepsia, diarrhea, dysentery, etc.) than any other remedy with which he was familiar.

Specimen from a Case of Diabetes.—Dr. Kinnicutt presented a portion of the large intestine and sections of the pancreas from the same individual. He said that the clinical history was of a patient, male, forty-three years, afflicted with diabetes for a doubtful period; the urine eighteen months previously was known to have contained 5 per cent. of sugar. He was admitted to the speaker's wards in the Presbyterian Hospital, suffering from diabetes, a perforating ulcer of the right foot, chronic nephritis, uremia, and chronic endocarditis. Lumbar punctures for the relief of the uremic symptoms recovered 150 c.c. of sterile cerebrospinal fluid under 235 mm. pressure, with marked relief of the uremic symptoms for a number of days. The urine gradually became sugar free, and continued so for a month previous to death. The perforating ulcer completely healed. During the last nine days of life there were signs of an acute colitis—very numerous stools of blood and mucus. The specimens were of interest in the almost complete obliteration of the islands of Langerhans, the pancreatic tissue otherwise showing little change; in the extent and acuteness of the colitis, which of a less severe grade was often seen in the terminal stages of nephritis, and in the presence of the staphylococcus aureus in addition to the colon bacillus. The organisms had penetrated even into the musculature of the intestine. The lesion of the submucosa in many places somewhat resembled that seen in phlegmonous gastritis. Finally, the lesion of the thyroid was of interest, in view of recent investigations and theories upon the functional interrelation of glands with internal secretion. In the present instance a definite lesion of the thyroid, although not extensive, existed as well as an advanced organic disease of the pancreas—pancreatic diabetes. The following was the laboratory report by Dr. Cecil:

Thyroid Gland.—Normal in size and consistency. Cut surface is pinkish red and gelatinous. Microscopic sections show a number of alveoli enlarged and filled with colloid material. These are separated by a large number of smaller alveoli, very irregular in outline and lined with cuboidal epithelium. The mucosa in these smaller alveoli is often thrown up into folds and their lumina are generally free from colloid material. The picture is that of a thyroid hyperplasia.

Pancreas.—Small and atrophic, weighing only 70 grams; 21 cm. in length. Body is 1½ cm. in thickness and 2½ cm. in breadth. The organ is of firm consistency, with small but distinct lobules. The islands of Langerhans are invisible. Microscopically, there is a slight increase in the interacinar connective tissue in some places. The arterial walls are thickened and hyaline. The glandular acini appear normal. The islands of Langerhans are numerous. Only a few of them present a normal appearance. The great majority have been almost completely converted into a structureless hyaline material, which takes a bright pink eosin stain. As a rule, the insular cells have been entirely replaced by the hyaline deposit; those which remain are compressed and atrophic.

Colon.—The wall of the large intestine from cecum to anus is considerably thickened. On opening the gut the mucosa presents a remarkable appearance. The mucosa is absent in many places. That which remains is a deep violet red, and stands out in marked contrast with the pale yellow ulcerated patches. The ulcers are generally shallow, with slightly elevated, irregular borders and rough, necrotic looking bases. Dark, reddish black haemorrhages are often found along the edges of the ulcers, beneath the mucosa. The ulcers vary in size from that of a pin head to several cm. in diameter. They are largest and most numerous in the descending colon and sigmoid flexure, but occur in all parts of the large intestine. There is considerable oedema and hyperplasia of the submucous tissue, a condition which often causes the ulcers to protrude above the surrounding mucosa. Microscopically, sections from the colon show partial absence of the mucosa. At these points the submucosa and part of the muscularis are necrotic. The necrotic tissue and the parts surrounding it are densely infiltrated with polymorphonuclear and lymphoid cells. Bunches of staphylococci occur in large numbers in the inflamed tissue. The muscularis and serosa are thickened. Smears from the ulcers show cocci and Gram negative

bacilli. Blood agar plates were inoculated with macerated mucosa and grown aerobically and anaerobically. *Staphylococcus aureus* and *Bacillus coli* were the only pathogenic organisms recovered.

THE AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-fourth Annual Meeting, Celebrating the Centennial of McDowell's Operation, held in New York City, April 20, 21, and 22, 1909.

THE PRESIDENT, DR. J. RIDDLE GOFFE, IN THE CHAIR.

(*Concluded from page 910.*)

A Method of Obtaining More Accurate Knowledge of the Exact Areas of Pain Complained of by Patients Afflicted with Visceral Disease.—Dr. PHILANDER A. HARRIS of Paterson, N. J., said that when a patient complained of pain she was at once asked by the nurse to indicate the exact area of pain, and also to point to the center or point of most severe pain. The nurse then marked the outer boundaries, as well as the center or centers of pain complained of, employing therefor a definite code. All markings were maintained on the body until they were transferred by the doctor to the history book or sheets. The nurse in entering upon her notes descriptions of pains thus avoided the necessity of reference to anatomical regions. He gave a description of the marking code. He presented a copy of the standing instructions to nurses for the prosecution of this work, and showed photographs from life of patients thus marked.

Further Reasons for Examining and Removing the Appendix Before Closing the Abdomen.—Dr. A. LAPTHORN SMITH of Montreal said that (1) abdominal section had now a very low death rate. The few deaths which occurred were due to something going wrong, the cause for which had not always been discovered, even after the abdomen had been reopened. He believed that this unknown cause was in many instances a chronic appendicitis, which either suddenly became acute or which caused obstruction of the disabled intestine by adhesions. (2) The death rate from puerperal sepsis was now very small, and the few deaths which took place could not always be attributed to infection by the doctor, nurse, or even by the patient herself. The author gave instances to prove that the abdomen should be opened and appendix examined in every serious case, as he believed that many supposed deaths from puerperal sepsis were really due to perforated or gangrenous appendix. (3) The removal of this dangerous and useless organ, when it could be done without adding materially to the danger of the laparotomy, would insure the patient against a serious risk at a subsequent confinement.

Ovarian Tumors Complicating Pregnancy, Labor, and the Puerperium.—Dr. HERBERT R. SPENCER of London, England, reported 41 cases of these tumors. The youngest patient was 20, the oldest 43, the average 30. As to the result of ovariotomy to the mothers, all the patients recovered, except one, who died of intestinal obstruction caused by adhesion of a coil of intestine to the pedicle. The treatment of ovarian tumors complicating pregnancy, labor, and the puerperium had been by some writers considered too much from a surgical standpoint. The obstetric aspect was not less important and in some cases was the dominant factor. Among the 15 cases which he had personally treated during pregnancy there were 3 cases of contracted pelvis which necessitated induction of premature labor in 2, and would have done so in the third had the patient not aborted. During the first half of pregnancy, ovarian tumors should be removed wherever their situation and whatever their size. As to the exceptions, the following tumors should not usually be removed: (1) Lutein cysts complicating hydatidiform mole. (2) Bilateral tumors causing no symptoms, if the patient was childless, or, if operated on, part of an ovary should be left behind. (3) Primary adherent malignant cysts. (4) Secondary malignant cysts. During the second half of pregnancy all large ovarian tumors and ruptured, inflamed, and strangulated tumors should be immediately removed. During labor the best treatment was abdominal ovariotomy, immediate in the case of large tumors, at the end of the first stage or after delivery in the case of small tumors. In the puerperium, ovarian tumors should be removed as soon as practicable, when possible within twenty-four hours of delivery. If there was doubt as to the aseptic condition of the uterus, a delay of a week or two might be advisable, unless indications of strangulation or infection of the tumor arose, when the tumor should be immediately removed.

Ovarian Tumor with Twisted Pedicle Complicating Pregnancy.—Dr. EDWARD P. DAVIS of Philadelphia reported a case of ovarian tumor with twisted pedicle in a Polish woman, married, pregnant for the third time. His study of the subject led him to the belief that but one course of treament was justifiable in cases of ovarian tumor with twisted pedicle complicating pregnancy, namely, removal as soon as the diagnosis of the condition could be made; or as soon as indications of this condition were present. The complication of twisted pedicle was so serious as to demand immediate operation. If an exact diagnosis before operation was impossible, the condition which simulated twisted pedicle in themselves demanded operation. In the absence of an exact diagnosis, the obstetrician should operate in the interest of the patient.

Ephraim McDowell, the Father of Ovariotomy.—Dr. J. RIDDLE GOFFE of New York selected this as the title of his Presidential Address. He gave a complete and valuable historical sketch of McDowell and his operation, and closed his address in the following words: "A hundred years—a century—have rolled by since that day, and yet the luster of McDowell's achievement has grown steadily brighter to the present time. It was a fertile seed which, planted in appropriate soil, has risen to a mighty tree. It has manifold branches and has borne abundant fruit. McDowell did not live to see his operation adopted as a recognized surgical procedure, but he did have the satisfaction of knowing that Dr. Johnson, the editor of the *Medico-Chirurgical Review*, who declared in 1825 that he did not believe the operation had ever been done successfully and probably never would, the following year published in the same journal a recantation, in which he said: 'A back settlement of America—Kentucky—has beaten the Mother Country, nay, Europe itself, with all the boasted surgeons thereof, in the fearful and formidable operation of gastrotomy, with extraction of diseased ovaries. In the second volume of this series we adverted to the cases of McDowell of Kentucky, published by Lizars of Edinburgh, and expressed ourselves as skeptical respecting their authenticity. Dr. Coates, however, has now given us much more cause to wonder at the success of Dr. McDowell, for it appears out of five cases operated on in Kentucky by McDowell, four recovered after the operation, and only one died. There were circumstances in the narrative of the first three cases that caused misgivings in our minds, for which uncharitableness we ask pardon of God and Dr. McDowell of Danville.'" A broad and searching examination of all the claims put forward by aspirants or their friends to the honor of antedating McDowell has proved them, one and all, entirely groundless. The wide dissemination of the facts upon which this decision rests, and the ripening influence of time have brought the members of the professional world into accord upon this subject, so that I think I am safe in saying that in this centennial year, McDowell is universally recognized throughout the world as the originator of the operation and entitled to be pro-

claimed the Father of Ovariotomy. McDowell was born November 11, 1771, and died January 25, 1830, in the 59th year of his age.

"Peace be to his ashes and glory be to his name."

The next order was a symposium on Anesthesia.

The Nurse as an Anesthetist.—Dr. J. Montgomery Baldy of Philadelphia said that a perfect solution of the problem of giving anesthetics would be a medical man of a high grade of intelligence, with a well-grounded medical and surgical education, as especial education in anesthetics, supplemented by a natural inclination in this direction as against any other. Are the attractions of anesthesia sufficient to overcome the disadvantages of the scientific narrowness and lack of opportunity for distinction and income to hold a sufficient number of men of this type, or even of great worth, in this field? The answer seemed apparent. Possibly the future might increase the number, but at present they were so scarce as to be readily counted. The great city of Philadelphia did not, to his knowledge, contain one. Personally, his own inclination, governed largely by the means at hand, and by past experience, lay in the direction of women as anesthetists—in other words, trained nurses. The education of the trained nurse lay largely along medical and surgical lines, and she had, therefore, unless we excepted the woman physician, a sounder basis than had other women on which to begin. Of this latter class, the women physicians, he could readily see that some would and will be available for the service, but in most instances many of the most serious objections obtained in their case as did in the case of men physicians. To the nurse, anesthesia would prove a stepping-stone to something better than she had originally chosen, a higher and more dignified position, and would appeal in its own way to her ambition and pride just as did the superintendency of a training school.

Administration of Anesthetics.—Dr. Herman J. Boldt of New York read this paper (see p. 931).

Anesthetics in Hospitals and Private Practice.—Dr. James T. Gwathmey of New York said the administration of anesthetics as a specialty was recognized in only a few of the larger cities of America to-day. So intense had been the interest in surgery that anesthetics had been used only as a means to an end, and this fully explained the attitude of the profession on this subject in America at the present time. The advancement in anesthetics in England had been rapid. In the light of recent discoveries no surgeon was justified in adopting some one anesthetic and method of administration exclusively. There were four general anesthetics in common use, and there were three methods of administration. These anesthetics and methods were mentioned. The mixture of nitrous oxide gas and oxygen was the only non-poisonous anesthetic available to-day. Unfortunately, it was considered by men of large experience adapted to only about 30 per cent. of the surgical cases that came to us, namely, weak, anemic men and middle-aged women. These patients should have the benefit of this anesthetic whenever possible. Nitrous oxide gas and oxygen, supplemented by ether, could be used in at least 60 per cent. of all cases. Nitrous oxide gas and oxygen could and should be used as a preliminary to ether in at least 80 per cent. of the surgical cases. Oxygen administered with warm chloroform, by either the closed or open method, doubled its value as regarded life, and given in this way it was as safe as ether and air. Ethylchloride was used principally as a preliminary anesthetic or for very short operations, and while not so safe, generally speaking, as nitrous oxide gas, was sometimes safer in certain selected cases. The problem to-day was not the matter of life and death upon the table, but what methods and combinations would give the best results and leave the patient just as we found him. To do this, the anesthetist should be responsible with the surgeon for the preliminary medication, to quiet the nerves of the patient, in addition to the usual routine procedure. He should also be informed and consulted if the patient was nauseated after the operation. In the vast majority of cases we now had no nausea or vomiting, but we should not be satisfied until we could assure all patients that they would come out of the anesthetic in an absolutely quiet and natural state.

The Proper and Improper Methods of Administration of General Anesthetics.—Dr. S. C. Gordon of Portland, Maine, read a paper on this subject, in which he said that the first and most important point to be observed in the administration of an anesthetic was a proper preparation of the patient, both physical and mental. The dread of the anesthetic was oftentimes much greater than that of the operation, and much might be done to prevent this. Second, there was usually too much haste in its administration, and too large a quantity was used. Inhalers were very faulty in construction. The simplest was always the best. The drop method of administration was the true one. The cover of the mask should be porous and allow the transmission of air through it during respiration. Third, careful attention should be paid on the part of the anesthetist, who should have an acquaintance with ordinary, normal condition of pulse and respiration—a medical man or trained nurse preferred.

Renal Excretion During the Administration of Chloroform and Ether in Gynecological Surgical Operations.—Dr. J. Wesley Bovée of Washington, D. C., read a paper with this title, in which he summarized as follows: (1) From the study of sixteen cases it would appear that the rate of excretion of urine was markedly lessened under anesthesia produced by ether or by chloroform. (2) That such diminution was greater from chloroform than from ether. (3) That while chloroform produced a diminution in urea output, this continued to maintain a nearly normal proportion to urinary excretion, while ether produced a greater proportionate lessening of urea than of the urine. (4) That these two anesthetics, when carefully and skilfully administered, had little effect on the production of casts and albumin in the urine, inducing it in some, stopping it in others, and in others either not producing it or not materially modifying such production. (5) The Trendelenburg position greatly retarded the rapidity of urinary output.

The Advisability of Making the Practical Administration of Anesthetics a Required Part of the Medical Course.—Dr. Reuben Peterson of Ann Arbor, Mich., read a paper on this subject, saying that the necessity of such instruction was shown by the experience of the past There was inconsistency in requiring proficiency in the so-called scientific branches of medicine, while the student was allowed to graduate without having given an anesthetic. It was feasible to establish such a course as a part of the already overcrowded curriculum. This could be done by the proper utilization of much time now wasted in unsystematic teaching. The whole question of the proper administration of general anesthetics in hospitals and in general practice was dependent upon the scientific teaching of the subject to undergraduates.

The Trained or the Untrained Anesthetist.—Dr. Hunter Robb of Cleveland, Ohio, tentatively proposed the following suggestions: (1) That a skilled anesthetist, holding an appointment in the medical school as one of the faculty, and in the hospital as one of the staff, be appointed at a proper salary to teach and demonstrate the administration of anesthetics, and to administer them personally to the private patients and to those in the general wards who were in a debilitated condition. (2) That in connection with a carefully prepared course of lectures on anesthetics and their physiological action, each student should be required to administer anesthetics to dogs or other animals a certain number of times. (3) That the lecturer

next take the students the rounds of the operating rooms and point out to them the details in connection with the service, and the points to observe in giving an anesthetic to the human being. (4) That each student should be detailed to give the anesthetic at a certain number of operations under the guidance and criticism of the instructor, or one of his more advanced students. In this way we could be assured that all of them would have at least a fair amount of general experience. (5) That the senior instead of the junior interne be detailed to administer the anesthetic, as he would have had the opportunity of following and also of assisting in the administration of the anesthetic in a considerable number of cases by the time he had reached the position of senior assistant.

Dr. Robert L. Dickinson of Brooklyn, N. Y., detailed his experience with visiting anesthetists in some Brooklyn hospitals.

Improved Methods of Obtaining Anesthesia in Hospital Practice.—Dr. J. Clarence Webster of Chicago said that the routine administration of ether, as practiced in America, was to be condemned because of unpleasant or dangerous sequelæ. His method consisted in administering nitrous oxide gas with oxygen (2 per cent.) until the patient was unconscious, then ether until complete anesthesia was obtained. The latter was then abandoned, and the operation was performed under the influence of the nitrous oxide gas and oxygen mixture. This might or might not be followed by pure oxygen for twenty minutes. This method meant greater safety and fewer unpleasant or serious after-results. Local anesthesia should also have a more important place in practice, and should supersede general anesthesia in certain cases.

Conservatism in Surgery of the Pelvic Organs.—Dr. Herman J. Boldt of New York said that the exsection of a part of an ovary, the seat of small cystic degeneration, or the puncturing of the small cysts, did not deserve the name of conservative surgery, because the small cystic degeneration was without significance. Plastic surgery on suppurating Fallopian tubes was considered as bad surgical judgment rather than as conservative surgery, because the patients upon whom such a procedure was undertaken were not cured by it. The removal of a pedunculated subperitoneal myoma should not be considered conservative. It was only a commonsense procedure. Good judgment must be used in interstitial multiple myomata, and in multiple subperitoneal myomata, if the latter had attained to more than four or five centimeters in diameter. To retain the uterus in such cases was conservative surgery. It was also conservative surgery to retain the whole or a part of the uterus in cases of an abscess in the uterus. A case of the latter class was related, in which about one-third of the uterus had been removed and the woman subsequently conceived and was delivered at term. In cases of ovarian tumors at attempt should always be made to regain functionating ovarian stroma from the base of the tumor. In all cases of doubtful character of the tumor a frozen section of it should be made, if possible, by the pathologist of the hospital, and his report on the character of the tumor be obtained before the abdomen was closed. The operation had been done 45 times in cases of bilateral tumors during the past twenty years, and, with one exception, there had been no occasion to regret the procedure. The menstrual function had been retained in all patients; some had conceived and were delivered at term.

Remote Results of Ovariotomy.—Professor Hofmeier of Würzburg, Germany, read this paper, in which he said that in Group I (retention cysts, fibroids, dermoids, pseudomucin-cystoma, carcinoma), with the exception of carcinoma, ovariotomy in all sorts of tumors of this group gave excellent results. The danger of secondary affection of the other ovary did not exist. The danger of a later spontaneous (idiopathic) affection was very slight. Therefore, the removal of the one diseased ovary would be sufficient. With reference to the slight possibility of secondary implantations of the pseudomucin-cystomata, special precaution during the operation was required. If there was a suspicion of carcinomatous degeneration of the removed tumor, the removal of the other ovary, which seemed to be healthy, was not absolutely necessary in younger women. In case of illness, as shown by microscopical examination, relapse would surely follow in spite of the removal. In case it was healthy, a cure was possible by leaving it. In every single case, younger women or their nearest relations should be consulted and notice of their wishes should be taken. Operation should be attempted in all cases where removal of the ovary or ovaries seemed to be possible. The resection of a beginning growth of the second ovary was allowed only in cases of retention cysts, fibroids, or dermoids. Of pseudomucin-cystomata it was only allowed if the patient was ready to risk a second operation later; it was absolutely forbidden in case of carcinoma. In Group II (comprising cystoma serosum papillare, pseudomyxoma, sarcoma, teratoma) complete cure was possible, especially for papillomata and pseudomyxomata, even when bilaterally developed; also for unilateral sarcoma and teratoma. If on thorough microscopic examination the second ovary seemed to be healthy, it might be left, as the removal of both ovaries was very detrimental to the general health of younger women, and as the danger of a spontaneous attack of the second ovary was not very great. The state of the ovary, however, must necessarily be controlled for several years. If both ovaries were diseased, they must be completely removed with the uterus. Resection of such a tumor from the ovary was not allowable.

Surgical Treatment of Dysmenorrhea and Sterility in Women.—Professor Samuel Pozzi of Paris, France, read a paper on this subject, describing in great detail an operation for the relief of dysmenorrhea and the cure of sterility, in which thus far he had not experience a single failure. After this operation cervical metritis due to stenosis rapidly disappeared, as did also leucorrhea. As regarded sterility, in more than 25 per cent. of his cases pregnancy followed the operation, the women going to term without any accident, and their labors were normal. Rigidity of the cervix was not to be feared, for there was no cicatricial tissue, as there was after some amputations of the cervix.

Postoperative Peritoneal Adhesions.—Dr. George Gellhorn of St. Louis, Mo., read a paper on this subject, detailing experimental studies of post-operative peritoneal adhesions. In summing up his experimental studies on the subject and trying to utilize them for practical purposes, he suggested that the multitude of causes of post-operative adhesions would also necessitate a multitude of preventive measures, and that, therefore, the following precautions should be considered, either wholly or in part: (1) All prophylactic measures mentioned in connection with primary adhesions. (2) Bier's hyperemia in the form of dry heat. (3) Hypodermic injection of fibrolysin or thiosinamin. (4) Drainage with the liquor of aluminum acetata after certain vaginal operations. (5) Prompt provocation of peristalsis by hypodermic injection of physostigmin, together with improvement of the passive mobility of the intestines by means of mucilage. (6) Interposition of lanolin, provided further experiments will prove its harmlessness to the human organism and efficacy as to the prevention of adhesions.

Significance of Peritoneal Adhesions Following Operations.—Dr. Henry T. Byford of Chicago said that operations which led to the production of adhesions were either imperfectly or improperly performed. Extensive adhesions following poorly performed operations sometimes caused more suffering than was felt before. He illustrated this by cases from his records, which showed

that serious conditions were some times due to post-operative adhesions of limited extent, and might be relieved by their separation. Also that the mere separation of adhesions about diseased organs might lend to a cure of the symptoms, and that when the original causes of the adhesions were removed, the secondary adhesions that followed a properly performed operation were less extensive and less permanent. When post-operative adhesions were intestinal in character, muscular exercise and intestinal activity tended to relieve them without the aid of operation. Omental adhesion caused less immediate trouble, but the omentum had not the power of separating itself as had the small intestines. They acted by interfering with the functions of the organs to which the omentum was attached, and by dragging upon the stomach and colon, causing or perpetuating gastroptosis and dilatation of the stomach. The prevention of these post-operative adhesions was not to be attained by any one procedure or remedial agent, but by a properly executed technique.

Intestinal and Omental Adhesions.—Dr. John G. Clark of Philadelphia discussed the anatomical and pathological factors concerned in the promotion of adhesions, and described some hitherto overlooked points in the technique which led to this sequel. He likewise spoke of the frequency of post-operative adhesions and discussed their treatment.

Dr. Henry C. Coe of New York compared the present with the former after-results of laparotomy. Of seventy to seventy-five patients who recovered from the operation in preaseptic days, many were practically invalids for life, due to imperfect technique. Complications that are now rare were then common. Examples were given. The reasons were unskilful manipulation, infection, the use of large silk ligatures, glass drains, bad after-treatment, etc. The etiology and pathology of omental and intestinal adhesions were discussed by him. He said that opposed raw surfaces were more likely to adhere. Gauze packing and early movement of the bowels did not prevent it. There might be a localized traumatic peritonitis, as in simple cases of interval appendicitis, etc. Medical treatment was of no avail in marked cases. It was necessary to reopen the abdomen, separate the adhesions, and cover the raw surfaces in such a manner that the adhesions would not reform. Although humiliating to abdominal surgeons to admit it, up to this time they had had no certain means of preventing the formation of adhesions in complicated cases. The introduction of foreign bodies, films, powders, etc., was foreign to the spirit of modern surgery. Early purgation was not always a prophylactic measure, and was often harmful. We could not obtain healthy peritoneal flaps when there were extensive raw surfaces. The future method of prevention of adhesions still remains to be devised.

Dr. J. Clarence Webster of Chicago spoke of adhesions following abdominal sections. He alluded to the faults in technique which were likely to injure the peritoneum and then lead to adhesions. In dividing the tissues with a knife or scissors, the operator should take care to bury the raw surfaces. The same procedure was demanded where adherent structures were separated, and although it was impossible to carry this out perfectly in all cases, various maneuvers may be employed, in many instances calculated to improve the condition of the parts. These were described in detail.

Ileus.—Dr. William H. Wathen of Louisville said that for post-operative ileus we should substitute post operative paralytic intestinal obstruction, partial or complete, temporary or permanent. The partial or complete post-operative obstruction in the gastrointestinal tract might be either primarily paralytic or mechanical, which, if not operated on promptly, was followed by a loss of motility, and then the symptoms were often so nearly identical that a differential diagnosis could not be made. The paralytic form might be caused: (1) By violent inhibitory impulses transmitted to the muscle walls of the intestines from the central nervous system by the splanchnic nerves through the sympathetics; (2) by the destruction or impairment of the neurogenic energy and the myogenic force in the walls of the intestines upon which motility and peristalsis depended, resulting from the poisonous action of bacterial enzymes from the intestines or the peritoneal cavity upon the nerves or muscles in the bowel walls, or from traumatism; (3) by the combined action of the central inhibitory splanchnic impulses, with impairment or destruction of the neurogenic energy and myogenic force in the intestines caused by bacterial poisons or traumatism. Reference was made to the researches upon the gastrointestinal tract bearing upon its anatomy, physiology, motility, and bacteriology. Where intestinal mechanical obstruction could be timely recognized, an immediate operation should be advised and sometimes resection of the injured bowel. Rapid work in these operations was very essential, and as little traumatism as possible to the intestines or the mesentery. In some instances enterotomy should be advised, and in others enterostomy. No foods or liquid should be given by the stomach, but stomach lavage should be frequently repeated where the bowel contents have regurgitated into the stomach and not easily vomited. The patient should be placed in the semi-sitting or sitting posture and the tissues of the body supplied with water by the rectum after the fashion advised by Murphy. In some instances relatively large enemata, to which might be added a little alum or some carminative might be used, but not repeated too often, and the bowel never over-distended. This might empty the colon, thereby removing colonic obstruction to the flow of the contents of the small bowel. Paralytic intestinal obstruction was now relatively infrequent when compared with the results of work in the past. This was due to a better preparation of patients, to a better technique, more rapid operation, more gentle handling of the intestines, and a better asepsis. Drainage should not be used where it could be avoided, but when necessary one should use the rubber split or fenestrated tube, and never use gauze except to control the dangerous oozing of blood or to isolate an infected area. Preventive treatment was more important than the post-operative.

Dr. Howard A. Kelly of Baltimore discussed the mental disturbances following abdominal sections, the nature of them, their frequency, the kinds of operations that they followed, the prognosis, and the treatment.

Dr. John Osborne Polak of Brooklyn, New York, said that acute dilatation of the stomach as a post-operative complication occurred eight times in one thousand abdominal sections. There were two deaths in patients with low hemoglobin percentages and low red-cell counts. All patients were operated on under general anesthesia. Six had had septic processes before operation. One had previous gastroptosis. Vomiting began from twenty-four to fifty hours after operation. There was diffuse abdominal pain and thirst, with continuous and persistent regurgitant vomiting, without peritoneal irritation, which enabled one to make the diagnosis. The treatment consisted of lavage, starvation, the right lateroprone position, with Murphy irrigation and nutrient enemata.

Ureteral Fistulæ as Sequelæ of Pelvic Operations.—Dr. John A. Sampson of Albany, N. Y., discussed certain important anatomical features of the ureters from the standpoint of ureteral fistulæ. In the first place, he spoke of their relation to the other pelvic structures, especially to the parietal peritoneum and to the uterus. He referred to the pelvic conditions in the operative treatment of which there was danger of injuring the ureter, as, for instance, extreme lateral displacement of the cervix; masses adherent to the parietal peritoneum covering the ureter; in-

traligamentary tumors; inflammatory exudates in the base of the broad ligament; tumors lateral to the ureter; cancer of the uterine cervix. He also discussed the various injuries to the ureter which might result in fistulæ, such as clamping, ligation, incision, failure of repair, and interference with blood supply.

The Pathology of Ovarian Tumors.—Dr. THOMAS S. CULLEN of Baltimore discussed under this head retention cysts, cystic ovaries, multilocular ovarian cysts, papillocystomata, carcinomata, dermoid tumors, and teratomata developing in the ovary.

The Influence of Corsets and High-Heeled Shoes on the Symptoms of Pelvic and Static Disorders.—Drs. EDWARD REYNOLDS and ROBERT W. LOVETT of Boston said that this was a preliminary report from the clinical and gynecological point of view only of some of the results of experimental observations which had extended over about three and a half years upon the general subject of the influence of attitude and proportion upon abdominal and skeletal disorders. There was a large portion of the clinical field in which the cases were either suffering from both static (orthopedic) and pelvic lesions due to a common cause, or present symptoms which might be due to either and demanded a differential diagnosis. Balance in the erect posture was a subject very difficult of investigation. The keynote to its comprehension was to be found by studying the relation of the center of gravity to the several portions of the skeleton. Certain types of figure tended to be free from ptoses and static ailments. Certain other types were inherently liable to them. The stable types of figure are but little affected by the varying types of corsets and shoes. The unstable types were greatly affected for good or evil by these articles of dress. In corsets there were types which were always productive of evil, and types which were sometimes thoroughly desirable and productive of good. From a gynecological point of view Drs. Reynolds and Lovett contended, further, it was very necessary to take into consideration the effect of shoes in connection with that of corsets. The authors exhibited a number of photographs and also presented several full-sized graphic studies made from living models under different conditions, intended to illustrate the different points brought out in their paper.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. Edward P. Davis, of Philadelphia; *First Vice-President,* Dr. Seth C. Gordon, of Portland, Me.; *Second Vice-President,* Dr. Edward Reynolds, of Boston; *Secretary,* Dr. LeRoy Brown, of New York; *Treasurer,* Dr. H. Wesley Bovée, of Washington, D. C. Washington, D. C., was selected as the place of next meeting, which will be held at the same time with the other societies constituting the Congress of American Physicians and Surgeons, 1910.

The Banquet.—The notable and culminating feature of this meeting, which was one of the most successful in the history of the society, was the dinner in commemoration of the first ovariotomy by Dr. Ephraim McDowell, given at the Waldorf-Astoria by the New York and Brooklyn Fellows on Thursday evening, April 22. Dr. J. Riddle Goffe acted as toastmaster. The toasts and speakers were: "Ephraim McDowell, the First Ovariotomist," by Dr. Lewis S. McMurtry of Louisville, Ky.; "Mrs. Crawford, a Type of American Womanhood," by Dr. Edward P. Davis of Philadelphia; "McDowell's Successors in America," by Dr. Howard A. Kelly of Baltimore; "McDowell's Successors in the British Empire," by Dr. Herbert R. Spencer of London, England; "McDowell's Successors in France," by Professor Samuel Pozzi of Paris, France; "McDowell's Successors in Germany," by Professor Hofmeier of Würzburg, Germany. Dr. E. C. Dudley of Chicago exhibited lantern slides, showing the home of McDowell, Mrs. Crawford before and after operation, etc.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending May 22, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	678	195
Diphtheria	355	20
Measles	1,365	12
Scarlet Fever	335	19
Smallpox	..	..
Varicella	226	..
Typhoid Fever	48	7
Whooping Cough	105	12
Cerebrospinal Meningitis	12	8
Malarial Fever	..	..
Totals	3,124	273

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending May 21, 1909:

			CASES.	DEATHS.

ALCOHOL INJECTIONS IN NEURALGIAS, ESPECIALLY IN TIC DOULOUREUX.*

By O. KILIANI, M.D.,

NEW YORK.

In marked cases of trifacial neuralgia, the clinical picture is self-evident. Whoever has seen any of the frightful attacks of pain will never forget the impression. But, in cases where the pain is more or less constant, and not of a spasmodic type, the diagnosis rests entirely upon the anamnesis. There is nothing to be seen, there is nothing to be felt, and the only basis for diagnosis is the history given by the patient. Occasionally mistakes, therefore, are not excluded, as most neuralgia patients are of a more or less highly developed neurotic constitution. The differential diagnosis between neuralgia and hysteria is not always very easy.

No definite pathological changes have been found in the nerves or their sheaths affected by neuralgia; or, at least, no constant changes, which could be accepted as pathognomonic of this ailment—for one can hardly call it a disease. A number of equal ingenious theories have been advanced by different authors, in the attempt to explain how these pains occur, but, so far as I am able to discover in the literature on this subject, none has been universally accepted. I, myself, with my comparatively large experience in these cases, am not at all prepared to suggest any theoretical explanation, but hope to be able at some future time to either give you the ideas of Professor Schloesser or my own, if the experiments of either of us shall result in definite conclusions.

Under these circumstances it is easy to understand that the etiology of this trouble is equally unknown. Nearly every sickness and constitutional disease, from a cold to syphilis, have been accused as being possible factors in producing neuralgia. All sorts of local irritation, as periostitis of the teeth, diseases of the antrum, and so forth, have been regarded as contributing factors.

Whenever there is no specific treatment for a disease, the remedies are always galore. So here. None, or all of the remedies known for treating nervous conditions, help. A certain improvement is possible with any treatment. But the well-defined cases of neuralgia resist all medical treatment, except the application of morphine, and the time comes when even that, taken up to the amount of 50 grains per day, subcutaneously, will no longer stop the pain. We all know the different operations which have been practised during the last years, in cases where medical treatment failed: Thiersch's tearing out of the nerves, peripheral resection of the nerves, intracranial operations, Abbe's, Hartley-Krause's gasserectomy. And in regard to the latter, I would say that, in spite of the enthusiasm of Cushing, it is doubtless a very serious undertaking, with a high death rate.

Since a number of years, all sorts of remedies have been used for subcutaneous injections, at the seat of the pain, osmic acid perhaps having been employed the most. But to Schloesser we owe the method of injecting with certainty into the trunk of the three branches of the fifth nerve, or, if it is so agreed upon, into its roots. He published in 1903 his method of injecting 80 per cent. alcohol into the nerve for facial neuralgia.

To hit the nerve with certainty, Schloesser advises injecting into the foramina through which the different branches enter the face from the skull; that is, for the first branch the supraorbital foramen, for the second branch the infraorbital foramen, and for the third branch the mandibular foramen (inferior dental) or at the base of the skull, the foramen rotundum and the foramen ovale. Besides these, there are a number of other foramina or anatomical points, where the nerve can be reached, as, for instance, the posterior palatine foramen, if the roof of the mouth is specially affected, or one has to inject into the mental foramen, if the pain in that region is persistent. Or, you may follow up along the ramus, above the mandibular foramen, up to the division of the third branch into the lingual and the inferior alveolar nerve.

All these points, however, as, for instance, the sphenopalatine ganglion, may be reached by Schloesser's method, with absolute certainty, by any one who masters the technique which, I admit, in some cases, is not very easy.

There is one other method of injecting into the nerves, advised by Levy and Baudouin, of Paris, which is much simpler, much easier, but also very uncertain.

My report to-day, before this society, is based upon 190 cases of facial neuralgia, which I have injected since September, 1906. I think that this number of cases entitles me to give you some brief statistics, bearing on the immediate and more remote result of these alcohol injections in such cases, and, ultimately, my view with regard to the value of the method.

Among the 190 cases I have had five failures. The other 185 patients were all entirely free of pain, and of their anxiety over expecting such (which is sometimes nearly as bad as the pain, at least in its mental effect) for a certain stated time, the length of which I shall dwell upon presently.

The number of injections necessary to produce this effect varied according to the number of branches affected, the severity of the case, and the anatomical peculiarities of the skull in question, from 2 to 10; three on the average.

*Read before the American Therapeutic Society at its tenth annual meeting, New Haven, Conn., May 8, 1909.

The amount of 80 per cent. alcohol injected is from 1 c.c. to 4 c.c. The injection is done without narcosis. First, because hardly any of the patients who have gone through so much, object to the pain produced by the injections, which, apparently, is not more severe than any of their paroxysms. Secondly, the patients ought to be awake, because they are in a position to describe, during the injection, the course the alcohol seems to take. They at once feel the nerve branches affected by the injection. The result, in many instances, where the injection has been well executed, is instantaneous and miraculous for the patients. Pain that has persisted for years in its most violent form, leading the patients to the most indiscriminate use of morphine or to repeated attempts at suicide, disappears instantly within one minute. Other cases, again, require a number of injections, and the improvement is more slow, consuming about two weeks of time.

What is the risk of the treatment? Of surgical accidents which I have personally experienced, I have to mention, first, that in one case where I injected the second branch through the infraorbital foramen, I got an oculomotorius paresis, which lasted for three weeks, and which was, of course, exceedingly annoying to the patient. In another case—the patient was a colleague—the result from injection into the third branch was an instantaneous paresis of the facial nerve, with drooping of the mouth, flowing of saliva, inability to whistle, and so on, which lasted for about two weeks. Schloesser has informed me that he got in three cases, from injections into the second branch, a herpes gangrenosus one of which was of a serious nature, with linear gangrene of the skin leading down to the bone of the upper jaw—a serious surgical complication, which lasted for several months. I, personally, had never seen anything of this. The nearest I ever got to it was a slight scaling of the skin of the wing of the nose, the upper and lower lip, showing a slight disturbance of the superficial sensory and trophic nerves of the skin.

As to the oculomotorius paresis, mentioned above, I must assume that I pierced with the needle the periosteum of the orbit, so that the alcohol affected primarily the muscles of the eye, and, secondly, from the end-fibers of the nerves in the muscles of the oculomotorius nerve. How I reached, in the second case mentioned, the facial nerve, or one of its branches I am unable to explain.

The treatment of motor or mixed nerves is an entirely different matter. *Tic convulsif* can be treated by alcohol injections, but the solution has to be weaker, 60 to 70 per cent., and the dosage has to be given very carefully, as we want to produce only a slight paresis, and not a paralysis.

The injection of alcohol into the sciatic nerve was in the beginning a failure, as the motor fibers were paralyzed with the sensory fibers in this mixed nerve. But since the injection into the trunk has been given up, to be supplanted by injection into the end branches, as the sural nerve, the peroneal branch, the posterior cutaneous nerve, and so on, combined with injections of 1-10th of one cubic centimeter into the sacral foramina—the results have been good. My personal experience in this line is so limited that I am not in a position to give any statistics of value. But in properly selected cases, where every other treatment fails, injections executed with the proper care are doubtless recommendable.

Let us return to facial neuralgia. Are those patients cured? No. There seems to be no permanent cure for facial neuralgia, gasserectomy included. After peripheral resection the pain always seems to recur. Gasserectomy is pronounced the only absolute, certain, permanent cure by its inventors and their followers. I have treated by injections and freed from pain six cases of intracranial operations, with complete recurrence of pain, worse than before the operation. Of these six operations there were four gasserectomies performed by our best surgeons and two Abbe operations, performed by himself. Therefore, it seems to me there is no permanent cure for neuralgia.

Of the 190 cases treated by me by injection, 42 per cent. have had no recurrence to date. If I take only those cases into consideration where at least eighteen months' time has elapsed since the time of the injection, 21 per cent. have remained free from pain for that length of time. In the other cases, the time when the recurrence apppeared, varied from three months to two years. Of course, it cannot be denied that it is possible that some of these cases, treated three years ago and free from pain since then, may show a recurrence at some future time. But what of it! One or two further injections into the branch affected will, in most cases, again allay the pain. My general impression is that the recurrences become rarer, their intensity less, and I expect that a number of these cases, which have recurrences at all, will eventually remain free altogether. On the other hand, it is my belief that, in a very few cases, the recurrent attacks are fully as severe and less prone to yield to treatment.

How well satisfied the patients are with the treatment is illustrated by the fact that, with the exception of three patients, I have reports from all patients concerning their condition, and that those who do suffer from a recurrence, come back to me only too gladly for another injection.

In conclusion, I wish to say that, with my unusually large experience, I know of no safer, less dangerous, more reliable method of treating this horrible affliction, while the final results of the method in question may be said to compare favorably with all other operative procedures where a high surgical risk is involved.

44 West Seventy-seventh Street.

ETIOLOGY OF ARTHRITIS DEFORMANS.

A PRELIMINARY REPORT.

By JACOB HECKMANN, M.D.,

NEW YORK.

INSTRUCTOR OF SURGERY, POST-GRADUATE MEDICAL SCHOOL; ATTENDING SURGEON, ST. MARK'S HOSPITAL; ASSISTANT ATTENDING SURGEON, GERMAN HOSPITAL DISPENSARY.

The fact that the nomenclature of this disease is so varied, that the classification and demarcation are indistinct, and especially that the treatment also varies to such an extent and is so often unsatisfactory, proves best that the nature of the affection is not sufficiently cleared up. The different denominations, as rheumatic arthritis, rheumatic gout, chronic rheumatic arthritis, nodular rheumatism, etc., indicate that what is called the gouty or rheumatic diathesis has been made responsible for this disease; arthritis sicca, dry arthritis, arthrite sèche, etc., indicate that the process, as a rule, is a dry one.

We adhere to the term "arthritis deformans" or proliferating arthritis, as it does not involve etio-

logical or pathological theories and is sufficiently descriptive.

In the following paper I distinguish two principal forms of arthritic deformans: the monarticular and the polyarticular types. Another form, affecting only the phalangeal joints and giving rise to what is called Heberden's nodes, I consider a mild form of the polyarticular type. With the so-called Still's disease of the infant I have not had enough experience to give an opinion whether it should be looked upon as a special form.

In certain cases of syphilis which I had under observation from the beginning of the disease and which came again under my observation at a later date, I have several times noticed an arthritis of the elbow, which was confined for a long time to the humeroradial part of the joint. This arthritis began like a subacute rheumatic affection, but soon periosteal swelling on the head of the radius and the opposite articular margins of the humerus developed, whereby motion, not alone rotation, but extension and flexion, became considerably impaired. The pain was not intensive on motion, but the articular bone-margins were very tender to the touch and there existed a dull aching, sometimes excruciating, pain, worse at night. The Roentgen photograph showed the articular cartilage swollen, the periarticular periosteum swollen and frayed. In a later stage the space occupied by the cartilage was narrowed (atrophy of the cartilage) and there was bony proliferation on the articular margins of the bones. In short, this arthritis had the characteristic symptoms and findings of the monarticular arthritis deformans, and later on extended over the rest of the joint.

I have seen this circumscribed form of arthritis deformans only in luetics in the late secondary and the tertiary stages, and regard it as pathognomonic. Appropriate antiluetic treatment in the early stage of these cases results in restitutio ad integrum, and only slight periosteal thickening of the articular margins sometimes remains.

In the past year I had occasion in the Orthopedic Department of the New York German Hospital Dispensary to observe a large number of cases belonging to this group and I found that some patients with monarticular arthritis deformans of joints other than the radiohumeral, who had not improved much with the ordinary hydrotherapeutic, medicomechanical, and massage treatment, responded readily as soon as antiluetic treatment was added to the regular routine.

A thorough investigation of the history of those patients confirmed the opinion more and more which I had expressed for the first time at the October, 1908, meeting of the clinical society of the New York German Hospital Dispensary, that "not only the monarticular type of arthritis deformans, but a large percentage of the polyarticular form is attributable to lues."

To prove this conclusion scientifically, I have kept all cases of arthritis deformans which came into the above-named department since September, 1908, under special observation, and, as much as it is possible in dispensary work, put them on specific treatment. Different serodiagnostic tests for syphilis were made of these cases by Dr. Hideyo Noguchi of the Rockefeller Institute for Medical Research, who has had the kindness to make those tests himself.

In most of these cases three tests were made: (1) The original Wassermann, (2) Noguchi's modification of the original Wassermann, (3) Noguchi's Globulin test.*

There were four cases, all in men, of monarticular arthritis deformans under observation: (1) of the left elbow, (2) of the left hip, (3) of the left knee, and (4) of the right elbow, 42 to 56 years old. All four gave a clear history of primary infection. This had occurred 16½, 19, 10, and 25 years ago, respectively, and 16, 16, 7, and 6 years before the arthritis deformans developed. Two of them showed well pronounced evidence of tertiary syphilitic affections, one (No. 1) had had very insidious and recurring ulcers on both legs. The scars of characteristic copper color were arranged in gronps of three to four and partly coalesced; the other one (No. 3) had a typical saddle nose.

None of the histories showed any rheumatic tendency. Two patients held trauma directly responsible for the disease. In the other two the disease came on gradually, but acute exacerbations were caused by slight injuries or overexertion.

The general condition, nutrition, color, etc., of three patients (1, 2, and 4) were good and they did not show any symptoms of an active lues actually present, but the third patient with the typical saddle nose was pale, emaciated, and had a fetid odor coming from the nose, owing to specific ulcers.

The serodiagnostic tests were made in those two cases which showed no lesions of active lues and no evidence of former lesions.

Case I.—Forty-three years old, beginning arthritis deformans of left elbow of four months standing, primary lesion sixteen and one-half years ago. Regular Wassermann = positive; Wassermann-Noguchi = positive; Globulin (Noguchi) = positive; Index = not exactly recorded.

Case II.—P. K., forty-two years, arthritis deformans of left hip, three years' standing, primary infection nineteen years back. Wassermann = positive; Wassermann-Noguchi = positive; Globulin (Noguchi) = positive; Index = 0.1915. (Blood taken after two months' specific treatment.)

Nine out of the eleven cases of polyarticular arthritis deformans were in females from twenty-two to forty-eight years old; two were in male patients, twenty-six and twenty-seven years of age.

In two patients (Nos. 1 and 2) only different fingers and metacarpophalangeal joints were affected, in the third case both hands and knees, in the fourth both hands and feet, in the fifth both hands and wrists with pronounced destructive changes in the carpal bones. The sixth patient showed advanced changes in both elbows and hands, wrists, and metatarsophalangeal joints with pronounced destructive changes of the carpal bones. The seventh case showed the characteristic end-result of the disease on both hands, and of an advanced process in both elbows. In the eighth case both hands, legs, knees, and lower part of spine were affected; in the ninth both elbows, hands, knees, and

*Quantitative estimation of globulin-fraction of the serum, namely, by ½ saturated ammonium sulphate pp. The amount of globulin stated in the article refers to the weight of globulin, from 0.5 c.c. of the serum, in moist condition after centrifugalization to a constant density. Normal sera contain in 0.5 c.c. usually less than 0.150 gm. In luetic sera the quantity is greatly increased, and it is not rare to meet a specimen with globulin as high as 0.300. See (1) Noguchi, *Journal of Exper. Med.*, 1909, XI, p. 84. (2) Noguchi: The butyric reaction for syphilis in men and in the monkey, Proceedings of the Society for Exp. Biology and Medicine, New York City, Vol. VI, No. 2, p. 51.

feet. In the tenth patient both elbows, hands, and knees were involved, and in the eleventh all joints of both extremities with the exception of both wrists were affected, and his cervical and lower part of lumbar spine were stiff. In the last four cases the patients were bedridden.

In seven cases the disease took a subacute or chronic course from the very start with occasional acute exacerbations and periods of improvement. In four cases it started as an attack of acute polyarticular rheumatism, which gradually passed on into chronic arthritis deformans. In eight cases the anamnesis indicated a well pronounced, hereditary rheumatic tendency, in three cases such history was negative. All patients were very anemic and with the exception of three (1, 2, 8) very much emaciated. Four patients (2, 4, 5, 8) were treated for anemia and chlorosis during puberty and for several succeeding years.

The history of specific infection was very difficult to obtain, inasmuch as the larger number were female patients, three of whom were single. Besides it is well known that in female patients the primary chancre and secondary eruption often pass unnoticed. The secondary symptoms may be rightly interpreted by the physician, but the patient is kept in the dark and unaware as to the real nature of her disease. But if we hear from a female patient that she was well up to a certain period of her life, that her health gradually failed, that she felt tired, had no ambition, grew pale and thinner, lost considerable hair for some length of time without having a definite disease, or that she was treated for months and months for malaria or nervous fever without being really confined to bed, and that she has never entirely recovered since, then she may be suspected of lues; and more so if that breakdown dates a few months after her marriage. If we can find in such cases specific data in the anamnesis, or through the examination of the husband, then the diagnosis "lues" is well established. The examination of the patient herself may show more or less characteristic symptoms (swelling of epithrochlear glands, etc.).

A short history of the eleven cases, taken from the above standpoint, follows:

Case I.—Mrs. L. (of above No. 3), 43 years old, married 18 years. Her husband, as widower, half a year before his second marriage, had contracted chancre in Germany, was treated for such by his cousin, an able German army surgeon for six months, and on his return married the patient. No children for six years. She soon grew weak, tired, and pale, lost at different periods considerable hair, lost thirty-seven pounds in weight. Her arthritis deformans started five years ago. Patient at present is very anemic and emaciated; weighs ninety-nine pounds. Chloasma uterinium on face and neck. On upper margin of forehead, extending to scalp, irregular but ring-shaped papulosquamous eruptions of annular syphilide. She had this more or less for five years. After one month's specific treatment it disappeared without local applications. Moderate swelling of submaxillary and epitrochlear, large swelling of axillary glands. Serodiagnose positive: Original Wassermann = positive; Wassermann-Noguchi = positive; Globulin (Noguchi) = positive; Index — 0.1750.

Case II.—(Of above No. 4.) Mrs. K., 31 years old, married 6½ years. Her husband had primary chancre four years before marriage, was treated specifically by his family physician for six months, then entered the German navy. He suffered four times from sore throat during the first few months of his service, was hoarse for four months, and had again regular inunction treatment for all that time in the navy hospital. At present he shows largely swollen epitrochlear and submaxillary glands and the diffuse shedding form of the typical alopecia syphilitica. His wife broke down physically a few months after marriage and was treated for nervous fever, as she styles it, but has never fully recovered since. Her arthritis deformans began four years ago. At present patient is highly anemic, very tall, emaciated. Weight = 116 pounds. Epitrochlear and submaxillary glands enlarged, no other specific symptoms. Serodiagnosis positive: Original Wassermann — (not made); Wassermann-Noguchi = positive; Globulin (Noguchi) = positive; Index = 0.1907.

Case III (of above No. 8).—Mrs. H. C., 48 years old; the history is analogous to that of the first two. Three and a half years ago she was married for the second time. Her first husband, with whom she lived sixteen years, suffered from a sexual disease for one and one-half years about ten years ago, but its nature could not be determined. Her second husband gave a luetic anamnesis and had unquestionable tertiary symptoms. Three months after marriage she suffered a general breakdown, followed by an acute attack of rheumatism, resulting in her present state of arthritis deformans. Pronounced swelling of both epicondylar glands. Serodiagnosis, positive: Wassermann-Noguchi = positive.*

Case IV (of above 5).—Mrs. H., 30 years old, was married five years, has been divorced for five years. She gives a well connected anamnesis of a pimple that she had shortly after marriage, on the vulva, which became an ulceration; a scaly, spotty eruption appeared on the chest a few months afterwards, for which she took sulphur baths and internal treatment. Eight months after marriage her present ailment started with a subacute attack of rheumatism. She has had loss of hair at different periods. Patient is of good nutrition, but anemic, shows enlargement of epitrochlear, less of the submaxillary glands. Serodiagnosis, positive: Original Wassermann = positive; Wassermann-Noguchi = strong positive; Globulin (Noguchi) = positive; Index — 0.2110 (high).

Case V (of above No. 7).—M. D., 23 years old, single, highly anemic and emaciated (97 pounds). Exhaustive anamnesis and examination were unobtainable. The tongue was deeply fissured dorsally and laterally, and on the left side was a diffuse, whitish blue, pearl-colored thickening of the epithelium, a psoriasis linguæ or leukoplakia, which we are accustomed to regard as a late tertiary or parasyphilitic affection. Serodiagnosis, positive: Original Wassermann = positive; Wassermann-Noguchi = strong positive; Globulin (Noguchi) = positive; Index — 0.2530 (very high).

Case VI (of above No. 1).—Mrs. N., 40 years old, well nourished, but highly anemic; no specific anamnesis, no luetic symptoms in husband. Patient, besides swelling of submaxillary and epitrochlear glands, presents a yellow mucous patch on inner side of left cheek, opposite the first molar tooth, which closely resembles a syphilitic mucous patch. Patient says that she suffered from those little sores

*The two other tests could not be made, as the amount of blood was not sufficient.

in her mouth quite frequently and that three years ago she suffered from hair falling out, and is afflicted with the same thing now. Serodiagnosis: First specimen six weeks ago, Wassermann-Noguchi = doubtful.* Second specimen six weeks later, Original Wassermann = doubtful; Wassermann-Noguchi = weak, positive; Globulin (Noguchi) = positive; Index = 0.1750.

Case VII (of above No. 6).—M. K., 26 years, single, moderately well nourished, anemic, no specific symptoms outside of swelling of epitrochlear glands. Arthritis deformans started in her tenth year. Patient was nursed by wet nurse, while her three healthy sisters were nursed by the mother herself. Her mother states that this patient from her second year on suffered from a very tedious eczema of the toes and between them, which resulted in the loss of the nails of the big toes, and that the attending physician made a contamination of her blood by the wet nurse responsible for this trouble. Serodiagnosis, doubtful: Original Wassermann = doubtful; other tests not made.

Case VIII (of above No. 2).—M. Kr., 41 years old, single, pretty well nourished, anemic. Arthritis deformans started gradually ten years ago. Specific anamnesis not taken. Moderate swelling of right submaxillary and epithrochlear glands on both sides—no other symptoms. But serodiagnosis was positive: Original Wassermann = positive; Wassermann-Noguchi = positive; Globulin (Noguchi) = positive; Index — 0.1880.

Case IX (of above No. 11).—Mrs. N., married 13½ years. Arthritis deformans started with acute attack five years ago. A few months before her general health had broken down. In the second year of the disease had loss of hair. Patient, confined to bed, highly anaemic and emaciated, has moderate enlargement of the right, more of the left epitrochlear glands. History and examination of husband negative, but positive serodiagnosis. Reg. Wassermann = weak positive; Wassermann-Noguchi = positive; Globulin (Noguchi) = positive; Index — 0.1925.

Case X (of above No. XI).—Mr. G. J., 27 years old, married five years, arthritis deformans started three years eight months ago with acute attack. No specific history. Patient, confined to bed, highly anemic, extremely emaciated (85 pounds). Multiple enlargement of inguinal and femoral glands on both sides, no symptoms otherwise. Wife not examined. Serodiagnosis positive: Original Wassermann = weak positive; Wassermann-Noguchi = positive; Globulin (Noguchi) = strong positive; Index — 0.2018.

Case XI (of above No. 10).—Mr. M. D., 27 years old, single, nine years ago suffered for quite some time from stiffness in lower limbs, pain in back, swelling of knees and ankles. Recovered and was able to work for three years. Six years ago present disease started gradually. Specific infection denied. Patient becomes reticent, further examination impossible. Serodiagnosis as follows: Original Wassermann = doubtful; Wassermann-Noguchi = weak positive; Globulin (Noguchi) = positive; Index — 0.1837.

Abstracting the above cases the following points are conspicuous:

The patients with monarticular arthritis deformans were, with exception of the one with the active luetic process in his nose, well nourished and not anemic. An hereditary rheumatic disposition existed in none of the four patients. All four gave a pretty clear history of specific infection and later manifestations, verified in two cases by the presence of active tertiary lesions or undoubted remains of such. In the two other cases the serodiagnostic tests were positive.

By two patients a trauma was held directly responsible for the disease, in the two others the acute exacerbations were caused by slight injuries or overexertion.

In reviewing these facts and comparing them with my general experience, I believe "that the monarticular arthritis deformans, at least the non-senile type, is an arthritis directly caused, or resulting from, a trauma. But the underlying cause of it is the luetic infection of the afflicted. The luetic constitution is responsible that the contusion of the joint with the resulting synovitis does not, as usually in a normal person, get well, but leads to the characteristic changes of arthritis deformans."

In 8 of the 11 cases of polyarticular arthritis deformans we found a, mostly well pronounced, rheumatic diathesis. Four of them were suffering from anemia during puberty and in several years following.

In four patients we can with certainty make the diagnosis "lues" from the anamnesis and the status præsens. In two others there are undoubted luetic affections. The history of patient VII is at least suspicious. How much we are justified in drawing conclusions from the anamnesis and the status of the last four patients, I leave to the reader to decide.

The serodiagnosis was in one case (VII) doubtful; in one (XI) doubtful to moderately positive; in two cases, weak positive; in the seven other cases, positive to very strong positive.

I come to the conclusion that there are two principal factors responsible for the disease in question: (1) the rheumatic tendency and (2) the constitutional lues. Polyarticular arthritis deformans, at least in a very high percentage of all cases, is a chronic articular rheumatism in the luetic. Here, too, the constitutional lues is the principal cause, in that the rheumatic affection does not get well, but goes on to a deforming polyarthritis.

Whether or not, and to what degree, the preexistent anemia or chlorosis plays a part in the etiology, I leave undecided.

The specific treatment has not been tried long enough to justify the publication of the results at present. Potassium iodide is usually badly borne by the anemic and run-down patients. I think for all cases mercury injections, and afterward potassium iodide added, after the general condition of the patient has sufficiently improved, are correct; or I give potassium iodide when I discontinue mercurial treatment. Exact results will be published later.

I express the hope that in the meantime some other colleague with a larger material at his disposal will further investigate the above conclusions.

My sincere thanks are due to Dr. Hideyo Noguchi of the Rockefeller Institute for Medical Research for his kindness in personally conducting the serodiagnostic tests, whose value is increased so much by being performed by a man well fitted and experienced in this work. I also thank Dr. Stadtmuller, visiting physician to the German Hospital, N.

*The two other tests could not be made; the blood was not sufficient.

Y., by whose permission I could enlist three cases from his service into the above statistics, and last but not least to Dr. Charles Jaeger, the chief of the Orthopedic Department.

A LITTLE ABDOMINAL SURGERY BY THE FAMILY PHYSICIAN;

WITH REPORT OF MY FIRST FIFTY CASES AND END RESULTS.

By WM. H. DUKEMAN, M.D.,

LOS ANGELES, CAL.

In my family practice during the period from November, 1903, to November, 1907, I was called upon to perform the following, my first fifty consecutive abdominal operations.

For convenience of analysis the cases are divided as follows: Hysterectomies, 6; Abdominal Sections, 16; Appendectomies, 26; Herniotomies, 2. The results were forty-eight recoveries and two deaths, cases Nos. 3 and 49, of which I will speak later. Of the forty-eight recoveries forty-seven are alive and well to-day. Case No. 32 died five months after operation of pulmonary hemorrhage.

In presenting this report I do not have anything new to offer, only a few facts to present. It is not the scientific and new things alone that keep up progress but the making a proper use of those things with which we have become familiar. In recognition of this, I followed and was governed by the acknowledged surgical principles of the day as laid down by our masters, giving precedence to simplicity of surgical technique in all cases, and I merely wish to show that a little surgery may be done in private practice by the family physician, with the average safety to his clients. The instruments in my kit are few and simple, combination and complicated instruments I do not possess.

Fig. 1.—Appendix distended with pus: Case II. on the left, Cast L. on the right.

Two of the operations were performed in the country at the residence of the patient. One was a Bassini herniotomy for strangulated right inguinal hernia on a boy, age 9 years, at a farm house, after midnight, with candles for light; the father and mother holding the candles. In another instance, case No. 45; I fitted up the bathroom for the operating room in a country cottage and operated for appendicitis on a very sick lady, age 40 years. Septic peritonitis had already so far developed that the entire abdomen was greatly distended and the patient was indeed in a very critical condition, pulse 140, temp. 104°, resp. 32. After opening the abdomen and my forefinger being introduced, a few small pockets were opened up and pus began to flow freely. In this case I made no extended search for the appendix on account of the serious condition of the patient. The abscess walls were not well defined and my better judgment demanded caution in not attempting to do too much. In these cases the appendix is usually gangrenous and undergoes dissolution and is eliminated with the discharges. Drainage by rubber tube was kept up for several days; afterwards by gauze for a few days, when the wound closed and the patient regained her health. From last report, now several months, she has had no return of symptoms.

All the other cases were operated on in the hospital, and in speaking of them I will do so by number of the case.

There were five more cases in the series of appendectomies wherein abscesses had been walled off. In three of these, cases Nos. 17, 21 and 22, the appendix had become gangrenous and foul pus flowed freely immediately on opening the peritoneum. In each case, however, I removed the appendix, and in one case, No. 21, two goodly sized pieces of angry-looking omentum were excised. I was called in late to see these cases. Had I been called during the first 24 hours I should have advised immediate operation.

In another instance, case No. 31, the appendix was found lying deep in the pelvis and behind the cecum imbedded in an inflammatory mass. On opening the pocket a little pus escaped and the appendix was found in three distinct separate pieces which were then removed, the parts were swabbed dry and the abdomen closed.

Case No. 6 was that of a school girl, age 15 years. Her parents would not consent to an operation until she was in a most critical condition with a general peritonitis. On the fourth day, not a very promising time, I operated. On opening the abdomen there was a copious flow of a serous inflammatory exudate. The appendix was not found by careful search, and as the patient was in a most critical condition, my anesthetist, Dr. Bullard, having already administered oxygen and fearing the patient would not survive any further search for the appendix, it was abandoned. I hurriedly closed the wound, except for cigarette drainage. The exudate flowed freely for three days. The patient ran an elevated temperature for nearly two weeks and then made a perfect recovery. It is now four years and she has been in perfect health ever since. Without the operation she surely would have died.

Twelve of the cases were chronic appendicitis and were interval operations. In most of these cases adhesions were extensive.

Case No. 4 was that of a large, fleshy lady, aged 47 years, who weighed 180 pounds. This was an interval operation after the third attack. Dr. Lasher assisted me in this case. After careful search and by breaking up many adhesions, the appendix was finally found adherent to the posterior wall of the cecum and to the peritoneum. It was in two separate pieces, each piece encased in a separate sac. The caliber of each portion was very

much enlarged and contained pus, the ulcerated ends having become sealed. Cigarette drain was used on account of extensive handling of the parts; there was no drainage, however, and on the fourth day I inserted two more stitches and the wound immediately closed. About three months later a hernia developed. As the patient wears a well-fitted bandage and the hernia does not cause her any inconvenience and she enjoys the best of health, she prefers not to undergo another operation.

In four of the chronic cases (two of which, Nos. 2 and 50, are here shown in Fig. 1) the appendix was greatly distended with pus and the size of one's middle finger.

They were very similar, each having had three attacks during the course of two years, and their health greatly reduced so that they were unable to attend to any business. The appendix was easily located in each case, being very large and filled with pus. In case No. 50 the patient had a chronic cough and had been treated by different physicians for several months for this. On recovery from the operation the cough ceased and the patient now

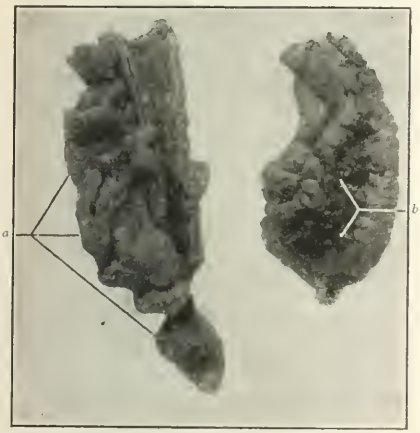

Fig. 2.—Case XLVIII, on the left—*a*, fat; the appendix is opened, showing the indurated walls; Case XLVI, on the right—*b*, seeds.

enjoys good health and is able again to earn a living for himself and aged mother.

In these four chronic cases the disease had existed from four months to two years from the date of the first attack, and in each instance the patient's life hung as on a delicate thread, in danger of a rupture at any moment. In such event, a most serious condition would have resulted. In each instance they were confirmed invalids and had, through false teachings and advice, been influenced not to undergo an operation. However, by the operation they finally did undergo their health has returned and four happy lives exist.

In three other cases, Nos. 17, 20, and 33, the patients were not cognizant of any disease of the appendix and had previously been treated for stomach trouble and constipation. On examination I located the disease in the appendix and after the removal of the appendix the stomach symptoms disappeared and health immediately returned. In case No. 17 the patient was in such a critical condition from vomiting everything she put into her stomach that she was reduced to almost a skeleton. I had her fed by rectum for ten days before venturing to operate. The appendix was bound down firmly by adhesions. On the third day after operation she began to eat and in two months had gained fifteen pounds. Mumford, in his book, "Surgical Aspects of Digestive Disorders," brings out the characteristic features of these conditions very clearly.

In case No. 46 (Fig. 2) the appendix contained seventeen logan-berry seeds and thirty-two tomato seeds. This appendix was more the shape and size of a normal gall-bladder. This was a chronic case of four months' duration. Case No. 48 (Fig. 2) was in a large, fleshy, muscular man, aged 33, who weighed 260 pounds. In this case I made the incision along the border of the right rectus muscle on account of the point of tenderness over this point. The depth through the abdominal wall, fat, and muscle was six inches. The appendix was found almost on a direct line of the incision about three inches deeper behind the cecum; the appendix and cecum were adherent to the posterior abdominal wall, and everything was literally imbedded in fat. To the touch the appendix felt like a whipcord, it was so indurated. It lay so deep and so hidden in the fat and so adherent to all the parts around that I was obliged to catch the tip of the appendix with forceps and have my assistant use traction while with catch forceps and finger tips deep in the abdomen I succeeded in slipping the ligature around it and ligated it as near the cecum as possible, probably one-half inch distant. It was then excised by guiding the scissors along, my fingers never letting go of the place of the ligature. I never got sight of the stump, but I was thoroughly satisfied I had my ligature doubly secure. This proved to be a fibroid appendix in a mass of fat as shown in the illustration.

In case No. 47 the appendix was likewise imbedded in fat, but it was soft and friable, and easy of removal.

Case No. 26 was in a school teacher. There was a broad adhesive band extending from the right pelvic wall over and completely around the cecum, encasing the entire length of the appendix, which lay deep along the posterior cecal wall to which it was adherent. Here I was somewhat puzzled, but by carefully dissecting the band for about four inches the appendix was uncovered where it was adherent to the cecal wall with a band of adhesion constricting it about one-half inch from its base. This patient had previously been treated for a chronic cough and asthma. She had never had any abdominal symptoms referable to the appendix. It was only by a thorough examination that I discovered tenderness in this region. Operation was advised; she at once consented. The result was the cough disappeared and she has had no return since, and is now in splendid health.

Case No. 35 was in a young man, aged 24 years, an epileptic since the age of two years when he had a severe attack of cholera infantum followed by a prolonged spell of enteritis. Preceding his epileptic attacks he always complained of a soreness over the appendix and then radiating toward the umbilicus, when he would immediately be thrown into an epileptic convulsion. As he had tried the usual remedies for his epilepsy, including circumcision, and was growing worse as he grew older, he very readily offered to see what might be accomplished from the removal of the appendix vermiformis. On opening the abdomen I found the appendix a

very long one, extending from the base of the cecum diagonally upwards with its tip adherent to the parietal peritoneum immediately under the umbilicus. After its removal I recalled to my mind that I had not noticed any omentum. As far as my finger reached I could not find the omentum, and I have wondered many times since whether this was the condition in other epileptics. However, he was benefited wonderfully for about four months, when his epileptic seizures returned almost as bad as before.

The remaining cases of appendicitis were acute and were operated on within the first forty-eight hours.

In no case did I find it necessary to rush the patient to the hospital for immediate operation, as I am sorry to say is so frequently done. But on the contrary I make it a point to relieve the patient of that dread and fear of operation and by encouragement get him in the proper frame of mind, thereby removing one great factor in the cause of shock. It is the alarmist, who rushes his patients to the operating table unnecessarily, whose records show the high death rate. In acute cases nothing is given by the stomach and only local treatment is followed.

Of the six hysterectomies, four were total hysterectomies. In case No. 32 the patient, aged 32, was recently married and in very feeble health. She was very anemic and weighed only ninety pounds; she had a carcinomatous uterus and was in the sixth month of pregnancy, fetus dead. There was also a tumor in the left pelvic cavity which on removal proved to be filled with about a half pint of creamy substance. A histological examination was made of a section of the uterus as well as of the tumor mass which proved to be carcinomatous. The uterus containing the fetus was removed without any great difficulty, drainage *per vaginam*. The patient made a complete recovery in five weeks, but five months later, while on the beach at Ocean Park, she was attacked with hemorrhage of the lungs and died about one hour later. This was a most interesting case and was reported in detail in the *New York Medical Journal* for May 2, 1908.

In cases Nos. 41 and 43, in women aged 50 and 59 respectively, the operations were for carcinoma uteri in the earlier stage, but there was no special history of importance.

Case No. 49 was in an insane woman, aged 50, the operation being for removal of a fibroid uterus and fibroid tumor of the fundus of the uterus on the right side. There were also two tubo-ovarian intraligamentous cysts. The left cyst was about the size of a child's head and contained 600 c.c. of a brown-colored fluid and a concretion the size of an English walnut. The right cyst was about the size of an orange and contained 100 c.c. of clear fluid. The entire mass was covered with intestines and adherent by numerous fibrous adhesive cords and bands over the entire surface and required many ligatures and much time was consumed in its removal. The entire mass was removed without clamps by double ligating the arteries and adhesions and dividing between ligatures, thus obviating the bruising of tissue and preventing any loss of blood. This operation unfortunately was on one of the hottest days of the season, the temperature being 95° Fahr. The patient was taken from the operating table in apparently good condition with pulse 110, full and strong. On my visit about four hours later I was dumbfounded on examining the patient to learn that on this hot day hot water bottles had been kept constantly applied because the patient ceased to perspire. I immediately ordered them to be removed and the temperature taken per rectum. The thermometer registered 108° F.; pulse 160, full and strong; resp. 30, skin dry and hot, pupils dilated, conjunctiva reflex not reacting to touch. The ice cap was immediately placed on the head and the patient sponged off with alcohol. The patient was catheterized and 120 c.c. of urine drawn. At 10 P.M. 150 c.c. urine per catheter. At 7 A.M. the following morning 180 c.c. urine per catheter. The temperature had now fallen to 103.4° in the rectum; pulse 120, full, regular, and strong; resp. 36. At 1 P.M. the pulse was 125, irregular but full and strong; temp. 103°, skin dry; resp. 40, very shallow and somewhat irregular; the patient was somewhat restless, there was involuntary bowel movement, and at 1.40 P.M. life became extinct, twenty-seven hours after operation. I reported this case in detail in *The Journal of the American Medical Association* for March 13, 1909, where I assigned the immediate cause of death as one of probable insolation. This was the forty-ninth case and the second death in the series.

FIG. 3.—Tubal pregnancy—Case XXXVI.—*a*, fetus; *b*, blood-clot.

The other two hysterectomies, cases Nos. 12 and 40, were for fibroid uteri, supravaginal abdominal amputation of the fundus. In case No. 40 the uterus was completely retroflexed and the fundus pointing outward lay between the vagina and rectum forming a rectocele which protruded from the vagina. The perineum had, many years previously, been severely lacerated during confinement almost to the sphincter ani. After the uterus was removed

and the wound closed, the perineum was also repaired. This patient still has a small cystocele.

In case No. 12, the fibroid uterus weighed ten pounds and was firmly impacted in the pelvis, but otherwise easy of removal, and the patient was again able to resume her work in a dental office at the end of the fifth week.

Of the remaining sixteen abdominal sections case No. 25 was for tuberculous peritonitis. Ten days after operation this patient developed a thrombosis of the left leg, but made a speedy recovery and left the hospital on the eighteenth day after operation.

Case No. 36 was for a left tubal pregnancy of the seventh week. Diagnosis and operation before rupture. The condition is shown in figure 3. The fetus lies in the first third of the tube, the remaining portion of the tube is filled with an organized blood clot. This case was reported in the MEDICAL RECORD, January 25, 1908.

FIG. 4.—Case XIX.—*a*, appendix; *b*, pus-tube above, ovarian abscess below.

In two cases, Nos. 19 and 45, I found the right Fallopian tube adherent and communicating with a diseased appendix vermiformis, as shown in Fig. 4.

In case No. 19 the lower end of the cecum had become drawn upwards and inwards under the colon, approximating the free border of the liver, and it looked as though in a short while the appendix, which was about five inches long and which was stretched taut, including the attached pus tube, was about to become adherent to the gall-bladder. This condition existed in a married woman from Yuma, Arizona, age 34 years, who, two months previously, had a criminal abortion produced. Sepsis followed, she was in a most critical condition and the above condition was the result. However, she made an uneventful recovery.

Case No. 45, the appendix was adherent to the upper surface of the right Fallopian tube, and both tube and appendix contained pus.

In case No. 39, the patient, aged 40 years, was a widow of broken down health for past several years. Diagnosis, appendicitis and left ovarian cyst. On opening the abdomen a beginning peritonitis was found. The ovarian cyst, the size of a pint mug, together with the left ovary and pus tube were removed. There was also a chronic salpingitis of the right tube; this, with the right ovary and the diseased appendix, was removed. The abdominal cavity was sponged dry of all exudate wherever that could be reached, and the wound was closed. The uterus was then curetted. After twenty-four hours pulse and temperature were normal, and on the sixteenth day after operation the patient went home.

Case No. 24 was a young lady whose uterus had been curetted nine months previously by her physician at that time. Her health, however, grew worse and she complained of a great deal of pain in the left pelvic region. On bimanual examination on the left side a mass the size of an orange, presumably a pus tube, was diagnosed. There was a little fluctuation and operation was advised. One week later I removed an old hematoma which included the tube and ovary. This mass was dissected out from between the folds of the broad ligament. The omentum and sigmoid were adherent to the upper surface of the mass. Before operation this patient suffered greatly from chronic constipation; since operation her bowel movements have been normal and she enjoys the best of health, having gained twenty pounds.

The remaining cases of the series are of no special importance. The operations were for simple removal of pus tubes, salpingitis, etc., and one for dermoid cyst uncomplicated and one for gall-stones, the gall-bladder containing three stones of irregular size.

In the remaining herniotomy case, No. 37, the patient had been operated on by one of our leading surgeons two years previously, but unfortunately the hernia, a right inguinal, reappeared within four months. It is now two years since and there is no sign of return.

I am sorry to say that only in a few instances did I have made a histopathological examination of the specimens. In those instances Dr. E. H. Leonard examined the specimens for me. When we consider that the frequency of malignancy of tumors of the ovaries is variously estimated by different authorities at from 15 per cent. to 25 per cent., we can readily see the importance of such examinations, and then only are we better prepared to care for such patients in the future.

In three cases, Nos. 43, 47, and 50, there developed stitch abscesses, due to faulty technique. There were no cases of post-operative pneumonia and no cases of shock worthy of mention.

End Results—Forty-eight recoveries and two deaths.

The first death was that of the patient in case No. 3, who died on the third day following removal of both tubes and ovaries and uterine suspension.

In case No. 49, previously described, the patient died twenty-seven hours following total hysterectomy. In case No. 32 the patient recovered from a total hysterectomy for carcinoma uteri and died five months later from pulmonary hemorrhage. The remaining forty-seven patients are alive and in improved health to-day. In one case, No. 4, an appendectomy, as before stated, the patient has a

ventral hernia. In case No. 40, a supravaginal hysterectomy, the patient still has a small cystocele. It is gratifying to me to say that all are my friends —and with the exception of four cases sent to me by my associates, all were of my own clientèle.

Forty-one of the cases are living in Los Angeles and vicinity, all of whom I see and communicate with occasionally; two are living in Chicago, Ill.; one at Attica and one at Columbia City, Ind.; one at Yuma and one at Prescott, Ariz., and one at Toledo, Ohio.

Dr. F. D. Bullard administered the anesthetic, ether, to forty of the patients; Dr. Chester L. Magee administered ether to five; Dr. J. Lee Hagadorn administered anesthol to three; and Dr. F. R. Frost administered ether to two, and assisted in three operations; Dr. A. Tyroller assisted in three operations; Dr. A. F. Zimmerman assisted in three; Dr. H. Y. McNaught assisted in two, and Dr. A. Godin assisted in the balance.

Perhaps my judgment at times in some of the cases, from my limited experience, was not the best, but the end results and the success achieved in these fifty consecutive abdominal operations speak for the work done. From this limited work and for guidance for the future I have drawn the following conclusion:

1. Make a diagnosis and with this in mind proceed deliberately but not hastily to remove this pathological condition and as much more as is present. But do not go mauling around in the abdomen in search of other pathological conditions when there is no hint or evidence of their ever existing.

2. Do not alarm the patients either by word or action, especially by unduly rushing them to the hospital, but eradicate all dread and fear of a surgical operation by calmness in action and thereby gain their full confidence and place them in as easy a frame of mind as possible.

3. Get your patients in the best possible condition before operating, and allow none other than a faithful, competent, sympathetic nurse to care for them after operation.

4. Yourself be strictly and thoroughly aseptic and see that all assistants and nurses are likewise, as well as everything else in connection with the operation, and be sure of your technique in every detail.

5. Handle all parts involved with the utmost gentleness and delicacy of touch; tie ligatures snugly but never too tightly, and avoid the use of compression clamps whereby bruised tissue would be left to slough.

With the advantages offered to familiarize one's self with the surgical technique of the more common abdominal operations, there seems to me no reason why the intelligent family physician should not fit himself for and be competent to perform such work.

410 Grant Building.

A STUDY OF THE URINARY ACIDITY AND ITS RELATIONS.

By HENRY R. HARROWER, M.D.,

CHICAGO.

The estimation of the urinary acidity has in the past been considered a more or less useless procedure, the simple test with litmus paper sufficing for all purposes. The study of this subject does not seem to have received nearly the attention that it deserves, and it is to be hoped that this paper will serve to emphasize the fact that the quantitative examination of the urine for acidity is a most important procedure and a part of the urine examination which should always be carried out.

The mixed 24-hour specimen of urine is normally acid in reaction, this condition being principally due to certain acid salts, in particular diacid sodium phosphate, NaH_2PO_4. The acidity is probably due, in a measure, to other acid salts which are also present, although in considerably smaller amounts. The experiments of Voit and others have conclusively proven that uric acid has nothing to do with urinary acidity.

The index of urinary acidity undoubtedly varies in direct ratio with the metabolic changes going on in the body. The manufacture, as waste products, in the body cells of acid substances—of which sulphuric acid is probably the most important—must have a decided influence upon this factor. In addition to this, certain products of intestinal putrefaction when absorbed into the blood are eliminated in the urine and thus serve, as will be shown later, to increase its degree of acidity.

Several factors cause the normal urinary acidity to vary considerably, such as an exclusive meat diet; excessive muscular exercise; highly concentrated urine, due, perhaps, to febrile conditions, after free perspiration, or diminished water drinking. Then, too, the internal administration of acids, such as benzoic, phosphoric or boric acid, and the presence of abnormal fatty acids resulting from pathologic conditions also play their part.

Undoubtedly the degree of acidity of individual voidings of urine is quite irregular, and in order that the physician in his diagnostic work may gain an accurate idea of the elimination and metabolism of his patients, it is distinctly necessary to make an examination of a part of a mixed 24-hour specimen of urine. This point cannot be too strongly emphasized. The urinary examination is usually not made nearly as frequently as it should be, and, unfortunately, when the physician realizes the necessity and importance of this procedure, he rarely bothers to have his patient make a complete 24-hour collection and take a specimen from it.

One of the most common factors which has to do with the degree of urinary acidity is the concentration of the urine. That is, if the amount of urine is large, it is normally faintly acid, while on the other hand, if the amount is below the average, the acidity should be relatively higher. While this is usually the case, it must not always be depended upon, because it is a very frequent occurrence to find the urine of patients passing considerably above the normal amount, even as high as three or four thousand cubic centimeters *per diem*, to evidence a considerable increase in the degree of acidity. In fact, an examination of a series of specimens of urine from diabetics and patients suffering from those forms of Bright's disease which are associated with the passage of large quantities of urine, leads me to believe that this depraved condition of metabolism is constantly associated with such conditions as are evidenced by an excess of acidity due to the increased amount of acid substances eliminated by the body-cells.

Dr. A. L. Benedict of Buffalo, N. Y.,[1] mentions a factor which I think should be much more frequently used and given more publicity. I refer to the term, "acid unit." An acid unit practically is

determined by the relation of the acidity of a whole 24-hour specimen to the amount, thus: 1 c.c. of urine with an acidity of 1° or 1 c.c. of urine exactly neutralized by 1 c.c. of decinormal sodium hydrate solution is equivalent to 100 acid units. Dr. Benedict believes that the average urine is from one-fourth to one-half the equivalent of the decinormal strength, and that the normal acid elimination in 24-hours should be about 40,000 acid units. This I believe is a very good average figure. It means that with one liter of urine the average acidity would be 40°, each degree representing the amount of decinormal sodium hydrate solution required to neutralize 100 c.c. of urine. On the other hand, 1,300 c.c. of urine with an acidity of 30° gives us practically the same number of acid units. The same is true of 800 c.c. with an acidity of 50°. It can readily be appreciated, however, that this last figure cannot be normal, as the total amount of fluid passed is too low, and consequently the acid-index too high.

As has been said before, the accurate estimation of the urinary acidity is a matter of vital importance, and by making much more frequent use of it the physician will gain many valuable pointers which will enable him to treat his patients more successfully.

It is unfortunate that so little attention is given to the value of this examination. There are many statements similar to the following, taken from recent books on the subject: "For the practitioner the mere determination of the presence of an excess of acid or alkali by litmus paper is sufficient."[2] "For clinical purposes the litmus test is sufficient. In view of the many variable factors that determine the reaction of the urine—it is usually an altogether futile task to determine the urinary acidity by titration."[3] This is a decided fallacy. The examination of a large number of specimens of urine associated in every case with the clinical findings present in the individual passing these specimens shows conclusively that many unpleasant symptoms and even dangerous conditions are associated with, if not actually caused by, high urinary acidity and those disturbed metabolic conditions causing it. It is well known that the urine is usually intensely acid in rheumatic conditions as well as in acute fevers, due in all probability to the increased manufacture of acids in the body tissues (a hyperoxidation of the body-cells) and, of course, the usual decreased amount of fluid secreted by the kidneys. That increased urinary acidity is distinctly abnormal seems to me to be proven by the findings which are given below.

In a series of over 250 analyses the average urinary acidity was 60°, the lowest being 10° and the highest 274°. (These specimens were examined in routine laboratory work.) Many of these individuals were passing urine with an acidity from 300 to 500 per cent. of the normal and with an acid-unit-index of from 100,000 to 200,000 per day (the minimum in this series being 8,030 and the maximum 358,050) very much above the normal amount.

The other findings show that in 35 per cent. of these cases casts and traces of albumin were found; and in 83 per cent. of these cases indican was present to a greater or less extent, usually in large amounts.

Eighteen of this series evidenced glycosuria with a sugar content varying from 0.3 to 13 per cent In these cases the average acidity was 77°, with an average acid unit elimination of 132,130 an increase of 330 per cent., and in only one of these was there is a positive test for acetone or diacetic acid.

From these findings it would seem to me (1) that there is a distinct association between highly acid urine and autointoxication due to putrefaction of the intestinal contents shown by the relation between indicanuria and high acidity; (2) that in diabetes an excess of acid (not necessarily diacetic or oxybutyric) is the rule, and in addition (3) that this condition of high acidity is very frequently associated with albumin and casts in the urine.

It must be evident that an excessively acid urine must be more or less irritating to the kidney cells and tubules secreting it, and it is not unreasonable to suppose that such urine is a distinct factor in the production of casts in the urine, predisposing to serious and definite kidney lesions. From these findings I am constrained to believe that a definite diagnosis of Bright's disease should never be absolutely made until the urinary findings aside from albumin and casts are normal. (Since compiling these results my attention has been called to an interesting article[4] from which I quote: "The occurrence of albumin in the urine, alone or associated with casts, is not the absolute indication of a nephritis, once believed, as we know that its presence does not necessarily indicate an inflamatory lesion of the kidney. The subject of faulty metabolism as a cause of albuminuria is one which is attracting more and more attention, and deservedly so; for there seems but little doubt that this is the direction in which we must look for the etiological factors of at least one type of nephritis, the interstitial form.")

This brings me to an important point. It is quite possible that, to a greater or less extent, the conditions found in the kidney known as chronic Bright's disease, or interstitial nephritis, are in a measure due to those conditions which produce indican in the urine and high urinary acidity, and consequently the regulation of these conditions, the elimination of indican from the urine and the reduction of the acidity to normal should be distinctly valuable *prophylactic* measures.

Another point of interest is that in the majority of cases, probably from 60 to 75 per cent., where the urinary acidity is excessive and indican is present, the urea elimination is invariably below the normal. From the findings in my 250 examinations the urea elimination was reduced to an average of 60 per cent. of the normal (taking 30 gm. as the normal daily output) in as many as 81 per cent. of the whole series. Dr. Foxhall, in a very interesting paper in the London *Lancet*[5] has said that if the average urea excretion is below 1.4 per cent. for 10 or 15 days it nearly always indicates definite renal damage. And so from this it would seem that conditions under discussion—high urinary acidity and indicanuria, and the low urea-index—are very closely related, and have a definite effect, the one upon the other.

Right here I wish to emphasize the fact that the quantitative estimation of the *normal* substances excreted by the body through the urinary channel gives definite information as to the actual metabolic activities of the body, which information should be of great value in the examination of the majority of those individuals consulting the physician; while even the most careful examination of a complete 24-hour collection for *abnormal elements* only assists in the diagnosis if certain definite disturbances are

present, the frequency of which is not to be compared with the abnormal metabolic states which are unfortunately so very common.

No one finding in the urine examination is of infallible diagnostic proof, as has already been stated regarding casts and albumin. Those laboratory facts which tell us of the exact status of the body functions are especially valuable when one is dealing with chronic conditions which do not prevent the patient from continuing his usual vocation. This general idea of the extent of the metabolic functions of the body is unfortunately very seldom known in the routine work of the average man. The test for albumin and perhaps sugar, in addition to the estimation of the specific gravity, is about all the "urine examination" usually done, and very rarely is a twenty-four-hour collection demanded. Rather than forestall possible difficulties he advises a complete urinalysis only *in extremis*, and even then not too frequently.

In this connection it might be well to quote from an excellent article by Dr. Cruise in the *Lancet*. In this article he says: "Every cautious physician examines the urine for albumin in all serious cases of ill health, and not infrequently comforts himself and his patients when he finds that this substance is absent. I doubt that I am in error in adding, on the other hand, that very few practitioners attempt the quantitative estimation of urea in such cases. Nevertheless the importance of ureametry is far greater than testing for albumin alone, because while the latter is often present, and signifies little, and may be absent in very grave cases, the quantity of urea is a matter of serious and often vital consequence."

And to this must be added that the estimation of the acidity will very quickly give an idea as to the general metabolic conditions of the patient, for, as has already been shown, this is nearly always associated with diminished urea.

Regarding the collection of the specimen of urine several matters of importance require consideration. In order to get correct results it is necessary for a whole 24-hour specimen to be collected, care being taken to instruct the patient as to the proper method of doing this. During the collection the vessel should be kept in a cold place, and preferably five or ten drops of chloroform placed in the vessel to preserve the urine from fermentation. The test is then made as soon as possible after the receipt of the specimen at the laboratory.

Of course some specimens will be alkaline in reaction, and in a majority of cases this will be found to be due either to retention of the urine, cystitis, or fermentation during the collection and transit of the specimen. The microscopic examination usually confirms this by showing the presence of either pus cells and various forms of epithelial cells, or crystals of ammonio-magnesium phosphate, or both. If the above methods are carried out, practically no error will be caused from the lack of proper preservation of the specimen.

So far nothing has been said regarding the method of estimating the urinary acidity. As yet no one method is scientifically accurate, for since the acidity of the urine is not due to any one acid or acid salt, the selection of a suitable indicator is a matter of considerable importance. Different indicators vary greatly in the degree to which they are affected. Methyl orange, congo-red, etc., are more sensitive to the OH-ions of the alkalies, while phenolphthalein, rosolic acid, etc., are more sensitive to the H-ions of the acids. Litmus in its affinities occupies a place somewhere between these two groups.

As has been stated before, the urinary acidity is due chiefly to the salt with the formula NaH_2PO_4, which reacts acid to phenolphthalein, the neutral point with this indicator not being reached until enough sodium hydrate solution has been added to convert this salt to that with the formula Na_2HPO_4. As a matter of fact, disodium-hydrogen phosphate, owing to dissociation into NaH_2PO_4 and NaOH, reads faintly alkaline to phenolphthalein. It has been found that this can be diminished by the addition of a saturated solution of NaCl which is neutral in reaction and consequently cannot itself affect the reaction. That the addition of salt solution is of value can be proved by titrating to the point where the pink color just appears, and then adding the salt solution, when it will disappear.

Salts with the formula Na_2HPO_4 also exist in the urine, and these react alkaline to methyl-orange and congo-red, while those of the formula NaH_2PO_2 are neutral to the same indicator. Consequently urine containing the above salts and which shows an acid reaction to phenolphthalein, when titrated with methyl orange as an indicator, will display an alkaline reaction, which is not destroyed until enough hydrochloric acid solution has been added to convert the salts of the formula Na_2HPO_4 into those of the formula NaH_2PO_4. Any carbonate present must also be decomposed by the hydrochloric acid before the pinkish tinge indicative of the neutral point is reached.

Litmus, which in the phesence of the abovementioned salts gives an amphoteric reaction, is absolutely useless in the titration of urine. A urine which shows a marked degree of acidity when titrated with phenolphthalein as indicator is often strongly alkaline to red litmus paper. Dr. Benedict, in his article[1], has well said: "The simplest way to deal with litmus is to discontinue it altogether, at least for such purposes as the present. All things considered, the best indicator for determining acidity not due to pure acids, is phenolphthalein, which, on the whole, places the neutral point about where it should be according to our general conception of acidity and alkalinity."

The most satisfactory method of ascertaining the urinary acid-index is by titrating a definite quantity with an alkali solution of known strength, using phenolphthalein as an indicator. The technique is as follows:

With a pipette or other measuring instrument measure out 10 Cc. of urine and add 2 or 3 drops of the indicator. To this add, drop by drop, from a burette, a decinormal sodium hydrate solution until a faint pink color is just obtained. (To those having no burette the use of the acidimeter is recommended.[7]) The amount of solution required to give this reaction is read off and multiplied by ten, to reduce the figures to terms of 100 Cc. This is the acidity in degrees or per cent. This figure multiplied by the number of cubic centimeters of urine passed in 24 hours gives the number of acid units passed.

There are other methods of estimating the acidity—involving other principles. Some add an excess of potassium oxalate crystals to the urine before titration, believing that this makes the results more accurate, by ruling out error from the pres-

ence of ammonium salts. Others have various ways of expressing the acidity; some use terms of phosphoric acid, others terms of oxalic acid, and again others terms of hydrochloric acid. These methods all make considerably more figuring, and they also necessitate the use of an empirical alkali solution which is standardized to equal a certain number of milligrams of phosphoric acid, etc.

The above method gives us a very good idea of the acid elimination, and enables one to obtain therapeutic information which is of value.

It must be remembered that the usual examinations made in quantitative urine analyses for medical purposes are all very crude when viewed from the strictly scientific standpoint. The hypobromite method, which is probably the best method for the clinical estimation of urea, gives 6 to 8 per cent. error. The estimation of the specific gravity is rarely corrected to temperature, and consequently varies quite a little from the actual specific gravity of the specimen; and the urinary acidity is probably from 5 per cent. to 10 per cent. away from the true figure if an ideal method could be devised for its estimation. But when the results are compared with the average of a large number of similarly obtained figures from normal individuals or with the estimations previously made on the same patient, it will be seen that approximate figures are distinctly valuable because they give *comparative information* that is just what is needed in the practice of medicine. It is (quite) possible that it is because of the difficulties associated with the *accurate* estimation of urinary acidity that the matter has remained so much in the background.

The physician will not, of course, be as interested in the scientific side of this paper as in the help that it may afford him in obtaining results, and so a few words regarding the principles of treatment which seem to be indicated in those conditions presenting high urinary acidity and the associated conditions may not be amiss.

It must be understood that the acidity of the urine varies in direct proportion with the alkalinity of the blood, and that in turn depends upon the general health and vital powers of the body. The normal blood-plasma is alkaline in reaction, due to the fact that it carries in solution certain alkaline salts, especially disodium phosphate, Na_2HPO_4, and sodium carbonate. Upon this reaction depends to a greater or less extent, the ability of the blood to absorb carbonic acid gas, and thus to carry on the good work of elimination by means of the lungs.

When the normal alkalinity of the blood is diminished and there is an excess of acid substances in the blood, an acid intoxication results which is called by some acidosis and by others acidemia. Both terms are correct, but since the word acidosis is almost invariably associated with serious organic lesions, such as are present with diabetes mellitus, after chloroform anesthesia, and in other serious toxic states, I believe that the term acidemia is more appropriate for the condition which is under discussion at present.[8] It is probable that the blood never becomes acid, as in such cases death would undoubtedly result, since the capacity of the blood for carrying excrementitious substances from the cells to the eliminative organs would be absolutely nil and thus a general paralysis of elimination would occur.

One function of the kidneys is to eliminate from the blood all excess of acid substances, and they are so constructed that they are able, not to filter, but to secrete from an alkaline blood-plasma an acid urine. Now, if the amount of acid substances formed in the body metabolism is excessive, the kidneys frequently can no longer accomplish the work required of them, when the condition termed acidemia results. These harmful substances are carried around in the blood stream, neutralizing to a greater extent the alkalies of the blood and thus diminishing its power to carry carbonic acid gas, hence making a bad condition worse.

It must be evident, therefore, that a diminished degree of the alkalinity of the blood-plasma, evidenced by increased urinary acidity, should be a danger-signal of extreme value to the practitioner, as it is positive that an excess of acid products of metabolism in the blood is most harmful, and it should therefore be the duty of physicians treating such cases to attend carefully to the modification of these particular conditions in addition to changing the causes of the abnormal metabolic functions.

For some time French investigators have been treating such diseases on the assumption that the reaction of the urine is a definite index to the state of the blood, and with excellent results. Their method of estimating the acidity is by Boussingault's titration method, using instead of sodium hydroxide a standard solution of calcium sucrate.(?) Boussingault does not claim that his method estimates the exact quantity of acid present in the urine, but that it represents the physiological acidity —the acidity which is of interest to the medical man.

In those conditions which have as one of their manifestations high urinary acidity it has been conclusively demonstrated that the judicious use of alkaline remedies is of distinct value.

My friend, Dr. Eugene S. Talbot of Chicago, has done much original work along this line and has accomplished excellent results in the treatment of pyorrhea alveolaris[9] and other serious mouth conditions by simply cleaning the mouth thoroughly and neutralizing the general systemic hyperacidity with the suitable alkaline remedies, such as sodium bicarbonate, magnesia, etc. Twenty to forty grains of sodium bicarbonate dissolved in water, with or without other synergistic remedies, is administered about one hour before meals and at bedtime. This very soon reduces the excessive acidity to normal.

That this treatment is of value is evidenced by the resulting influence on the unpleasant conditions which are so commonly associated with the high acid-index. The mental dulness, many aches and pains, irritability and general restlessness, dyspepsia and biliousness, together with the lowered vital resistance evidenced by frequent colds, etc., is modified, the patient begins to mend immediately, and the change is both favorable and marked. The alkalies should be given judiciously, and for not longer than a few days, and a careful watch over the urinary acidity made from day to day. This procedure, associated with the removal of the principal causative factors—intestinal putrefaction, constipation, indigestion, excessive feeding, the sedentary life in general—soon brings the patient to a more normal condition.

Right here I can do no better than to quote from a very able article by Dr. Eustace Smith in the *British Medical Journal*[10] as follows: "Alkalies when absorbed into the circulation increase the alkalinity of the blood, modify secretion, and if

continued too long, may become a fruitful source of anemia and languor. Carried out through the kidneys, alkalies reduce or annul the acidity of the urine, and are at first beneficial, but in a moderate dose or in too protracted a course may cause cystitis or even vesical hemorrhage. The effect of alkalies is not alone limited to the local action on the stomach, for when used with judgment they seem to have the power of influencing the whole system for good and setting up a very favorable change, which is not always a merely transitory improvement. We often have occasion to notice the prolonged benefit which follows a course of alkaline waters at one of the many spas both at home and abroad. Acting in this manner the salts of the alkalies are not so much antacid as alterative drugs, which, given in moderate doses for a period of weeks and months, are able without producing any immediate or striking change to correct a morbid condition of an organ or of the whole system and set up an improvement which if not permanent is slow to pass away. In addition to their value in derangements of digestion, alkalies are of special service in the treatment of urinary acidity and the discharge of sand and gravel."

Careful investigation will prove that in the majority of chronic diseases, and especially in those diseases which are so very common, such as tuberculosis, rheumatism, neurasthenia, etc., together with the hundred and one other conditions associated with autointoxication, will usually show a decidedly high degree of acidity, and also a marked increase in the number of acid-units eliminated *per diem*. When the conditions causing this are modified and the findings in the urine changed, the chances of the patient for recovery are greatly increased, because the body and its cells do not have the extra work of getting rid of these poisons, and hence can better attend to the work of overcoming the ravages of the tubercle bacillus and of building up the body-structure in general.

The study of the urinary acidity and its relation to disease is yet in its infancy, and it is to be hoped that in the future more time and effort may be expended on the investigation of this important subject. My sincere wish is that this paper may serve to arouse greater interest in this important matter.

In closing I will say that the time spent in making the quantitative acidity test as a routine will be more than repaid to the general practitioner in the indications for treatment he will receive from this information and the more satisfactory results derived from the better adjusted treatment.

ADAMS-STOKES' SYNDROME (HEART BLOCK).

BY ALF. A. ROBINSON, M.D.,
OGDEN, UTAH.
ATTENDING PHYSICIAN, UTAH HOT SPRINGS.

OF the various cardiac diseases giving rise to arrhythmia, Adams-Stokes's syndrome seems to be, at the present time, foremost in the realm of experimental medicine as well as in the field of journalistic comment. The great problem of the phenomenon of the heart beat, upon which much light has recently been thrown, is involved in a study of this symptom complex. The investigation of this disease takes one into the hypotheses of the myogenists and the neurogenists of the rhythmic quality of the heart beat, which also adds interest to the study.

Adams-Stokes' disease is a functional disturbance of the heart, associated, frequently, with organic change in the auriculoventricular or in the sinoauricular muscle bundles, characterized by (A) ventricular bradycardia, usually permanent but sometimes paroxysmal; (B) visible auricular impulses in the veins of the neck, the rhythm being at variance with that of the arterial pulse; and (C) cerebral attacks—transient vertigo, syncope, pseudo-apoplectiform attacks, or epileptiform seizures.

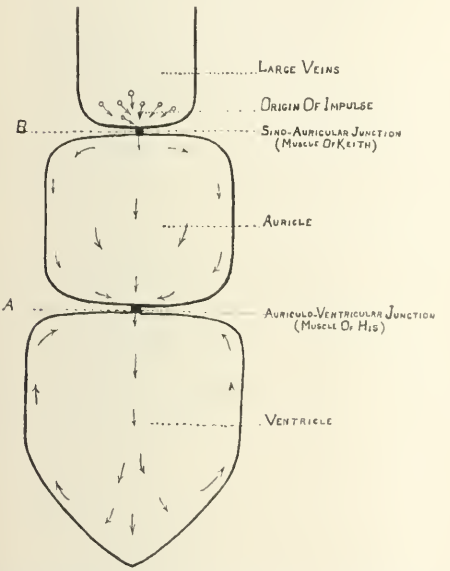
Our present knowledge of the morbid physiology of this disease has evolved from the works of several observers. In 1883 Gaskell[1] and also Wooldridge[2] laid the foundation upon which other workers have built. These investigators succeeded in producing independent atrial and ventricular contraction of the heart by constriction or destruction of the muscle at the atrioventricular junction. To the younger His[3] is due the credit of the anatomical discovery of this muscular connection between the auricle and ventricle. It remained for Erlanger[4] to show that the symptoms of the Adams-Stokes' syndrome are due to an interruption of the function of this atrioventricular bundle of His—heart block.

This muscle bundle, in the adult heart, is about 18 mm. long, 2.5 mm. broad, and 1.5 mm. thick. Its fibers arise in the auricular septum just below the foramen ovale, and pass downward and forward through the trigonum fimbriosum of the auriculoventricular septum, at which place they are in close relation with the mesial leaflet of the tricuspid valve. The band passes along the upper edge of the muscular septum where it joins the posterior edge of the membranous septum, and terminates in the muscular septum just below the root of the aorta.

This discovery by His gave to the myogenists additional substantiation of their theory. It is quite likely that they possess the path of conduction of the impulse passing from the auricle to the ventricle, but a summary of the works of both sects seems to give to the neurogenists the origin of the impulse responsible for the beat as well as the control of the heart.

Hoffman[5] demonstrated the rhythmic contraction of the large veins at the atrium of the heart and suggested that they are probably the seat of origin of the heart's action. Now comes Keith[6] with the anatomical discovery of a bundle of muscle fibers in the junction between the great veins and the atrium of the heart, which fibers ramify about the atria and are lost in the septum. It is not unlikely that this is the path of conduction from the site of origin of the beat (the large veins?) to the atrium. The fact that it has many ganglion cells and nerve fibers suggests that it may be the connecting link between the muscular conduits and the nervous control.[7]

Cardiac mechanism has, of course, been studied in the lower animals. As the origin of the heart beat has been pretty well located in the venous sinuses, it must be remembered that the sinus region in the human heart is not so well separated from the auricle as it is in the lower animals. Recent observations of Koch,[8] however, upon the dying heart of a human fetus, tend to support the view that the sinus is the site of the primary motor centers. He found the last part of the heart to die was that situated in the wall of the coronary vein. This situation, he believes, belongs embryologically to the sinus venosus. The fact that the ramification of the conducting muscle bundle has been traced to this region gives color to the original hypothesis of Hoffman. Schoenberg,[9] from examinations of about fifty arrhythmic hearts, also thinks that the stimuli for contraction originate at the sinoatrial junction. In five cases he demonstrated inflammatory changes in this region.



Diagrammatic illustration of the transmission of stimuli to contract through the heart. The arrows represent the course of the impulse, not the blood current. A block may take place at points A or B (?).

The propagation of the stimulus to contraction has been traced from the auricular to the ventricular portions of the heart by way of the muscle band of His. Because of the proximity of the base to the auricles, one would think that the basal portion of the ventricle contracts first. Tawarra and Retzger,[10] however, have shown that the stimulus-conducting system, continuous with the muscle band of His, passes downward into each muscle to the region of the papillary muscle, where the fibers break up into arborizations and are distributed partly toward the apex and partly toward the base of the heart. From this distribution it would seem that the roots of the papillary muscles and the lower portion of the ventricular wall receive the stimulus to contraction earlier in the cycle than the fibers at the base of the heart. This hypothesis seems to have been confirmed by Rehfish.[11] He has been able to demonstrate in graphic curves that the impulse is received at the apex before any other part of the ventricular wall and that this stimulus to contraction is propagated from this point to the base.

Summarizing the above works, then, we find that the impulse causing the heart to beat originates at the venous end and is transmitted in such a way that the auricles contract first and the ventricles an instant later. In passing from the great veins to the atrium the stimulus traverses the bundle of muscle fibers described by Keith, is then propagated like a peristaltic wave through the auricles, thence by the muscle band of His to the bases of the papillary muscles and lowermost portion of the wall of the ventricle, and finally to the base (see diagrammatic illustration).

Interruption of this impulse is known to take place at the auriculoventricular band. As has been said, Gaskell and Wooldridge produced independent atrial and ventricular contractions by constriction or destruction of this muscle. Erlanger, by an ingenious contrivance, has been able in the dog to compress the bundle of His and produce various stages of heart block, namely, one ventricular silence in twenty-seven auricular beats and one ventricular silence in every other auricular beat, giving a rhythm of 2:1 and proceeding to a 3:1 and a 4:1 rhythm, until finally no impulse passes from the auricle, but the ventricles beat with their own inherent rate, which he estimates to be about twenty-three to twenty-eight beats per minute in man (Osler).

Gibson has suggested that heart block may take place at a higher location than in the auriculoventricular junction, namely, at the sinoauricular junction. In view of the hypothesis that the impulse to contract originates at the large veins, and the discovery by Keith of a muscle band in the sinoauricular junction, Gibson's belief seems to be a well-founded one.

As Holst[13] has suggested, this is not a specific affection but merely a combination of symptoms with constant phenomenon of heart block, and the pathogenesis and etiology may differ in each case. Of thirty-seven cases from which I have been able to compile data, few furnish information that makes statistics on age, sex, or occupation of much value in considering the etiology. The disease seems to be more common, however, in those of advanced years, due, perhaps, to sclerotic changes or a greater susceptibility to fatigue of the muscle fibers.

There is a neurotic group of cases in which all the symptoms may be present but in which no lesions are found post mortem. Heineke, Muller, and v. Hosslin[14] state that this arrhythmia may be due to pathological processes in the vagus nerve.

Syphilis must be named among the etiological factors. Jagic[15] reports the study of a case of the Adams-Stokes' syndrome in a man of thirty years of age in whom no suggestion of syphilis was found until at autopsy a syphilitic gumma was detected in the interventricular septum and bundle of His. Karcher and Schaffner[16] summarize twelve cases, in six of which the muscle band of His was the site of syphilitic change. This symptom complex may also occur in the course of acute infections.

Gerhart[17] tells of a case developing the first week of an attack of acute articular rheumatism in a man aged twenty-five. Symptoms of heart block recurred at intervals and finally disappeared. The patient contracted enteric fever from his attendant and succumbed to hemorrhage in the fifth week. Autopsy revealed considerable anatomical change in the bundle of His, which sooner or later would probably have induced renewed symptoms.

During the normal rhythmicity of the heart's action, sufficient time elapses between successive beats to permit these muscle bundles to return to their normal state, but when they are injured the irritability of these fibers seems to be considerably reduced and therefore may not react to the stimulus from higher up. The impulse is then blocked. If blocking takes place at the muscle band of His, the auricles continue to beat, but there is an asystole of the ventricles, for a time at least.

The macroscopic appearance of the heart may fail to reveal any pathological changes but sections from the organ under the microscope usually show the seat of trouble to be in or encroaching upon the auriculoventricular or sinoauricular bands. These changes vary from a cloudy swelling to complete obliteration of the muscle fibers. Gerhart, Schoenberg, and others have demonstrated inflammatory changes in the musculature between the veins and the atrium or the atrium and the ventricle.

Gummatous infiltration in the interventricular septum and bundle of His is recorded by Jagic[15] in one case, and in half a dozen of the cases summarized by Karcher and Schaffner,[16] the band of His was the site of syphilitic change.

Turrell and Gibson[18] record the autopsy in a case studied for eight years in which the microscope showed a tendency to fibrosis in the region of the central fibrous body of the heart, extending down to and encroaching on the bundle of His. Fibrous myocarditis with atrophy of the muscle fibers of the bundle of His is reported by Beck and Stokes[19]. These changes were due to pressure from calcareous infiltration of the auriculoventricular groove and its surrounding muscular and fibrous tissue.

In spite of the fact that there was a complete obliteration of the bundle of His in one of the three cases of Heineke, Muller, and v. Hosslin,[14] the ventricles frequently contracted with the auricles. These writers assume that under certain circumstances and long duration of the affection, other routes for the conduction may be developed.

In this connection Lewis[20] says that we are not justified at present in assuming that heart block will invariably arise from such lesions in the band of His or that it is invariably dependent upon such a lesion.

That we have not yet come to a full knowledge of the morbid physiology of heart block, is quite evident. When more is known of ionic influences (Loeb) and also the coincidence of vagus impulses and the liberation of potassium in the heart (Howell and Duke), some of the present inexplicable phenomena of this arrhythmia may fade into the dim past.

Adams-Stokes' disease manifests itself primarily upon the vascular system and secondarily upon organs suffering as a result of faulty cardiac action. A constant feature is bradycardia of the ventricles. This, of course, varies in degree. Erlanger estimates the ventricular beat to be about twenty-three to twenty-eight per minute. With the auricles contracting at the usual rate there may be a rhythm of 2:1, 3:1, 4:1, or even as few ventricular systoles as six per minute.

In the case of Karcher and Schaffner[16] tachycardia of the auricles was present; there was a radial and carotid pulse of thirty-three with a jugular pulse three to four times as rapid. This arrhythmia usually progresses to a complete asystole of the ventricles. On the other hand it may be transient. Gerhart[17] reports two cases of retrogression of the Adams-Stokes' symptom complex, in both of which the beats returned to normal.

Failure to empty itself on the part of the right ventricle causes a distention of the auricle and great veins of the neck. Stokes drew attention to the visible auricular impulse in the veins of this region.

The great reduction in the output from the left ventricle of arterial blood serves to explain the various cerebral manifestations of this disease. This anemia may give rise to vertigo, syncope, pseudo-apoplectiform attacks, or even epileptiform seizures. In a case studied by Beck and Stokes[19] the attack was usually preceded by a distinct aura in the form of sounds resembling the ringing of bells or music. The patient suffered from severe pain in the right side of the head and face and spasmodic contraction of the muscles of that side. Unconsciousness for from five to fifteen seconds would come on, when the face would be ashen gray, the lips cyanotic, and the breathing slow, irregular, and stertorous. In the early history of the case unconsciousness was not complete and other symptoms were not so severe.

The development of this symptom complex is of ill omen. The underlying cause, of course, influences the prognosis. If it comes on suddenly, the patient soon perishes; but if the development is insidious death may be stayed for days, months, or even years. In a case studied by Turrell and Gibson[18] the patient lived eight years. Retrogression of symptoms has been reported, but such are uncommon occurrences.

It will be remembered that the late president of one of our greatest railway systems succumbed to this affection.

I have been able to find but little bearing on treatment. Jagic[15] obtained good results from small doses (0.05 gm per day) of digitalis, claiming that the amount was too small to excite the vagus but large enough to act upon the heart muscle alone. He emphasizes the necessity of antisyphilitic treatment in the young. When we consider the nature of the local disease, its etiology and pathogenesis, it must be acknowledged that expectant and symptomatic treatment is at present the method of handling Stokes-Adams' syndrome.

My thanks are due Dr. H. Smith for abstracts of a number of the valuable articles listed below.

THE PRESENT STATUS OF PROSTATECTOMY.*

By J. BENTLEY SQUIER, M.D.,

NEW YORK.

When your President gave me the courteous invitation to address your society, he requested me to speak about prostatectomy, but did not specify to what particular phase of the subject I should limit my remarks. Therefore, it has seemed to me that it would be most interesting to approach the subject broadly and take "account of stock," so to speak, and see if we can arrive at some definite conclusions concerning the present status of the operation. There is somewhat of a selfish motive on my part in presenting this paper before this society. Composed as it is of workers in so many diverse branches of medicine, I am taking advantage of the opportunity to get from the discussion, which I hope will be free, the views of men whose experience with prostatectomy has been other than that of a genito-urinary specialist.

Surgical attack upon the prostate has been known to surgical literature for some centuries past, but it is only during the last twenty-five years that any real advance in the total removal of the organ has been accomplished. Some of the earlier operations which apparently offered much for the relief of prostatic obstruction, fell into disfavor only to be revived years later as original work on the part of other investigators. A notable instance of this is the operation of vasectomy, which in the early nineties was exploited as the great cure for hypertrophied prostate, even though, as early as 1825, Sir Astley Cooper had proven that vasectomy had absolutely no effect upon prostatic enlargement. Although the specimens of his investigations are still extant and on exhibition at the Royal College of Surgeons, Guyon and others had to repeat the experiments which he made in order to disprove the revived theory. I merely mention this to emphasize the need of our occasionally stopping in our work to study the work of those gone before, to see whether our work is really original or whether we are developing some theory of an earlier observer. The names of recent operators are attached to various surgical procedures on the prostate which differ only in detail of technique, where the names of the original investigators whose work made the present operations possible have become unknown. The names of Mercier, Goulet, McGill, Bellfield, and Goodfellow should never be forgotten, for they were the ones that really paved the way for the present complete operations. Fortunately we have practically passed through the period of Bottini-ism and partial removal of the prostate and have come to appreciate the necessity of radicalism when operating upon it. Surgery of the prostate, like surgery of the appendix, has resolved itself into one operation, removal. Whether this can be best accomplished by the abdominal incision, or by a perineal one, is the bone of contention between the various operators. This difference in operating has brought out an interesting observation. The perineal operation requires more elaborate dissection than the high operation, therefore it has especially appealed to the deft skill of the surgical members of the Latin race; whereas the Anglo-Saxon surgeons, with their ancestral boldness have largely been champions of the high operation. The suprapubic operation is a comparatively simple surgical procedure; the perineal operation rightly executed is a delicate, artistic performance. But leaving these considerations out of the question, feeling that the prostatectomist should be equipped to do either operation equally well, what are the points which should make us choose one rather than the other? Let us first consider the difference in mortality in the two operations. By going over a vast amount of literature one is struck by the fact that the death rate is higher when the operation is done suprapubically, but even this is now open to criticism because the death rate from the suprapubic operation has been materially lessened in the past two years. In 1906, Lynn Thomas, in the *British Medical Journal* for November, collected the statistics of 677 perineal and 583 suprapubic operations. The death rate of the suprapubic operation was 7 7/10 per cent. and 6 1/8 per cent. in the perineal. Freyer has since published the statistics of mortality in one hundred and nineteen cases of suprapubic prostatectomies as being 7.5 per cent. The average operative mortality of eight hundred cases of perineal prostatectomy performed by twelve surgeons, viz., Young, Ferguson, Goodfellow, Albarran, Hartman, Watson, Paucet, Legueu, Murphy, Mayo, Rafin, Syms, from results published from 1904 to 1908, was 6.1 per cent.

The combined mortality of my own cases of suprapubic and perineal prostatectomy in the first one hundred cases was 7 per cent. In the last fifty cases of perineal prostatectomy I have had but one death.

Young has published one hundred and twenty-eight consecutive perineal prostatectomies without a death. Deaver believes that the mortality of the two operations is practically the same in equally good hands, provided the statistics are honestly made and not doctored. From a study of statistics, it is very apparent that as we have gained in knowledge of which are the proper cases to operate upon and carefully limited ourselves to the selection of these cases, the death rate between the two operations probably will vary but little.

In contrasting the two operations, the following points present themselves. By the use of various prostatic tractors the perineal operation can be made a visual one. The suprapubic, necessarily, must be tactile. This is no advantage in favor of the perineal, because if the proper plane of separation is entered in removing a prostate suprapubically, the sense of sight is absolutely unnecessary, whereas in the perineal operation it is of the utmost importance. The point is just this, the question of incontinence of urine following prostatectomy, either performed suprapubically or perineally, depends largely on the condition in which the compressor urethræ muscle is left following operation. In the suprapubic operation all the surgical work is performed behind the posterior layer of the triangular ligament, and, therefore, this muscle lying as it does, between the two layers of the triangular ligament is not disturbed. In the perineal operation one encounters this muscle in the approach to the prostate gland, and to save its integrity it must be carefully retracted out of one's way before prostatic enucleation, and it is principally on account of this that the visual sense is such an aid to the proper performance of the operation. The almost complete guarantee which we can give our patient that there will be no incontinence following operation, is one of the great factors which makes the suprapubic operation so attractive. But I believe that if the operator has suffi-

*Read by invitation before the Physicians and Surgeons' Club of Jersey City, on March 16, 1909.

cient knowledge of the structures of the perineum, he can give this same guarantee by the perineal method. The saving of this muscle is the crucial object in prostatectomy, because injury causing a lack of function may leave the patient in a more deplorable state from incontinence of urine than his former retention produced by the obstruction.

The size of the prostate might bias our judgment for or against one or the other operation. A very large prostate unquestionably can be removed more easily through the suprapubic route and a small, hard fibrous one through the perineal. The presence of stone would argue for the suprapubic operation. The presence of carcinoma of the prostate would indicate perineal operation, although surgery for this condition is still in its infancy. The time required to perform the two operations is practically the same. The length of time the patient is confined to bed following operation is possible a little longer after the suprapubic operation, although by proper dressings a patient can be gotten out of bed in twenty-four hours following either operation if the necessity arises through signs of complicating pulmonary hypostatic congestion. Operative results are practically identical disregarding added danger of incontinence following the perineal operation. The wounds heal in about the same length of time. Strictures following operation may occur alike both after the suprapubic and perineal operations. I have seen one following the suprapubic operation and one following the perineal. In one of these, the perineal, which has been reported by Dr. L. Bolton Bangs, it was necessary to open the bladder suprapubically and do a retrograde instrumentation of the urethra and division of the stricture in order to relieve the condition. The case following suprapubic operation by a prominent New York surgeon also especially skilled in suprapubic prostatectomy. Some months later I had to open the bladder and incise a stenosed vesical neck for a practically complete retention. I make but brief mention of this case at this time as it is of such interest that I expect to report it in full before the American Association of Genito-Urinary Surgeons. The majority of text books on the subject refer to stricture following prostatectomy as an extremely rare occurrence. My own belief is, that it occurs more frequently than is reported.

A word or so now in regard to the recovery of the bladder. In patients who have been suffering from cystitis for a long period prior to operation, we must naturally expect some disturbance of the function of micturition even after removal of the prostatic obstruction. Outside of any existing inflammation of the mucous membrane which may increase the frequency of the act, the condition in which the walls of the bladder have been left by the local inflammation will have an important bearing upon the amount of urine which the bladder will hold. Therefore, it is always wise to be guarded in our statements concerning this detail, because even after the removal of the prostate a contracted bladder may be a source of intense discomfort to the patient from the uncontrollable frequency of urination which it produces. On the other hand, a bladder which has been greatly overdistended for a long period sometimes never regains tonicity enough to absolutely evacuate itself, even though the obstruction is removed, and this inability to empty the bladder may prolong the convalescence from a chronic cystitis almost indefinitely, from the tendency of residual urine to decompose.

While the end result of a well performed prostatectomy is alluring to a degree, I think it is only after mature deliberation and a careful weighing of the pros and cons that a patient should be advised to submit to it. The impetus which prostatectomy has had in the last ten years has been tremendous. Prostatectomists have sprung up everywhere, and consequently patients have been submitted to operation without justification. The subject of prostatectomy cannot come up for discussion anywhere without numerous unfortunate results being related. The question should be one of conservatism in the selection of patients for operation. I believe this is the keynote to the situation. It is only minor details which we take into consideration in our choice of operative route, because as I have stated, the difference of mortality between the two methods is not relatively great, but the question of whether the patient is fit to stand any surgical procedure is the one of paramount importance. Palliative treatment has been said to have a practically absolute mortality. The majority of patients succumb to some infection of the bladder or kidneys directly responsible to it. Nevertheless, we all of us have under our care many patients who have enjoyed an infinite measure of comfort by the intelligent use of the catheter for years. I have one gentleman under my care at the present moment who has been using a catheter since 1873 and has never yet suffered from any complication directly attributable to the use of the catheter. Notwithstanding this, if operation has been elected, early operation would naturally give us a better percentage of results than by delaying until some infection has engrafted itself upon the obstructive condition. In summing up my own experience, which is now considerably over a hundred operations, I feel that the future of prostatectomy depends absolutely upon our wisdom in determining the personal equation of operative risk, and that our decision in each case should be chiefly influenced by the functionating ability of the kidneys.

Histology and Pathogenesis of Condyloma Acuminate.—Pietro Stancanelli has examined many specific condylomata and compared their histology with that of *condyloma aconinato*, and as a result gives us the following conclusions: This growth is a product of chronic proliferation which begins in the mucous corpuscles of Malpighi, resulting in infiltration and proliferation of the papillae; a new formed tissue of embryonal type arises, which tends to organization and histological differentiation. From their mode of origin and tendency to necrobiosis the beginning is in the mucous bodies. The tissue is of an inflammatory-hyperplastic type which tends to organization. It is furnished with a peripheral nervous reticulum fibrillar and ganglionic. Bacteriological and bacterioscopic researches indicate that it is not caused by bacteria. The cause is probably an inflammatory substance of chemical nature coming from without and penetrating through the epithelial strata.—*Giornale Internazionale delle Scienze Mediche.*

Rare Observation of Acute Primary Latent Diphtheria of the Middle Ear.—Olimpio Cozzolino records a somewhat rare observation of primary diphtheria of the middle ear. There was no evidence of primary diphtheria of the nasopharynx, although the child had adenoid vegetation and hypertrophied tonsils during the course of the disease. It began with an acute otitis media which rendered paracentisis necessary. Through the opening of the drumhead was to be seen a grayish white membrane covering the structures of the middle ear. When removed with forceps this disclosed a bleeding base. Antitoxin was administered and relieved the general symptoms, but did not cause the disappearance of the membrane. The serum was then used by instillation into the middle ear, and the membrane promptly disappeared. The exudation from the throat showed no diphtheria bacilli; neither did the membrane removed from the middle ear. Still, the author considered that there were enough characteristic symptoms to show a true primary diphtheria of the middle ear.—*Lo Pediatria.*

THE CUBAN MENACE.

ELEVEN years ago, when it seemed probable that the United States would be compelled to take over the government of Cuba after Spain had been forced to withdraw from the island, we called attention to the sanitary benefit to both countries which would follow this change of government, and expressed the conviction that the result would be that yellow fever would be driven from its stronghold there.

That our prediction of a sanitary regeneration of Cuba was realized and more than realized is now a matter of history. Through the brilliant work of Major Reed and his associates in establishing as a fact the previously unaccepted theory of Finlay regarding the rôle of the mosquito in spreading yellow fever, and the practical application of this fact by Gorgas, the age-long endemic of yellow fever in Havana was terminated. Havana was cleaned and made a popular winter resort; the handful of hardy Northerners whom curiosity had sent to the island each winter was succeeded by crowds of tourists with pockets full of money and of settlers with capital, bringing the beginnings of prosperity to the country. One would think that a people as acute as the Cubans are reported to be would have seen that their prosperity was dependent upon a continuance of the sanitary condition established by the medical officers of the United States Army, and for a time, indeed, they did endeavor to continue the methods of Colonel Gorgas. But the politicians had their myopic gaze turned toward the fleshpots and failed to realize that there would soon be no fleshpots if they went back to their old dirty ways of living. Yellow fever reappeared in Havana and other parts of the island, but fortunately the quarrels of the greedy politicians among themselves brought about a second intervention in the autumn of 1906. While the United States Army was keeping the Cuban "generals" quiet and restoring order and financial integrity to the island government, the medical officers were instituting a fresh campaign against the yellow fever mosquitos, and with considerable difficulty freed the country once more from this disease.

The seeds of the fever, however, are still there. What they are and where they lurk is a problem that calls for further study; it may be that the disease persists in attenuated form among children in the country districts, or there may be fresh importations from time to time from Mexican ports. In any case it is certain that there will be a return of the yellow fever endemic in Havana and other Cuban cities unless the American methods of warring on the Stegomyia mosquito are maintained. That they will be maintained there is unfortunately little reason to hope. It is only a few months since the control of the government was turned over to the Cubans again, and already cases of yellow fever, as we are informed by a trustworthy correspondent, have occurred in different parts of the island. The authorities, he writes, declare these cases not to be yellow fever, but pernicious malaria or malignant jaundice (*ictero grave*), nevertheless it is believed by many that they are cases of genuine yellow fever.

That the Cuban legislators are so shortsighted as not to see that the prosperity of the island, and consequently a full treasury for personal needs, depends upon keeping their country in a sanitary condition and so attractive to tourists and settlers, is a matter that concerns themselves. They may sink their island to the level of Haiti, if they please, but it is intolerable that they should suffer conditions to be renewed in Havana which endanger the health and prosperity of our entire Gulf Coast. The United States government may let the Gomez administration run Cuba as it will, waste its resources, pile up an unpayable debt, and put an end to public improvements, but that Havana can be allowed to become again a pest hole and a menace to the lives and the property of our own citizens is unthinkable. If the Cuban government will not give a free rein and ample funds to the sanitary authorities on the island—there are capable men there to do the work if they are only permitted—then our government should take the matter in its own hands. The sanitation of the island should be entrusted to the United States Marine-Hospital Service, with absolute authority in all matters of public health, and the Cuban administration should be compelled to vote a sufficient appropriation, untouchable by the politicians, to defray the cost. An appropriation for sanitary purposes was made before the Gomez administration came in, but this, we understand, has been covered back into the treasury, and has been or will be spent by men who are "not in politics for their health," nor for the health of their countrymen or ours.

SEWAGE DISPOSAL FOR SMALL TOWNS.

THE disposal of sewage, so that it is not a menace to health, is a question that is still exercising the minds of sanitarians. Although vast improvement has been made in this direction, the last word on the subject has by no means been said, and the problem yet awaits its final solution. The encouraging feature of the situation is that the ordinary unscientific but intelligent citizen is manifesting an interest in the matter, and is beginning to apprehend that effective sanitation is a long step on the road to good health, and that slipshod methods of carrying out sanitary measures bear with them their own punishment, from the standpoint of both health and expense. The primitive modes of get-

ting rid of sewage in rural districts are undoubtedly a fruitful cause of mortality and sickness. The old oaken bucket is not infrequently the conveyer of dread epidemics of disease, and many of the picturesque spots of the country side, regarding which poets and painters are so wont to rave, are often but whited sepulchres, concealing and fostering the germs of numerous fell maladies. Of course, it would be impossible in a sparsely populated country as is America to dispose of sewage matter everywhere in an effective way. In strictly rural districts, the only thing to be done is to endeavor to educate the inhabitants themselves to take elementary and necessary precautions to prevent the spread of disease, that is by exercising ordinary care in the disposal of sewage.

In small towns, however, more than this should be attempted, and more elaborate schemes for treating sewage are assuredly indicated. In Great Britain, where, on account of the far denser population, the conditions as regards disposal of sewage are more pressing and acute than in this country, the question of small towns in this relation is arousing general concern, and the decision has been come to that modern methods of sewage disposal must be introduced, and in fact in a large number of instances these have been already instituted. There is, however, no agreement with regard to the particular form of sewage disposal best suited to small towns.

In the *Sanitary Record* of April 22, this matter is treated at some length, and it is shown from the report of the British Royal Commission on Sewage Disposal, issued a few months ago, that in the majority of cases land treatment is the best and cheapest method to adopt. At the same time it should not be forgotten that the old idea that sewage farms could be so managed as to be a source of profit to the town has been wholly exploded. When it has been decided that such a farm shall be made near a town, there are certain rules to be observed which may almost be termed axioms and which are laid down in the article in the *Sanitary Record* above mentioned:

"The farm should be placed in such a position that while it is within easy reach of the town it should be sufficiently remote to be neither an agency for the spread of disease nor an offense to the nostrils. All sewage works are liable at times to give off unpleasant smells; they should therefore be situated away from dwelling houses wherever this is practicable. The area of a sewage farm should be large enough to allow of ample space for the proper treatment of sewage that is placed upon it. Again, the farm should be situated if possible upon low-lying lands, so as to avoid to a great extent the expense of pumping, which adds very materially to the cost of up-keep. The success of a sewage farm depends very largely upon its management. A well conducted farm will yield excellent results, and a badly managed one will be a source of constant danger, nuisance, and expense." All the foregoing is without doubt true, and it is desirable in the interests of public health that the sanitation of country districts and of small towns should be more carefully supervised than is at present the case. Modern methods of sewage disposal are expensive and for this reason many inhabitants of small towns are opposed to the institution of the system, but on the other hand, the gain in healthfulness is so great that it is at all times money well spent.

PUERICULTURE.

Diseases of the body politic, like many of those of the human body, naturally produce in the course of time their own correctives or antitoxins and so cure themselves. The civilized world at present is suffering from a more or less severe epidemic of "race suicide," but already the reaction is beginning and in the movement of puericulture, naturally enough taking its origin, or at least undergoing its greatest development, in France, where the death rate exceeds the birth rate, there are signs of the working of the antitoxin which will eventually restore the normal ratio of births to deaths. The movement is not without interest to us also in a country where the so-called pure American is dying out and is being replaced by a conglomerate of all the races of the world. G. Eustache, in the *Journal des Sciences Médicales de Lille*, for March 27 and April 3, 1909, divides the subject of puericulture into three divisions: the duty of having children; the duty of bringing them into the world healthy; and the duty of preserving them in good health so that they may have the chance of living to adult age.

As to the first of these duties he arraigns his countrymen as too lazy to bring forth children, and cites this fact as a sign of degeneration in the race and the greatest peril of society. He calls it pediophobia in an age of phobias. It is a product of the egoism of the parents which increases as they rise in society. As to the second duty society should be warned of the dangers to the child of the possession of certain hereditary diseases by the parents, which will inevitably lessen his chance of a healthy life. Did the public understand fully these dangers it would protect itself against them. Marriage would be regulated by laws which would require healthy parents. The care of the mother during pregnancy would be greater and more rational, so as to allow her to produce a stronger and better child. The State would aid the pregnant mother when she was too poor to care properly for herself and her family, and would allow her to live without severe work during the last two months of pregnancy. All measures that would tend to produce abortion during the early months of pregnancy would be guarded against.

Under the third head—that, namely, of keeping the child in good health, are included the prevention of the avoidable diseases of childhood, most of which are the result of infections. This is a question of advanced hygiene. Preventing the effects of cold is important, and may be done by suitable clothing that allows the infant to exercise and produce his own heat, while the air is kept fresh by proper ventilation. The whole question of infant feeding comes next, and we need not discuss it here, further than to say that we must as-

sure every mother that she is capable of suckling her own child, and that it is her greatest duty to do so. Very few women cannot nurse their children, provided they wish to do so. Here, says Eustache, we have to combat the wishes of the grandmother and all the female members of the family, who will try to persuade the mother that she is too refined to nurse her child. Next in importance come the consultations for nursing mothers which have been so successful in France that they may well be imitated here. At these consultations the mother is taught how to manage the feeding and care of her infant, and she is shown how to obtain sufficient nourishment for herself to produce good milk for the child. When she is too poor to live properly she is furnished with nourishing food at cheap restaurants or without cost. All the hygienic measures necessary for the care of the child are taught her, and the infant receives medical care when sick. If artificial feeding becomes necessary proper milk is supplied. Could we have such "consultations" for healthy infants and such stations as the *Gouttes de Lait* of Paris we would need fewer Straus stations for the distribution of pasteurized milk because of less artificial feeding. As the author puts it, we should have no need of so many specialists in children's diseases since there would be few such little patients to care for, and percentage mixtures prepared by trained nurses would sink into the background with the increased knowledge of the mother and the rise of maternal alimentation.

Uncinariasis in the Army.

Considering the careful physical examination undergone by each applicant for enlistment in the United States Army, one might suppose that a recruit depot would contain a comparatively healthy body of men. One would certainly not expect to find there a widespread infection of a chronic disease. When, therefore, among these supposedly healthy and physically perfect men at Fort Slocum Captain Siler, as he reports in *The Post-Graduate* for May, 1909, found 90 per cent. of all those recruited from the Southern Atlantic States suffering from hook worm disease, it would seem that the infection in those districts must be more nearly universal than even the recent work of Stiles had led us to believe. Stiles a few years ago asserted that from 20 to 50 per cent. of all the inhabitants of the Southern States suffered from this form of anemia, and stated that the physical backwardness, lack of energy, and industrial inferiority of the "poor whites" were due to the disease, and not to simple laziness. The crusade of Stiles and his coworkers caused a decided awakening through Georgia, Alabama, and the Carolinas, an awakening so sudden that within a few weeks the supply of thymol in the country was practically exhausted. Later it was found that in Porto Rico 80 per cent. of the population were victims of the disease and that 30 per cent. of the mortality was due to it; and now Captain Siler tells us that 90 per cent. of the apparently healthy youth of the South are in reality infected with uncinariasis. Though many seem to be but slightly affected and appear to be in fair health, at least for some time after contracting the disease, many more are so debilitated that they become incapacitated for any prolonged labor, and as such are unproductive citizens and a care and expense to the State. It would be well if the health authorities in the States affected took up this subject and carried out an extended and systematic warfare against the parasite. The treatment of the disease is simple, and the cure is practically certain and quick. The expense of such a campaign would be negligible in comparison with the industrial and agricultural advance which would be sure to follow its successful undertaking.

Bedside Teaching.

The method of teaching medicine in this country is gradually undergoing a change from the didactic to the practical, from the systematic lecture in the amphitheater to the informal talk at the bedside. In some instances this great step has been made at one bound in the foundation of a new institution. In others it has come about gradually and insidiously more by the quiet work of the younger instructors who here introduce a ward round and there assign a student to a patient for the taking of a history or the making of a physical examination, thus planting the seeds which have grown to the formation of regular systematic dispensary and bedside study. Those who have been most enthusiastic in bringing about this change in method have been the Americans who have spent some time in the great universities and hospitals of England and Scotland, where the system of clinical clerks had its origin. It has, in fact, been common to speak of the clerking system, as the Edinburgh method of teaching medicine. That we, of the United States, have not been backward in this change is emphasized in a recent article by Byrom Bramwell in the *Edinburgh Medical Journal* for May, 1909, on the teaching of medicine in Edinburgh University. Bramwell appeals strongly for an increase in the bedside work and a reduction in the didactic lectures. The number of clinics should be greatly increased provided the number of students is kept small, and the clinical lectures should be abolished entirely. The author then refers to an American university in which the lecture has been displaced by ward teaching, and says that they may learn a great deal and get many hints for improvements in Edinburgh by a study of the methods of the younger and smaller school.

News of the Week.

Abuse of Medical Charity.—At a meeting of the Chicago Medical Society, held May 26, this subject was discussed at great length, and a systematic business administration scheme was proposed which it is thought in itself will largely relieve the situation of the able-to-pay patients. The medical profession, at last, proposes to introduce business methods in the hospitals and dispensaries. The United Charities of Chicago is willing to cooperate with the medical profession in establishing a central registry, which will be a further aid to this end, and has kindly offered the services of its investigators who are scattered through the city to help determine the merits of doubtful cases.

To Enlarge the Mt. Sinai Hospital.—Plans have been filed with the Building Department for improvements in the dispensary and training school

buildings of the Mt. Sinai Hospital, at Madison avenue and One Hundredth street, New York. Two stories will be added to the dispensary, making five in all, and a seventh story will be put on the training school. The ornamental roof house of the medical pavilion will also be considerably enlarged. The two new floors of the dispensary building will be fitted up for a laboratory and a neurological ward, rooms for internal medicine and skin and eye treatment, and a special *x*-ray room.

New Laboratory Facilities.—A large animal house to be used by the laboratories of the College of Physicians and Surgeons, New York, will shortly be erected. The building will have a steel frame, filled in with plaster, and will cost about $10,000. It will be placed back of the present college buildings on Sixtieth street.

Professor Irving Hardest, the head of the Department of Anatomy at the University of California, has been appointed to the head of the Department of Anatomy in the Tulane University of Louisiana.

Diphtheria in School.—Public School No. 61, in East New York, was closed by order of the Department of Health, on May 28, because of an epidemic of diphtheria among its pupils. At that time four deaths had occurred, and thirty cases were under observation. The school will be thoroughly fumigated before the children are allowed to return.

Typhoid Epidemic.—A large number of cases of typhoid fever are reported from Madrid, Spain, where the disease has been epidemic for some months. It is said that the deaths have averaged about twenty a day, and at the end of May there were over eight hundred cases in the San Juan de Dios Hospital.

Free Treatment of Diphtheria and Hydrophobia.—The appropriation bill which passed the House of Representatives of Illinois recently gives the State Board of Health $46,000 for the purpose of distributing free antidiphtheritic serum throughout the State. For this purpose $30,000 was appropriated by the last General Assembly. The Board has also been allowed $4,000 for the free treatment of poor persons said to have been bitten by rabid animals or otherwise in danger of hydrophobia.

Outdoor School.—The Board of Education of New York City has approved the plan to establish a public school annex on the roof of the Vanderbilt Clinic, Amsterdam avenue and Sixtieth street, for the benefit of children attending the Red Cross Day Camp at the clinic.

The Harvard Medical School Alumni held their triennial dinner at the Hotel Somerset, in Boston, on May 20. President Eliot, President A. Lawrence Lowell, Dr. William Osler, and Gen. Leonard Wood were the guests of honor.

Medical Graduates.—Eight students, one of them a woman, were graduated from the medical department of the University of Nebraska on May 20. Dr. W. W. Keen of Philadelphia delivered the address to the class.

The Denver College of Medicine, the medical department of the University of Denver, graduated twenty-three students on May 13, the diplomas being bestowed by Chancellor Buchtel.

At the annual commencement exercises of the Baltimore Medical College, on May 25, fifty-seven students were graduated. The address to the graduates was delivered by ex-Governor Warfield, and the diplomas and prizes were presented by Hon. J. Charles Linthicum.

Compulsory Vaccination in Venezuela.—Acting upon a recommendation of the Sanitary Commission, President Gomez of Venezuela has issued a decree making vaccination against smallpox compulsory throughout the republic. The ruling applies alike to native and foreigners, and non-compliance will be punishable by fines and imprisonment.

Charitable Bequests.—The will of the late Miss Mary E. Lewis, who died in Brooklyn recently, provides for the gift of $1,000 to the Seney Hospital of that city.

By the will of the late Rev. Samuel E. Appleton of Philadelphia the sum of $10,000 is bequeathed to the Episcopal Hospital for the endowment of two memorial beds.

Home for Nurses.—Mr. James A. Patten of Evanston, Ill., recently donated $40,000 toward the erection of a home for nurses at the Evanston Hospital. This home will provide accommodations for forty employes, including internes and nurses.

Removals.—Dr. James W. Markoe has removed to 20 West Fiftieth street. Dr. Frederick Peterson has removed to 20 West Fiftieth street.

The Franklin County (Vt.) Medical Society, at its annual meeting at St. Albans on May 20, elected the following officers for the ensuing year: *President,* Dr. Alan Davidson; *Vice-President,* Dr. A. I. Pratt of Enosburg Falls; *Secretary-Treasurer,* Dr. G. C. Berkley of St. Albans; *Delegates to the State Convention in October,* Drs. J. R. Patton, Arthur Morton, and C. S. Scofield.

The Missouri State Medical Association held its annual meeting in Jefferson City during the third week in May. The following officers were elected for the ensuing year: *President,* Dr. Tinsley Brown of Hamilton; *Vice-Presidents,* Drs. J. M. Bell of St. Joseph, J. A. Harris of Mount Vernon, H. G. Schobe of Paris, B. W. Hayes of Jackson, and J. L. Thorpe of Jefferson City; *Secretary,* Dr. A. W. McAlester, Jr., of Kansas City; *Treasurer,* J. Franklin Welch, Salisbury. The next meeting will be held at Hannibal, in May, 1910.

The Iowa State Society of Medical Women was in session at Dubuque on May 17 and 18. The election of officers for the ensuing year resulted as follows: *President,* Dr. L. Means, Des Moines; *First Vice-President,* Dr. Kate Horpel, Boone; *Second Vice-President,* Dr. Pauline Myers-Townsend, Marshalltown; *Secretary,* Dr. Lena Beach, Cherokee; *Treasurer,* Dr. Clara Whitmore, Cedar Rapids.

The Montana State Medical Association, in session at Missoula on May 12 and 13, elected the following officers: *President,* Dr. T. D. Tuttle, Helena; *First Vice-President,* Dr. J. J. Buckley, Missoula; *Second Vice-President,* Dr. F. C. Cuttle, Hunters Hot Springs; *Third Vice-President,* Dr. F. E. Buchen, Hamilton; *Secretary,* Dr. H. C. Kistler, Butte; *Treasurer,* Dr. C. T. Pigott, Butte. Hunters Hot Springs was selected as the meeting place for next year.

The Oklahoma State Medical Association, at its meeting at Oklahoma City on May 13, elected the following officers for the ensuing year: *President,* Dr. W. C. Bradford of Shawnee; *Vice-Presidents,* Dr. C. L. Reeder of Tulsa, Dr. D. A. Myers of Lawton, Dr. J. W. Duke of Guthrie; *Secretary-Treasurer,* Dr. Claude Thompson of Muskogee.

The Middlesex East District (Mass.) Medical Society, at its annual meeting, on May 19, elected the following officers: *President,* Dr. Philip Hammond of Winchester; *Vice-President,* Dr. Ernest D. Richmond of Reading; *Secretary,* Dr. F. Robertson Sims of Melrose; *Treasurer,* Dr. Charles Dutton of Wakefield.

The California State Homeopathic Medical Society held its annual convention at San José on May 12 to 14. The election of officers resulted as follows: *President,* Dr. Francis B. Kellogg of Los Angeles; *Vice-President,* Dr. Edgar R. Bryant of San Francisco; *Second Vice-President,* Dr. Eleanor Martin of San Francisco; *Secretary,* Dr. Guy E. Manning of San Francisco; *Treasurer,* Dr. Charles M. Tisdale of Alameda; *Board of Directors,* Dr. William Boericke of San Francisco, Dr. Sidney Worth of San Francisco, Dr. A. K. Crawford of Oakland, and Dr. Charles L. Tisdale of Alameda.

The Iowa State Medical Society, at its annual meeting in Dubuque on May 19 to 21, elected the following officers for the ensuing year: *President,* G. E. Crawford of Cedar Rapids; *First Vice-President,* M. L. Bolding, Cherokee; *Second Vice-President,* H. H. Clark of McGregor; *Secretary,* V. L. Treynor, Council Bluffs; *Treasurer,* W. B. Small of Waterloo; *Delegate to National Convention,* A. L. Dwight of Carroll. Des Moines gets the next meeting.

The Illinois State Medical Society, at its annual meeting in Quincy on May 18 to 20, elected the following officers: *President,* Dr. J. Leaming Wiggins of East St. Louis; *Vice-Presidents,* Dr. C. U. Collins of Peoria, and Dr. James E. Stubbs of Chicago; *Secretary,* Dr. Edmund W. Weis of Ottawa; *Treasurer,* Dr. Everett J. Brown of Decatur; *Delegates to the American Medical Association,* Drs. Frank Billings, Charles S. Bacon, and James W. Pettit.

Obituary Notes.—Dr. Thomas J. Happel of Trenton, Tenn., died at his home, from tumor of the brain, on May 24, aged 62 years. Dr. Happel was graduated from the University of Virginia medical department in 1871, and in the following year received a degree from New York University. He had long been active in the affairs of the American Medical Association of which he was vice-president in 1897, and a member of the Board of Trustees from 1898 until his death. He was a member of the Tennessee State Medical Association, the Gibson County Medical Society, the Tri-State Medical Association of Tennessee, Arkansas, and Mississippi, and the West Tennessee Medical and Surgical Association. In addition to other public interests he had served as health officer of Gibson County for sixteen years, and as president of the Trenton Board of Health for twenty-eight years.

Dr. Dorrance William Aldrich of Galesburg, Ill., died at his home on May 8, aged 63 years. He was graduated from the Bellevue Hospital Medical College in 1874, and was a veteran of the Civil War, and a member of the American Medical Association.

Dr. Salvatore Gomez, formerly acting assistant surgeon of the Public Health and Marine-Hospital Service at Gibara, Cuba, and recently head physician of the Spanish-American Iron Company's Hospital in Cuba, died in that institution on May 16, aged 47 years. Dr. Gomez was graduated from the Long Island College Hospital in 1891, and practised in Brooklyn until 1898, when he enlisted for the Spanish-American War. Since that time he had made his home in Cuba.

Dr. Thales Irving Stanton of Willimantic, Conn., died suddenly on May 26, aged 60 years. Dr. Stanton was graduated from the medical department of New York University in 1878, and was widely known throughout the eastern part of Connecticut.

Dr. Adele Stewart Hutchison, for twenty-eight years a practising physician of Minneapolis, died, on May 20, at Andover, Mass., after a long illness, aged 62 years. Dr. Hutchison was graduated from the Boston University School of Medicine in 1877, and the following year settled in Minneapolis. She was a member of the American Institute of Homeopathy.

Dr. Elizabeth D. Kane of Kane, Pa., died on May 26 at the age of 73 years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1883. She was the widow of General Thomas L. Kane of the famous Bucktails that figured in the Civil War. She was the mother of Dr. Eva O'Veal Kane and Dr. Thomas L. Kane.

Dr. L. E. Zech of York, Pa., died suddenly on May 22, from heart disease, aged 47 years. Dr. Zech was graduated from the University of Maryland Medical School in 1892.

Dr. William L. Steele of Helena, Mont., died at his home on May 16, aged 76 years. In 1857, Dr. Steele was graduated from the Medical College of the State of South Carolina, and in 1863 settled in Montana, where he practised until 1898. He was a member of the Montana State and Lewis and Clarke County Medical Societies, and had been active in public life.

Dr. Roger Brooke of Sandy Spring, Md., died at his home, on May 9, of heart disease, aged 63 years. Dr. Brooke was graduated from the medical department of the University of Maryland in 1887. He was a member of the American Medical Association, and was long a member and at one time vice-president of the Medical and Chirurgical Faculty of Maryland.

Dr. J. L. Hedleston of Woodlawn, Ala., died on May 19, aged 70 years. He was a graduate of the Medical College of the State of South Carolina in the class of 1855.

Dr. John Hammel of Buckshire, Ind., died at his home, on May 12, after a long illness, aged 54 years. He was graduated from the Kentucky School of Medicine in 1880.

Dr. Joseph B. Kinley of Denver, Col., died suddenly, on May 13, while presiding at a banquet given by the medical college of which he was Dean. Dr. Kinley, who was fifty years of age, was graduated from the Hahnemann Medical College and Hospital of Chicago, in 1885. He was Dean and professor of dermatology and genitourinary diseases in the Westminster University College of Medicine, and a member of the American Institute of Homeopathy, the American Society of Microscopists, the Colorado State Homeopathic Medical Society, and also of the Colorado Academy of Medicine.

Dr. C. B. Paul of Des Moines, Iowa, died suddenly at his home on May 8, aged 48 years. Dr. Paul began the study of medicine at the Iowa State University, and completed the work at the Marion Sims College of St. Louis, from which he was graduated in 1883.

Correspondence.

THE ILEOCOLIC CIRCLE.

To the Editor of the Medical Record:

Sir:—I read in the Medical Record of December 12, 1908, a most interesting article by Dr. B. Robinson of Chicago entitled "The Ileocolic Circle." I only regret that Dr. Robinson, without doubt insufficiently informed, should have neglected to mention in his article that I had already, at the close of 1906, described and illustrated the ileocolic circle, which was the subject of his article. He will find in "Les Travaux de Chirurgie anatomo-clinique," published under the direction of H. Hartmann, professor of the Paris Faculty of Medicine ("Chirurgie de l'Intestin," 3e Série, 1907, G. Steinheil, Paris), an article wherein I devote several pages to an account of my researches concerning the vessels of the colon. There are four illustrations in my text, in which one may clearly see the ileocolic circle described two years later by Dr. Robinson.

On page 127 of my article I wrote as follows: "Entre l'artère cœco-colique et la première branche de l'iléon formée par la terminaison de la mésentérique, autrement dit, entre le territoire artériel du gros intestin et celui de l'intestin grêle, il existe d'une façon constante, *hormis l'anastomose qui suit le bord mésentérique de l'intestin*, un espace triangulaire, avasculaire, libre de toute anastomose, dans l'épaisseur des feuillets mésentériques, mais où les ganglions lymphatiques abondent."

And also, on page 126, the origin of the appendical arteries: "L'artère colo-cœcale se dirige vers l'iléon, en décrivant une arcade qui passe dans l'aire de l'angle iléo-cœcal; *c'est elle qui abandonne le plus souvent les artères cœcales antérieure et postérieure et l'artère appendiculaire.*"

I would request the insertion of this letter in the Medical Record, the object of which is solely to promote the exact bibliography of the ileocolic curve.

Dr. J. Okinczyc,
Prosector at the Paris Faculty of Medicine.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HEART FEVER—MONGOLIAN IMBECILITY—LINACRE LECTURE—NURSING QUESTIONS, DEPUTATION TO GOVERNMENT, DISTRICT NURSING JUBILEE—ROYAL SOCIETY'S CONVERSAZIONE.

London, May 14, 1909.

In continuation of my last week's notes on Dr. Norman Moore's lectures on rheumatic fever, or, as he would like to have it called, "heart fever," I may remark that, in accordance with his view of its pathology, the cases of recurrent attacks are in reality instances of a long-continuous disease. As we hold that a recurrent tertian fever is due to the parasite having remained in the system just as the various indications of tubercle bacilli become active from time to time, so the several attacks of "heart fever" from which many patients suffer he regards as successive developments of an organism which remains in the endocardium throughout the series of attacks. Thus heart fever has a very variable duration; it may last two months and no longer, but that is rare; it often lasts three to ten years or longer still. A long attack is more probable when it begins in childhood. While endocarditis is thus to be regarded as an essential part of the disease, Dr. Moore admitted that some few cases recovered without permanent damage to the valves, and a further small percentage received damage the signs of which in time disappeared, but he maintained that the great majority acquired permanent valvular disease. He added that the proportion of those which are not permanently damaged may be increased by judicious treatment and that the commonest cause of continuance of the disease is the patient getting up too soon. A condition of absolute rest in bed as much as in enteric fever was advised. Dr. Moore's experience was that redevelopment is to be feared whenever the patient is allowed to leave his bed before the temperature has been absolutely normal, without any rise whatever, for three weeks at least from the last rise. Even after this the chart should be watched day by day and if any definite rise occur he should go back to bed for another three weeks. If no rise occur, he should, when possible, continue under observation for three months, taking salicylates in diminishing quantities, and great care being taken that no strain be put on the heart. Thus a school boy must not join in games all this time, and a lad at home should have carefully regulated exercise and get one rest or more in the day, as well as a long night. Of course, so experienced a hospital physician sees that three weeks before getting up is a serious call, but may not be enough in such cases—a point which would be discovered if three weeks were to be adopted as the minimum. He said he was "certain" an earlier day would only tend to prolong the disease.

The result of an attack of rheumatic fever to the valves of the heart cannot be estimated until the patient has been up and about for some time, and the tone of the myocardium has been quite restored. Then the damage may prove either less or greater than anticipated. One remark made by Dr. Moore was that in every case it is safe to predict that there will be no permanent damage to the joints. This shows how rigidly he would exclude from heart fever all cases of chronic rheumatism or any other form of arthritis. Yet the experience of most spa physicians supplies cases in which various forms of so-called rheumatic affections began, according to their history, with attacks diagnosed by their attendants as rheumatic fever.

A point of practical importance when a case of valvular disease is brought before us was urged by Dr. Moore, viz., taking the temperature. Thus only, he declared, can we be sure that there is not endocarditis present, and that treatment need not be rest in bed. Most physicians have seen patients walk to hospital who had been playing about the day before, but when examined had marked alteration of cardiac sounds with raised temperature, proving that they had had endocarditis for days. Some arthritis would be present, perhaps, with a little pain in a small joint. In such case the first question should not be when he had rheumatic fever, but has he got it now? Must endocarditis be treated or only an attempt made to relieve the difficulties of valvular defect? In conclusion the learned lecturer reiterated his firm conviction that (1) rheumatic fever is a single definite disease; (2) that endocarditis is always an essential part of it; (3) that its duration may extend over many years, and that these circumstances but half demonstrated, as they necessarily are at present the safest indications for treatment. Quoting Lord Lyndhurst's remark that the "worst exaggerator is he who understates." Dr. Moore said he had tried to avoid that fault, too common in books on this subject, and to state the conclusions to which his own experience had led him, without abatement and without reservation. He had risked censure for this because he believed the adoption of his views would not merely lead to the saving of lives but also to the prevention of many of the fatigues, disappointments in work, checks in usefulness, and other inconveniences which follow valvular disease consequent on the endocarditis of rheumatic fever.

Those who are interested in Mongolian imbecility had an excellent opportunity of studying its features at the meeting of the Clinical Section, Royal Medical Society, on the 30th ult., when no less than fourteen examples were exhibited by five members. The ages varied between nineteenth months and nine years. Some had congenital heart disease, others had not. Some had been treated with thyroid gland, others not. There was just as great variety in the degree of intelligence, though in none was it very great. Some were dirty, but others were fairly clean in their habits. Some were remarkably imitative, some fond of music, some playful, some mischievous, some very ill-tempered, and so on. A selection of the remarks made by the exhibiting members may interest you. Dr. Sutherland, having spoken of the chief features of the condition, said to deal successfully with these cases we need to know the cause, but it remains quite unknown. He thought thyroid was useless and a case improved by it was probably not Mongolian. Many died from tuberculosis in the first two or three years of life.

Dr. Poynton said he had treated a number of cases of the usual type for prolonged periods with thyroid, but thought it had little if any influence on the constitutional deficiency. Full doses soon brought on excitment and disturbed health. He only gave 1 grain doses of powdered gland when the treatment was continued a long time.

Dr. Langmead said one of his cases was the first-born of a young healthy mother, aged twenty-six. Contrary to the usual rule of birth toward the end of childbearing or late in large families. In his second case the patient was the tenth child and the mother thirty-nine at its birth. Both had congenital heart disease, one an accessory right auricle.

Dr. Fletcher said it was difficult to explain the almost constant presence of blepharitis. The flushed cheek only appeared after the second year and was preceded by a paleness and transparency of the skin.

Dr. L. Guthrie said thyroid was no use unless there were signs of cretinism. His cases were very imitative. One of them would mimic all he saw in hospital, as feeling pulses, auscultating, and simulating the walk of a lame patient. Notwithstanding this, neither of them seemed to profit by teaching.

Dr. Shuttleworth feared there was much confusion in the mind of many as to the distinction between Mongols and cretins. He did not think thyroid improved Mongols. They mostly died early, but some had survived to full age. The condition was seen in 5 per cent. of the defectives in the Royal Albert Asylum and in 2.6 per cent. in the Earlswood Asylum.

The Linacre lecture of St. John's College, Cambridge, the establishment of which dates back to the time of Henry VIII., was delivered this year on the 6th inst. by Sir Victor Horsley. He took as subject "The Motor Area of the Brain" and said it had been gradually discovered by researches carried on for a good many years that the movements of different parts of the body were under the control of various parts of the brain and one object was to determine how far those parts which controlled the movements of the arm were the recipients of sensation. He described a number of experiments he had made on animals and on men, the latter being of the greater importance, because only man could obey directions and indicate his sensations. In professional work, when tumors had to be removed from the brain, their presence was detected and located by failure of arm, hand, or fingers to perform their functions. When a tumor was removed from a part of the brain which was believed to control these movements, sensation was gradually recovered. The experiments that had been made were described and illustrated by lantern slides.

Yesterday the Prime Minister received a deputation got up by the Society for Securing Registration of Nurses. Sir V. Horsley's help had been secured and he said he made the amazing statement that the British Medical Association was the only body that could represent the medical profession—thus ignoring the General Medical Council and all the colleges and setting up a mere trading company. Mr. Asquith quietly corrected him and showed that there was not the unanimity he had represented in the profession. The Premier added that he had a list of 100 of the most eminent members of the profession, in all departments in London, and about 120 of the highest distinction in the provinces, who were entirely opposed to the legislation suggested. Also 49 matrons of London hospitals and 109 of provincial hospitals equally opposed. The question, therefore, was controversial and he only promised to give it careful consideration.

Yesterday, too, at Liverpool nurses were in evidence, though of a different order. The Queen Victoria District Nursing Association had organized a congress to mark the jubilee of the first establishment of district nursing in England. Messages from Miss Nightingale, Lady Aberdeen, and others were received. The Princess Louise and Duke of Argyll paid a visit and Her Royal Highness brought a sympathetic message from the Queen, who was sorry to be away, but would learn all that went on. "She feels that this is a thing that only women can do. The women try to be like men at the present day, but this is a thing which men cannot do, so we feel that here we are superior to anybody." You may guess Her Royal Highness was highly applauded. The congress is being continued to-day.

The Royal Society's conversazione was held on Wednesday, when many exhibits illustrating the advances in science were on view. Nothing seemed more generally attractive than Dr. Bushford's diagrams shown for the Cancer Research Fund and the Kashmir fire-basket, to the wearing of which cancer of the abdominal skin is attributed; the microbe of tick fever, radium in various forms, and other interesting exhibits made this meeting notable even for the Royal Socety.

Incontinence of Urine in Children.—Meuljikovsky of St. Petersburg divides cases of incontinence of urine in children into two classes. One in which the bladder is hypersensitive he treats with cocaine and adrenatin. The other, characterized by a bladder of reduced sensibility, and consequent overdistention and dribbling, he stimulates with 1 to 3 per cent. silver nitrate.

OUR LETTER FROM ROME.

(From Our Regular Correspondent.)

ROME AS A HEALTH RESORT—OPEN-AIR HOSPICES FOR CHILDREN—WAR AGAINST MALARIA—UNAUTHORIZED EMBALMING.

Rome, May 6, 1909.

There are two important factors that are almost always lost sight of in looking at Rome from a hygienic and climatic standpoint, and these are the sea and the mountains. Rome is really a seaport, although the Tiber is not freely navigable to all vessels. Only a short time ago we had a torpedo destroyer actually moored in the city, and the distance from the mouth of the river is a short fifteen miles, while an air line from the city to the sea reduces the distance greatly. About the same distance on the other sides are the Sabine Hills, Mount Soracte, the Alban Hills, and farther north the spurs of the Apennines, the city itself being about 200 feet above sea level. There is not a better watered city in the world, and few as well watered, with its excellent drinking water and copious fountains in every piazza or open space. Nor is there one that affords purer and more health-giving air, as might be expected from the topographical situation. The winter climate is cold enough to make indoor fires comfortable, and we always have a stretch of some six weeks of unbroken cloudless weather in December and January—just crisp enough to be invigorating. The temperature of the summer months averages about 85° F. For bronchial affections in all their forms and neurasthenia a winter in Rome is usually very beneficial, and one can be assured of being cooler all through the summer than in either New York or Boston.

The municipality evidently favors open air, whether for prophylaxis or treatment, and realizing how many cases of incipient phthisis or those predisposed to it may be thus cured or benefited have established hospices in the hills for the climatic treatment and recreation of children during the summer months. These hospices are entirely gratuitous, the only requisites for admission being that the child must be between 7 and 12 years of age and must have an attestation of poverty and a physician's certificate of vaccination.

Roman fever, so called, no longer exists. It was really a malarial fever with every now and then a malignant case. Since the Campagna has been drained and cultivated, and old portions of the city, where fevers of this nature were of more frequent occurrence, have been demolished and new buildings with modern improvements put up, no one ever hears of Roman fever. To find malaria one must go farther nowadays to the district known as the Agro Romano, which is to the south of the Alban Hills and toward the sea, where are the famous and deadly Pontine marshes. Even there, by means of draining the marshes and planting eucalyptus trees, the percentage of cases of malarial fever among the inhabitants is rapidly and constantly diminishing. For instance, according to a recent report by the Medical Inspector, Professor Postempski, the average percentage of malarial cases collated was as follows: From 30 in 1900 it fell to 10 in 1903, to 5 in 1905, to 4 in 1906, to 3 in 1907. The number of those belonging to the fixed and moving population, whether presumed immune or presumed malarial, who received the quinine treatment at the three stations in the Pontine Marshes was, collectively, 19,283, the number of cases of malarial fever observed among them being 1,443. Professor Postempski advocates an all-the-year-round antimalarial campaign instead of one of five months, such as have been undertaken thus far, the last one having been the eighth. The commune of Rome furnishes for the Agro Romano such quantities of quinine as may be demanded, according to need and without limit. The distribution of quinine for the Pontine Marshes is less regular and more difficult. The favorite ways of administering it are in the form of tannate of quinine chocolate lozenges, which, it seems, are most efficacious; tabloids, and Baccelli's mixture, which is akin to Warburg's tincture.

It is noticeable that employees of the customs, railway employees, and others who live in these districts, and who have the doors and windows of their cabins closely screened with a very fine wire gauze, through which it is impossible for mosquitos to pass, remain exempt from malarial fever, which is, however, prevalent among those who have not their doors and windows thus protected.

The Pope's recent attack of influenza has left him as well as he was before, and thus far no unpleasant sequels have manifested themselves. There have been no further consultations between Professor Marchiafava and Commander Giuseppe Petacci, the physician-in-ordinary to His Holiness. Dr. Petacci at present visits the Pope professionally twice a week, Dr. Marchiafava going once a week, usually on Sunday. His Holiness is following the régime prescribed for gout and uric acid diathesis, using as a beverage Fiuggi water. This mineral water is furnished directly from the springs at Anticoli, on the road to Naples, and is analogous to that of the "Hôpital" or "Grandi Grille" of Vichy. It is used also as a table water. He takes daily exercise walking and driving in the gardens of the Vatican.

After denunciation made by the Municipal Hygienic Physician of Rome, two doctors of the city have been brought before the judicial authorities for having made preservative injections on cadavers before the period fixed for observation had expired and before the Municipal Physician had attested the deaths. Their names are withheld, but the infraction of the law is considered a very serious one here, although they undoubtedly acted from the best of motives, such as the request of the family of the deceased or from threatened rapid decomposition of the bodies. The offense is rather a technical one, but still it may have unpleasant consequences for the offenders.

Progress of Medical Science.

Boston Medical and Surgical Journal, May 20, 1909.

A Functional Relation of the Tonsil to the Teeth.—G. H. Wright calls attention to the four periods in the development of an individual from two to eighteen years, when the tonsils become slightly enlarged without inflammation and without obstruction or evidence of inflammation, and these four periods are represented practically at the time when four groups of molars are in the process of eruption. These periods, with slight variation, are from two years from the first group, six years the second group, twelve years the third group, and seventeen years the fourth group. The author demonstrated his paper by the exhibition of patients, and supported his theories by references to the findings of other observers. He offers the following conclusions: Infection from the external surface of normal tonsils is rare. The usual source of infection is secondarily through the lymph channels. Tonsils though slightly enlarged when not infected return to normal with complete eruption of the teeth. Diseased teeth are prolific sources of enlargement of the glands through proximity of membranes either directly, by infections, or by the tonsils.

The Value of Ethyl Chloride as a General Anesthetic.—A. H. Miller says that the relative danger from an anesthetic depends on two factors: the margin of safety of the drug, and the character of the danger signs. The margin of safety of an anesthetic may be represented by the proportion of the drug which may be administered beyond the amount required to produce anesthesia without causing symptoms of danger. Nitrous oxide has a small margin of safety, but the danger signs are so marked that nitrous oxide anesthesia is the safest known. Ether has a fairly large margin of safety and quite well-marked danger signs, so it is quite a safe anesthetic. Chloroform has but a small margin of safety, and the danger signs are readily overlooked. It is always a dangerous anesthetic, but especially so in inexperienced hands. Ethyl chloride has a large margin of safety, but the danger signs are not marked. While it is very safe when administered by an expert, it may be very dangerous in unskilled hands. With an expert administrator, it should be safer than ether but less safe than nitrous oxide. With an unskilled or careless administrator, it is probably more dangerous than ether, but not as dangerous as chloroform.

New York Medical Journal, May 22, 1909.

The Medical Importance of the Study of Anthropology.—A. E. Woodruff discusses, among other topics, the greater mortality among the blonds, who appear to have a lower birth rate and a higher death rate. The preponderance among the population of blonds is due to immigration. What diseases, he asks, carry them off in the country at large? Here is where the medical profession can be of immense value to anthropology by simply recording the complexion of patients of each group of diseases. By a study of cases which have been under identical influences we can quickly determine what diseases afflict brunettes most and which the blonds. Then we can evolve therapeutics and preventative means. At present we have only the general law to guide us—men who migrate to a climate where the native is heavily pigmented are in some way damaged by the light. Experiments and observation in India during the last three or four years have established that generalization on a firm basis. The medical director of the British army has proposed to take up the matter of protecting the soldiers. In other words, pigmentation is of survival value, and men the world over instinctively hide from the light or protect themselves. Sambon, of the London School of Tropical Medicine, has devised a cloth with the outer surface light to reflect the rays as much as possible and an inner opaque surface to stop the rays which are not reflected. It is cool and comfortable. In the Philippines there is a growing tendency to wear black underclothing, and if one must go abroad in the daytime, the outer garments are of light color. It must be remembered that though black absorbs heat it aids radiation when the surroundings are cooler than the body, so that black tropical animals tend to hide in the daytime to avoid absorption, and are cooler for their black skin. In like manner, it is found that in the evening and indoors in the daytime, dark outer clothing is more comfortable than white of equal thickness and porosity. The blackest negroes do not live in the hottest parts of the world, and, contrary to popular opinion, they cannot stand a high degree of heat as well as white men, and suffer more from thermic fever in such conditions.

Electricity in Genitourinary Diseases.—S. Tousey utters a caution with reference to the dangers to the operator from careless use of this therapeutic agent. In the special field referred to in his paper, he reports the discovery in several instances of prostatic calculi not revealed by the other usual means of examination. Much benefit has resulted from the use of the ray in cases with considerable residual urine and frequent and painful micturition. In one case of tuberculosis of the prostate, the ray applications proved resolvent, causing a mass of exudate to break down into pus, while high frequency currents applied from an ultraviolet ray vacuum electrode in the anus were eliminant. The latter action caused the abscess cavity to contract and expel its contents, to be voided in the urine. Cases of cancer of the prostate treated by the author have not been cured, but the pain and tenesmus have been greatly relieved, the urine has cleared up to some extent, and life has been prolonged. The technique employed differs according to circumstances. In case of cancer and hypertrophy of the prostate the *x*-ray has been applied from an ordinary *x*-ray tube in a localizing shield which allows the rays to shine only upon the perineum, while in tuberculous cases a special tube has been introduced into the rectum and the *x*-ray has been generated almost in contact with the diseased tissues.

Blood-Pressure Observations and Life Insurance.—F. A. Faught describes and figures a portable instrument for estimation of blood pressure. He says that, while gross lesions of the heart and vessels are easily discovered, he feels certain that many applicants for insurance who are really good risks are rejected because of an inadequate appreciation of the difference between vessel contraction and vessel disease, and that a diagnosis of arteriosclerosis is often made erroneously. The feel of the radial pulse is not always a reliable guide as to what the instrumental reading will be. Cases have come under observation in which the reading of the sphygmomanometer was above 200 mm. Hg., while the vessel felt neither hard nor incompressible. On the other hand, the reading of the pressure may be lower than palpation of the vessel would suggest. Conclusions follow: (1) Recent increase in clinical data, which is the result of finer methods of observation, demand greater recognition by the practising physician and the medical examiner. (2) To facilitate a better understanding of the conditions met, more care should be exercised in the employment of clinical terms. (3) More careful study should be made of the vessels in an effort to distinguish atheroma, hypertension, and arteriosclerosis. (4) The sphygmomanometer is a valuable aid in determining arterial tension, and in differentiating diseases of the cardiovascular system. (5) Our present knowledge of the subject of diseases of the circulatory apparatus demands a critical revision of the present examination questions to be answered by the life insurance examiner.

The Therapeutic Use of Alcohol in Internal Medicine.—G. B. Twitchell believes that in alcoholic pneumonias the use of alcohol is very important to prevent

the nervous disturbance its discontinuance would cause, but in the nonalcoholic its value appears as a therapeutic agent, pure and simple. It is rarely needed in children and many adults do well without it. In the severer forms of the disease it is very useful. The pulse and first heart sound are the best indications of its need. The temperature comes down a little, the pulse is quieted and strengthened, and the livid face is flushed. Keep it up and the case, apparently lost, will meet the crisis successfully. The trouble from alcohol in this disease is that we give it too sparingly. A quart of whiskey in twenty-four hours may not be too much. In septic conditions also alcohol is very valuable. In pyemia, septicemia, and in the suppurating stage of smallpox it is a great help to the physician. In typhoid fever, especially toward the end, when we have to deal with a septic fever which in a worn-out patient may be dangerous, its use is very valuable, nor may we dread any untoward effect it may have on the ulcerated Peyer's glands, if, indeed, it ever reaches them. In cases of ptomaine poisoning a good dose of alcohol in some form will relieve symptoms that are left after a thorough cleansing of the alimentary tract. Probably the relief in some cases of uncomfortable stomach is attributable to the fact that we are dealing with mild forms of ptomaine poisoning. The danger of formation of the habit must always be borne in mind. *Journal of the American Medical Association, May 22, 1909.*

Typhoid Fever.—M. P. Ravenel and K. W. Smith describe a localized outbreak of typhoid fever occurring in a student's boarding house at the University of Wisconsin shortly after its opening, October 1, 1908. Commencing with the scholastic year, it soon had from 95 to 100 boarders, many applicants being turned away. The working force consisted of the landlady and her two sisters, a cook, two young women just from Norway, and thirteen student helpers, most of them waiters. Two or three of these students assisted in dishwashing, etc., but while hot water was used there was no attempt at thorough sterilization. About the middle of October, 50 or 60 of the boarders were attacked with diarrhea and nausea, some being ill for several days. The majority, however, recovered promptly without consulting a physician and the outbreak was attributed by some to veal and by others to bananas. During the last week of October a number of the boarders became ill with symptoms of headache, lassitude, loss of appetite, and pains in the limbs. These symptoms were generally attributed to grip, and by the middle of November more than 40 cases of illness were known to exist. Typhoid fever was suspected in several by the physicians, but the first Widal test made in the laboratory was negative. A number of the sick went at once to their homes without seeing a physician, some returned to work, though in a poor condition, others did half work. So far as possible all the cases were investigated, and in all a positive Widal was obtained. In less than a month 41 cases of typhoid fever were diagnosed among the boarders or workers, three of which terminated fatally. During the same time there was only one case of typhoid fever among the students not boarding there, and only three or four in the city of Madison, which has a very pure water supply at all times. Every possible source of infection was studied, the water, the ice, the milk supply, raw vegetables, oysters, etc., but no adequate cause was found. Attention naturally turned to a possible typhoid carrier, and one was found among the student waiters, and the exclusion of every other possible source has forced the conviction that the infection came through him. One fact seems to militate against this, however, namely, the rapidity with which the patients came down, which may indicate that a large number of persons were infected at the same time. Probably suggestion had something to do with it, as it was just at this time that the house was inspected, closed, and fumigated, and there was considerable excitement over the large number of students taken ill. This, however, only explains the breaking down. The possibility that the outbreak may have been due to a massive dose of typhoid bacilli suggested itself, but if so the source of the germs is a great mystery. Paratyphoid could be excluded, as all the cases gave the typhoid agglutination. Certain features seemed predominant in this outbreak—the headache was in the occiput and the pain extended down the back of the neck; constipation was more common than diarrhea. All precautions were taken and no case of sickness has developed since November.

The Combined Course.—J. M. Dodson defends the combination in universities which have a medical department of the two curricula, literary and medical, so that a student can obtain his degree by taking his junior and senior years, those branches which constitute the first two years of his medical curriculum. He gives at some length the history of how the adoption of this plan originated through the elective principle adopted in the literary courses of the higher schools, and shows how, in his opinion, certain medical subjects, like chemistry, histology, embryology, and bacteriology, are unquestionably such as can be considered branches of general learning. Human anatomy, though more directly medical, is still properly an important branch of zoology, and the same may be said of physiology. Two other branches, pharmacology and fundamental pathology, are essential branches of physiology, and as such are entitled to a place in the university curriculum. The idea maintained by some that teaching these medical sciences to medical students must be entirely different from the teaching given those who do not intend to enter the medical profession, is in his opinion entirely fallacious, and he does not consider the change which would have to be made degrades at all the baccalaureate degree. This does not, as it formerly did, stand for a classical education, but is a testimony that the student has spent so many years in liberal studies. The elective principle which is so generally accepted is a concession to the discovery that the student is capable of selecting his studies at the age in which it comes in play. "There is no line," he quotes from a prominent educational authority, "between cultural subjects and professional subjects." Similarly he maintains the change has not degraded the medical degree. The question whether two degrees are desirable, M.B. and M.D., the latter being the higher, he considers as decided in the negative on account of the lack of uniformity of the practice requirements in the different States, but he thinks that the giving of a second degree of M.S. or Ph.D. for advanced requirements is perfectly practicable and desirable. It is objected by some of the detached colleges in the country that the combined course is unfair to them, as they do not possess any relation to a university with a medical course. This can be obviated by the medical school giving credits for time spent in college for work in medical branches, and the proscription of this by certain examining boards he considers illogical. There is doubt of the legality of such proscription, and at least one attorney general has rendered an opinion in flat opposition to the contention of the examiners. Undoubtedly some colleges have attempted the teaching of medical branches for which they were not prepared, but the remedy for this is for the examination of their curricula by the examining boards and their classification accordingly.

Gallstone Disease.—J. R. Eastman says that it has been conclusively proved that smooth foreign bodies do not of themselves produce gallstones, and Mignot has found in his investigations that even when carrying virulent microorganisms they do not give rise to gallstones unless the infection is attenuated. Much, of course, must be presumed to depend on the character of the foreign body, a rough or irritant one being more apt to produce the irritation that would favor infection than would a smooth, unirritating substance, and we may assume also that bacteria may easily pass up from the intestines by way of gall ducts. It is well known that intestinal parasites are frequently found associated with gallstones and they doubtless furnish at once the foreign bodies and the atria of infection. Sutures, wandering needles, etc., have been found incrusted in the cavity of the gall-bladder, and Eastman reports a case of this sort in which the needle was presumably swallowed and had penetrated through the intestinal wall at one of the points where the gall-bladder is in immediate apposition with the intestinal canal, carrying in infection and producing sufficient inflammation of the gall-bladder and duct with consequent obstruction as to lead to precipitation of the bile salts and gallstone disease. The symptoms accompanying these conditions disappeared on its removal.

Removal of Arterial Obstruction.—J. B. Murphy reports the removal of an embolus from the common iliac artery which had completely obstructed the circulation in the left leg. The patient was a woman of 41, who after an attack of rheumatism suffered from shortness of breath and heart disease was diagnosed. Three years after the last rheumatic attack on April 5, 1909, she was seized with a sharp pain in the lower part of the left chest and upper abdomen which was considered pleuritic and treated accordingly. The next morning she was taken with an attack of nausea and vomiting, followed by pain in both legs which became cold and remained so till the morning following, when the pain in the right leg ceased and it regained its normal temperature, the left leg remained cold, was blue in the thigh, and very pale and shriveled at the toes. It was cold to half way between the knee and the

trunk, and there were large blue blebs scattered over the middle third of the thigh. On admittance at Mercy Hospital, Chicago, careful examination showed that the patient had a mitral, direct, and regurgitant murmur. There was no pulsation in the left femoral artery. The upper margin of the area of the demarcation was then about four inches below Poupart's ligament. The limb was undergoing dry gangrene from arterial obstruction, and it was decided to operate at once to remove the embolus which was diagnosed as obstructing the iliac artery. Nitrous oxid was given for thirty seconds and an incision four inches long was made downward from an inch above Poupart's ligament parallel to the femoral artery, which was exposed for a length of two and a half inches. Two provisional catgut ligatures were put around it, but not tied, so as to aid in elevating the artery, which was then incised for one inch parallel to its long axis. It was completely thrombosed. With the delicate forceps the clot (a bifurcated plug an inch and a half long) was drawn from below upward, causing a flow of fresh arterial blood, evidently collateral, through the femoral profundus. This was stopped by finger pressure and the extraction of the clot from the proximal side was begun, but the artery did not empty at once. A spoon was then used and more clot withdrawn, but no flow. A number six soft catheter was passed up the artery a distance of seven and a half inches, bringing away grumous bloody débris but no arterial blood. It was reintroduced but could not be forced through an obstruction at that point. Finally, by the use of a ureteral catheter passed up nineteen inches, a small quantity of arterial blood was released. Then a uterine sound was employed, and on the third attempt it seemed to penetrate a free space at a distance of eight and a half inches, and was followed by an intense arterial flow carrying much embolic débris. This was stopped by finger pressure in the ligature loop and the incision in the artery was closed with a rapid continuous suture of silk. One or two additional supporting stitches were inserted to control the hemorrhage completely. Unfortunately, the operation was made too late to save the limb, and it was amputated four days later. Murphy remarks on the symptoms of occlusion of large arteries, and refers to his own former experience since he first made a successful end-to-end union of a severed femoral artery. The suture of an incision in an artery is as easy as an incision of the intestine, provided a sufficiently small needle is used. He believes that even cerebral ischemia should be amenable when due to an embolus arrested in the common or internal carotid. He thinks, however, that aspiration through a catheter is better than the method he employed in removing the plug, for if the catheter is divided on the slant with the end open it can be readily introduced, and unless the embolus is very hard it can be removed by suction or fragmented by the catheter. Murphy does not advise incision into the exact site of the obstruction, as there would be less tendency to thrombosis if the point selected is above or below, preferably the latter. As in other types of emergency surgery, the operation must be done early to be successful. This applies especially to the cerebral ischemias. The removal of an embolus from the pulmonary artery by Trendelenburg, though unsuccessful, is worthy of special mention.

The Lancet, May 15, 1908.

A Plea for the Use of Antidiphtheritic Serum in the Laryngitis of Measles.—A. A. Warden believes that in the laryngitis of measles we should not wait for the result of a bacteriological diagnosis, but inject serum immediately. Laryngitis is a frequent complication of measles and is occasionally membranous in character, while nondiphtheritic membranous laryngitis is rare. We should inject the serum as early as possible when once laryngeal symptoms are noted. One case illustrative of the advisability of the author's plan is described.

Calcium Lactate in the Treatment of Epilepsy.—A. R. Littlejohn gives notes of two cases and relates his experience with a ward full of patients in hospital. He gives 15 grains of the remedy three times daily. In one case, that of a woman of forty-six years, with attacks of the petit mal type, the seizures were reduced from 45 to none in 24 hours after a three months' treatment. In a second case, a woman of thirty-three years, from 31 to none in the same length of time. No remarks are made with reference to the mode of action of the remedy.

The Histology of Endocarditis.—C. Coombs says that the reaction to the rheumatic invasion of the endocardium is characterized by the formation of very large fibroblasts in groups, which, so far as his own experience goes, are constant in rheumatic but absent from other forms of endocarditis. The valvular inflammation of rheumatic carditis is set up by microorganisms carried to the endocardium by the coronary arteries and their branches. There is evidence to show that the inflammatory reaction of rheumatic endocarditis begins deeply and spreads to the surface. The inflammation begins as a lymphocytosis, sparsely scattered through the valve, with greater concentration at some spots. Another form of leucocytosis is occasionally seen in rheumatism. Over those surfaces where the fibroblasts are plentiful and the endothelium stripped off polymorphonuclear leucocytes are sometimes deposited freely, especially on the patches of mural endocarditis. The changes remaining after acute inflammation has cooled down are summed up in two words—fibrosis and vascularization.

The X-Ray Treatment of Ringworm of the Scalp.—J. M. H. Macleod concludes from an experience of three years: (1) That the *x*-ray treatment of ringworm by the single dosage method with the dosage regulated by the pastille is practically safe and harmless. (2) That it is a method of treatment of such delicacy that even in the hands of an experienced operator an accident such as an overexposure might happen, but that such accidents should be of such extreme rarity as not to discredit a mode of treatment possessing such obvious advantages. (3) That severe dermatitis followed by permanent baldness is the result of an overexposure or is due to some accident such as the exposing of an area the resistance of which has been lowered by the previous application of strong irritants before the inflammation has entirely subsided, the use of wrong or inaccurately standardized pastilles, or from overlapping. (4) That permanent baldness or delayed hair growth without marked dermatitis is the result of overexposure, but that it might in rare instances be due to some idiosyncrasy on the part of the patient in the same way as the occurrence of alopecia areata after ringworm. He has been unable to obtain any definite evidence of injury to the brain by this method of treatment from his own cases, from the literature on the subject, or from anyone with experience of this treatment whom he has asked, and the experiments which he has done in this connection strongly negative the possibility.

British Medical Journal, May 15, 1909.

The Causation of Appendicitis.—W. S. Shepperd refers to the case of a man of thirty-six years with all the signs and symptoms of appendix inflammation, who experienced a sudden relief, followed by a desire to evacuate the bowels. A hard body was passed, looking like a date stone. There were no further symptoms, although tenderness over the region lasted some days. Examination of the body passed showed it to consist of calcium and magnesium phosphates, calcium and magnesium soaps, fecal detritus, inclusive of a small amount of inspissated mucus. The shape of the mass was elongated and from this and its composition the author thinks it probable that it had been formed in the appendix.

Treatment of Sleeping Sickness.—A. Balfour suggests that the same method may be applied to trypanosomiasis and sleeping sickness as has given good results in cerebrospinal meningitis, viz., the local introduction by spinal puncture of a highly immune serum obtained from the blood of patients who have recovered from the disease. In the past great difficulty has been experienced in attacking the trypansomes present in the cerebrospinal canal, and Kopke has made special efforts to overcome the difficulty when treating patients with atoxyl and other chemical substances. It is true that comparatively few cases of human trypanosomiasis recover, but a suitable serum might be obtained from the blood of patients subjected in the first instance to chemotherapy. A combined treatment might prove useful, attacking the trypanosomes in the blood by some of the more promising of our present drugs, and attacking those in the cerebrospinal fluid by performing lumbar puncture and injecting the patient's own serum, or the serum from a case which is improving, obtained by defibrinating and centrifuging the blood. It would seem that so far as the cellular contents go, the fluid in trypanosomiasis may approximate to the conditions found in cerebrospinal fever, a fact which is rather in favor of adopting the line of treatment indicated.

Surgical Considerations Connected with the Anatomy of the Maxillary Sinus.—A. S. Underwood dis-

cusses the anatomy of the antrum with reference to transillumination. He says that if the apices of the roots of the cheek teeth terminated below the antral floor or even protruded a little into it the transillumination might show a darkness where a small amount of pus was collected in one of the basins between the two septa, but if the roots of the molar teeth are imbedded in the walls of the cavity the buccal roots in the outer wall and the palatine roots in the inner wall, the thickening of these regions would prevent any transillumination and the deep pocket of the antral floor descending between these roots might contain certain things quite undemonstrable by transillumination. The first, second, and third molars in order are most commonly in relation to the sinus, the third invariably, and the cavity extends a little behind the third molar root. Moreover, the bony septa which divide the part of the sinus embraced by the roots of the third molar from the part in relation with the second molar are generally simple septa of bone, whereas the septa which are in relation to the front portion of the cavity are very often traversed at their upper edge by canals in the bone, sometimes closed and sometimes partially opened, which convey nerves and vessels across the cavity. Finally, in rare instances the whole of the third molar region of the sinus is entirely shut off from the rest of the sinus except for an insignificant hole very high up on the nasal side.

Acute Rheumatism, Its Allies and Its Counterfeits.—F. de Haviland Hall discusses this question under the headings of life insurance, pleurisy, tonsillitis, chorea, skin affections, subcutaneous nodules, diagnosis from pyemia and influenza, infective endocarditis, antitoxic arthritis, pneumococcic arthritis, and gonorrhea. His paper is a most readable one and we can refer to only a few of the salient points. There is much evidence in favor of the specificity of the *Diplococcus rheumaticus*. Insurance companies would save money if they would refuse all applicants who had suffered from an attack of rheumatic fever. The occurrence by preponderance on the left (cardiac) side would seem to indicate that it arises in connection with some cardiac infection. It is the lacunar form of tonsillitis which is most frequently associated with rheumatism. Chorea is probably caused by the toxins of the rheumatic bacillus affecting the motor areas in the brain. The most common skin affections in rheumatism are erythema papulatum and marginatum or circinatum. Less common are erythema nodosum, urticaria, and angioneurotic edema. Purpura may occur, also herpes labialis and zoster. The exact relation of the so-called "peliosis rheumatica," to rheumatism is uncertain. Large subcutaneous nodules mean persistent cardiac disease and add a grave prognosis. Infective endocarditis may or may not be of rheumatic origin. Antitoxin arthritis is certainly nonrheumatic. A peculiar form of eye inflammation frequently accompanies gonorrheal arthritis. Usually first one eye and then the other is attacked. There is injection of the small radiating vessels of the sclera which surround the cornea, sometimes accompanied by iritis and catarrhal ophthalmia. The paper closes with a short description of pneumococcic arthritis. The general style is sketchy, but the paper presents some very suggestive information along the lines of our present conception of rheumatism.

Münchener medizinische Wochenschrift, May 4, 1909.

Bacterial Antiferments and Bacteriolysis.—Kantorowicz says that the protective forces of the organism in its fight with bacterial invaders have been carefully studied. Similar forces exerted by the bacteria, on the other hand, have escaped attention. The latter, however, would throw light on the general problem of resistance of living tissues to the action of ferments, exemplified in the resistance of stomach to pepsin, of the intestines to trypsin, etc. Bacteria introduced into active solutions of trypsin continue growing; that life is not the attribute which explains their resistance to digestion is proved by the fact that dead bacterial bodies likewise resist digestion. Protection by capsules is excluded by first destroying the latter by thorough shaking of the bacteria in a special apparatus. High temperatures, however, have a remarkable effect: all the members of the colon group become susceptible to tryptic digestion after being heated to 75°. On the other hand, staphylococci, streptococci, the organisms of diphtheria and of anthrax undergo a temperature of 100° and yet resist tryptic digestion. The remarkable fact is thus learned, that Gram-negative organisms are the less resistant bacteria, while Gram-positive organisms resist digestion after heating. The supposition is warranted that these differences in behavior are due to the existence of antiferments, which are destroyed by a different amount of heat in different cases. Kantorowicz has succeeded in procuring such antiferment from the bodies of bacteria and in demonstrating its action in various manners, for which the reader is referred to original paper. That this factor is active in the living organism is shown by the staining qualities of bacilli after their ingestion by leucocytes; the previous application of heat, on the other hand, seemed to remove the resistance of the bacteria as shown by their failure to stain. Long action of leucocytes is also capable of affecting solution of bacteria; it may, therefore, be assumed that the leucocytes produce some substances which overcome the antiferments in bacterial bodies. These substances are contained within the leucocytes and are also given up by the latter to the serum of the blood. The bacterial extracts obtained by the author could oppose or delay such action of leucocytes, thus showing their content in antiferments.

The Action of Digalen.—Müller says that Cloetta's Digalen has been critically examined by the French clinicians, who have shown that it possesses no such advantages over other preparations of digitalis as have been claimed. The substance, too, should not be termed soluble, because it probably does not go into solution in pure water, but only in a mixture of water, alcohol, and glycerin. The objections held against other preparations of digitalis prepared for subcutaneous use hold therefore with equal force against this substance. Other authors, on the other hand, have found digalen superior to other preparations because of the lack of cumulative action and of irritating effect upon gastric mucosa. Müller has personally studied the action of digalen in eighteen cases of heart disease. In general, he has found digalen as effective as other digitalis preparations, but could not convince himself of its superiority or even of the absence of cumulative toxic action of the drug. Given by mouth, digalen seems to have less irritating action, but subcutaneous and intramuscular administration has led to such severe local irritation that it was altogether given up in Müller's clinic. Digalen, therefore, simply forms an additional preparation of digitalis, but little differing in its action, and affording not any marked advantages, but simply variety in the administration of digitalis.

Carbohydrates and Proteins in Diabetes.—Gigon says that Naunyn's old advice to limit protein as well as carbohydrates in the diet of diabetics is being proved correct by the results of most recent researches. It has been shown that excess in protein may lead to increased elimination of sugar by the urine, and in some of Falta's cases the patients responded with glycosuria after protein more readily than after carbohydrates. Gigon has made complete studies in the metabolism of five diabetics in order to throw light upon this point. He concludes that in lighter cases of diabetes it is not necessary to omit carbohydrates from the diet, for limiting the protein often leads to the disappearance of glycosuria. A protein-poor diet is much easier for patients than one poor in carbohydrates. In severe cases of diabetes the diminution of protein should go hand in hand with the limitation of carbohydrates; it may prove possible to continue with a certain amount of carbohydrates, so that threatened acidosis may be prevented.

Hematic Cysts of the Breasts.—Pons describes an interesting case of cyst of the mammary gland that required enucleation. These cysts occasion no inflammatory reaction, but when the fluid is drained they rapidly occur. They are lined with pavement epithelium. The contents consist of a fluid that is serous, mixed with blood, seromucous, or oleagenous. The pathogenesis is uncertain. Most authors refer them to an obliteration of the milk ducts, at their excretory extremity. The blood contained seems to be the result of injury to the mammary gland. Or it may be extravasated as a result of the congestive condition that arises in the breasts at menstruation. Another more modern theory refers them to an inflammatory lesion of the gland. The wall of the cyst removed by the author consisted of layers of fibrous tissue, the cavity being lined with cubical and plorostratified epithelium. The surface of the cystic membrane was covered with villosities, each one containing a dilated vessel. These vessels frequently had undergone extravasation of blood into the villosities. The structure resembled a fibroadenomatous tumor. This would show that extirpation was necessary on account of the danger of cancerous degeneration.—*Gazette de Gynécologie.*

Book Reviews.

THE BOOK OF PRESCRIPTIONS (BEASLEY). Containing a complete set of prescriptions illustrating the employment of the materia medica in general use; comprising also notes on the pharmacology and therapeutics of the principal drugs and the doses of their preparations, according to the imperial and metric systems, with an index of diseases and remedies. Rewritten by E. W. LUCAS, F.I.C., F.C.S. With an Introduction by ARTHUR LATHAM, M.A., M.D., F.R.C.P. Ninth edition Philadelphia: P. Blakiston's Son & Co., 1907.

BEASLEY'S Book of Prescriptions has been well known for a number of years. The present edition has been rewritten so as to bring it up to date by including the large number of recent additions to the materia medica. The directions are all given in English, and the doses are in both systems. Properly employed, this volume will be of much value; but it should be used in conjunction with some standard work on materia medica and therapeutics.

A SYSTEM OF MEDICINE, by many writers. Edited by SIR CLIFFORD ALLBUTT, K.C.B., M.A., M.D., LL.D., D.Sc., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge; Fellow of Gonville and Caius College; and HUMPHREY DAVY ROLLISTON, M.A., M.D., F.R.C.P., Senior Physician, St. George's Hospital; Physician to the Victoria Hospital for Children; Some time Fellow of St. John's College, Cambridge. Volume IV, Parts I and II. London: Macmillan & Co., Ltd.; New York: The Macmillan Company, 1908.

VOLUME IV of the original edition of Allbutt's System has been so amplified in this revision that it was found necessary to issue it in two parts, constituting actually two volumes of 764 and 566 pages respectively. Volume II was similarly divided, so that the first half of the work is now represented by six volumes, instead of the four of the original edition. No one, we venture to affirm, will object to this increase in size when the new matter is of such value and so excellently presented as it is here.

Part I of the fourth volume contains sections on Diseases of the Liver, Diseases of the Pancreas, Diseases of the Ductless Glands, and Diseases of the Kidneys. The first section opens with an article on the anatomy of the liver, including congenital deformities, by Dr. A. Keith, and following this is an account of displacements of the organ by the same author. The section on functional disorders of the liver, jaundice, Weil's disease, congestion of the liver, and delayed chloroform poisoning, which is included among disorders of the liver, since the anatomical changes are most pronounced in this organ, are written by Dr. William Hunter, who also writes in collaboration with Dr. E. I. Spriggs on acute yellow atrophy and phosphorus poisoning. Dr. John Thomson contributes the article on jaundice of the new-born, Dr. Herringham one on diseases of the blood-vessels of the liver, Dr. W. Hale White treats of perihepatitis and of tuberculosis and tumors of the liver, Dr. Herbert P. Hawkins on portal cirrhosis and syphilis of the liver, and Dr. H. Morley Fletcher on biliary cirrhosis. Diseases of the gall-bladder and bile-ducts, including gallstones, are discussed at length and very clearly by Mr. Mayo Robson. The Diseases of the Pancreas are covered in two articles by Dr. Bosanquet and Dr. G. Newton Pitt. The section on Diseases of the Ductless Glands is the most interesting part of the book, perhaps because it is the most original. The chapter on diseases of the thyroid is rather unnecessarily divided into four parts, three of which are discussed by Dr. Hector Mackenzie, and one, that on myxedema, by Prof. George R. Murray. The section on cretinism is good, and no exception can be taken to the manner in which it is treated, but the unity of the subject would have been better preserved had it been included with myxedema in one article. Anomegaly is written by Prof. E. F. Trevelyan, diseases of the adrenals and of the spleen by Dr. H. D. Rolleston, lymphadonoma by Prof. George R. Murray, and status lymphatics by Dr. John Thomson. In this part are included, rather illogically, four other subjects, namely, infantilism by Dr. John Thomson, obesity and adiposis dolorosa by Sir Dyre Duckworth, and edema by Dr. W. D. Halliburton. The Diseases of the Kidneys are considered under five heads: General pathology and nephritis by Prof. J. Rose Bradford, nephroptosis by Prof. A. Macalister, and other diseases of the kidney and malformations and diseases of the ureter by Mr. Henry Morris. This volume is very sparingly illustrated, only nine pictures being found in the edition of 764 pages. Many books err on the side of too profuse illustration, but there is such a thing as sinning in the other direction, and we think many of the articles in this volume would have been improved in clarity by a more liberal use of cuts.

Part II is devoted to Diseases of the Nose, Pharynx, Larynx, and Ear, the latter being a new subject not treated in the original edition. Although the diseases of the ear belong rather more definitely to surgery than do the other affections here treated, they are logically considered in connection with the latter, and the editors have done well to include them in this volume. Articles on diseases of the nose are contributed by Dr. Gerville MacDonald, Mr. Herbert Tilley, Mr. Ernest Waggett, Dr. F. de Havilland Hall, Sir Felix Semon, and Dr. P. Watson Williams. The two last named have also written the chapters on diseases of the pharynx, of the larynx, and of the trachea, and on foreign bodies in the air-passages and upper food-passages. Mr. Ernest Waggett treats of direct examination of the air- and food-passages. The articles on diseases of the ear are contributed by Dr. Thomas Barr, Dr. W. G. Porter, Mr. Hunter F. Todd, Dr. Dundas Grant, Dr. Milligan, Mr. C. A. Ballance, Dr. Cresswell Baber, Dr. Albert Gray, Dr. McBride, and Dr. Kerr Love. Some of these authors are not recognized as authorities on this side of the Atlantic, even among specialists, but their articles are for the most part well written and justify their selection by the editors. In contrast to the first part of Volume IV, this one is profusely illustrated by 14 colored plates and 61 figures in the text; the plates are excellent, but some of the text illustrations leave much to be desired in the way of beauty, though they are for the most part clear enough and elucidating. For the very good plate illustrating transillumination of the antrum acknowledgment is made to Dr. Coakley of New York.

Those two volumes constituting Volume IV of the series are perhaps not so interesting as some of those that have preceded, notably the one dealing with tropical diseases, but that is the fault of the subjects, and not of the manner in which they are treated. In the latter respect the volumes are fully on a par with the others, and they sustain the high reputation which the series won in its first edition and which has been increased by the first half of the present revision. It compares very favorably with the System of Medicine now being edited by the Regius Professor of Medicine of Oxford, though we cannot accord it superiority over that excellent work. It would be a very difficult task, indeed, to judge between them, and, fortunately, the reviewer is not called upon to do so. Suffice it to say Allbutt's work is thoroughly satisfactory in every respect, and while one might say how happy he would be with either, he would really be far happier with both, and there is no law but that of economics to prevent him.

NEURASTHÉNIE ET NÉVROSES, LEUR GUÉRISON DEFINITIVE EN CURE LIBRE. Par Dr. PAUL-EMILE LÉVY, Ancien Interne des Hôpitaux de Paris. Paris: Felix Alcan, Editeur, 1909.

THIS is a continuation of and sequel to the author's very popular book entitled "L'éducation rationelle de la volonté, son emploi therapeutique." It exploits his theories in regard to the great value of reeducation and mental and moral training in the treatment of the neuroses and psychoneuroses, while the dangers are pointed out in the prevailing treatment of these affections by suggestion, isolation, and the rest cure, etc. He sums up his method in the formula: "Rééducation totale en cure libre." Among the disorders discussed are: neurasthenia, hysteria, spermatorrhea, pseudoappendicitis, pseudodyspepsia, and periodic depression; treatment by hygiene, medicines, hydrotherapy, psychotherapy, etc., is also described and recommended where appropriate. Reeducation is in the air. The book is timely.

THE CHANGING VALUES OF ENGLISH SPEECH. By RALCY HUSTED BELL. New York: Hinds, Noble & Eldredge, 1909.

ALTHOUGH the author's intention is to emphasize the need for preserving the purity of the English language, it must be said that there is very little need for the kind of a book he has given us. For the most part the work is made up of quotations from writings on the history of the English people and the English language, and various excerpts from the poets and Crabb's "English Synonyms." The entire volume is lacking in that wholesome restraint of the commonplace which makes for dignity in any essay which is not distinctively humorous; consequently the style is not of the best. The author thinks that the English language has stopped growing, is "dead," in fact, and "probably reached its perfection several centuries ago." However, he brings no sufficient argument to bear upon this extraordinary assertion.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS

Twenty-fourth Annual Meeting, Held in Washington, D. C., May 11 and 12, 1909.

DR. VICTOR C. VAUGHAN OF ANN ARBOR, MICH., IN THE CHAIR.

(*Concluded from page 949.*)

A Case of Stenosis and Insufficiency at the Pulmonary Orifice of the Heart, with Exhibition of the Specimen.—Dr. JOSEPH SAILER of Philadelphia reported the case of a negro, thirty-five years old, who had at the age of fifteen a form of venereal disease, probably a chancre. Shortly after he had an attack of some form of articular disease, which affected especially the knees, compelling him to use crutches. He was a laboring man and undoubtedly addicted to great excesses. He was admitted to the hospital, giving a history that he had had pain in the region of his heart for eighteen months, and that three weeks before he had been compelled to quit work. There was marked edema of the feet and great dyspnea. When admitted there was noted the Corrigan pulse, also pulse in the veins of the neck, and a large and distinct pulsating liver. He was edematus, with a marked degree of ascites; there was fluid in both pleural cavities and an intense orthopnea. The apex beat was not palpable. There was a marked pulsus alterans; the radial pulse was 51, while the heart beat was 102. A diagnosis was made of involvement of all four orifices. The physical signs, however, suggested some pulmonary lesion. At the autopsy a large gumma was found occupying the pulmonic orifice and causing stenosis and insufficiency. The lesions were so numerous as to distract the attention and make the diagnosis very difficult.

A Case of Brain Tumor Presenting a Very Unusual Clinical Course.—Dr. R. D. RUDOLF of Toronto, Canada, reported the case of a patient, forty-six years old, who, after a prolonged period in which she presented no definite symptoms except those of neurasthenia, with some hesitation in speech, was suddenly seized with what appeared to be a condition of acute cerebral compression, with vomiting and profound coma. She recovered from this, but had similar seizures during the following six months, with intervals in which she was comparatively well and able to get about the house. In each of the acute attacks the blood pressure would rise from about 120 mm. to about 200 mm., and some hours before the acute compression symptoms would lessen, the pressure would fall to normal again. There were practically no localizing symptoms. She died in a compression attack; and the post mortem revealed two large tumors growing from the pia mater, the one over the left occipital lobe, and the other over the left brain just behind the ascending parietal convolution.

Dr. R. SACHS of New York spoke of the importance of two symptoms in diagnosing such conditions,, the headaches, periodical or persistent, and occasionally or frequently the convulsive seizures without epileptic symptoms. He had had a young man under observation, and he positively had no other symptoms but an occasional convulsive seizure at intervals of three or four months. Although he had examined this patient very closely, he had never been able to find any other symptoms. He had been under his observation for three or four years. Last year he died suddenly and at autopsy was found an enormous glioma which occupied almost the entire left hemisphere; it was so huge in size that it hardly seemed possible that so few symptoms resulted. The glioma grew very slowly and very few symptoms in some cases were produced. Such a case, of course, was only an exception, the vast majority of these cases presented such definite symptoms that no difficulty was encountered in making a diagnosis.

Dr. LOUIS B. WILSON of Rochester, Minn., reported the case of a woman with symptoms the replica of those in the case reported by Dr. Rudolf. At autopsy there was found an encapsulated epithelioma extending from the tentorium on the left side 3x2x5 cm. in diameter. Only four weeks before death the patient had convulsive seizures, and there was nothing else to indicate a brain tumor.

An Experimental Study of the Changes in Metabolism Produced by the Total Exclusion of the Pancreatic Juice from the Intestine.—Drs. J. H. PRATT, P. D. LAMSON, and H. K. MARKS of Boston presented this report. The head of the pancreas was separated from the duodenum, the ducts tied and a portion of the great omentum placed between the pancreas and the duodenum. In a dog in which the ducts were tied, but no barrier of living tissue placed between the cut ends and the intestinal wall, a small fistulous tract formed and pancreatic juice entered the intestines. Failure to exclude all the pancreatic secretion explained the results obtained by recent investigators who found no marked disturbance of metabolism after ligating the ducts. In all the four dogs of this series there was a great interference with the absorption of nitrogen and fat. There was a marked loss of weight. The stools were very large; one dog passing feces equivalent to his own body weight in three days. The splitting of the fat was normal.

Study of the Development of the Bones in Childhood by the Roentgen Method, with a View of Establishing a Developmental Index for the Grading of and for the Protection of Early Life.—Dr. THOMAS MORGAN ROTCH of Boston gave the results of an investigation by means of the Roentgen ray of the development of the bones in early life. An examination of a large number of cases, perhaps a thousand, in children in regard to the development of their joints, showed that the development of the wrist might be taken as an index of the development of the entire skeleton. The investigation also showed that the development of the various carpal bones seemed to indicate that an index of strength for the early years of life might be based on the gradual development of the carpal bones and the lower epiphyses of the radius and ulna. These studies also seemed to indicate that children could be graded according to the stages of their development rather than according to their chronologic age. Dr. Rotch gave a lantern slide demonstration.

Exophthalmos in Chronic Nephritis.—Dr. L. F. BARKER and Dr. HANES of Baltimore illustrated by lantern slides several instances of exophthalmos with associated eye signs of chronic nephritis, and the condition was regarded as toxic in origin.

The General Movement of Typhoid Fever and Tuberculosis in the Last Twenty-five Years.—Dr GEORGE M. KOBER of Washington gave a lantern slide demonstration showing the influence of water supplies upon typhoid fever and the results achieved by purification of the water supplies. The general movement of typhoid fever since 1880 in different countries and cities and the percentage of decrease he discussed; but the general fact appeared to indicate that in spite of the many factors concerned in the dissemination of typhoid fever, the water supply played the most important rôle in the spread of the disease. The movement of tuberculosis in the last fifty years in England and Massachusetts, and the general movement in the cities of New York, Baltimore, and Washington, seemed to indicate that the introduction of sewers and general sanitation had influenced to a great extent the gratifying decrease of this disease.

Experimental Infection with Leishmania Infantum.—Dr F G. NOVY of Ann Arbor, Mich., gave a lantern slide demonstration. At present three infections (Leishmania-

ses) due to the Leishman-Donovan bodies were recognized. These were the kala-azar of India, the oriental sore, and an infantile splenic anemia. The organisms of the last two diseases could be readily cultivated on blood agar, the same as trypanosomes, and an abundant growth of flagellates thus obtained. A number of animals had been tested as to susceptibility to infection with the cultures derived from infantile anemia. The diagnostic importance of the cultural method was shown.

The Pathological Relationship of Gastric Ulcer and Gastric Carcinoma, Based on a List of 180 Cases.—Drs. Louis Blanchard Wilson and William Carpenter McCarthy of Rochester, Minn., gave a lantern slide demonstration. Their report was based on the study of specimens from gastric resections for ulcer and carcinoma by Drs. W. J. and C. H. Mayo from January 1, 1905, to April 1, 1909. One hundred and eighty cases in all The morbid anatomy and histology of simple ulcers, the transitional cases, the cases of early but undoubted carcinoma showing evidences of previous ulcer, and cases of carcinoma showing no evidence of previous ulcer were illustrated with lantern slides.

Symmetrical Adenolipomatosis.—Dr. Irving P. Lyon of Buffalo reported some cases and gave a lantern slide demonstration.

Experimental Study of Leucocyte Extract and Its Action on the Course of Pneumonia.—Drs. C. H. Ernst, C. Floyd, and William P. Lucas of Boston presented this paper, which took up the rôle of the leucocyte in the protection of the body against bacterial invasion and its powers of phagocytosis and bacteriolysis. The mere matter of englobing the bacterium was only a small part of its action, and the application of intercellular substances of the leucocytes upon ingested organisms was important in their destruction. That these cellular juices might be used in the treatment of disease was first shown by His in both experimental and clinical work. In carrying on this work rabbits were used, and leucocytes were obtained by interpleural inoculations of aleuronat. The result of pleural irritation had varied considerably, some animals showing dry adhesive pleurisy, others pleural effusion, and still others sterile empyema. The cellular content of the fluid obtained from the chest had shown great numbers of eosinophiles and large phagocytic cells, with an occasional small cell. Clinical application of this method of treatment had been made by the writers in a series of cases of pneumonia, some thirty in all. The apparent action of the leucocytic extract had been to diminish the toxic manifestations of the disease and possibly to aid in a lower mortality.

Wednesday, May 12.—Second Day.

Election of Officers.—*President,* Dr. Henry Hun of Washington; *Vice-President,* Dr. F. Forchheimer of Cincinnati; *Secretary,* Dr. George M. Kober of Washington; *Recorder,* Dr. Solomon Solis Cohen of Philadelphia; *Treasurer,* Dr. J. P. Crozer Griffith of Philadelphia; *Councilor,* Dr. Henry Sewell of Denver.

The Resemblance Between the Clinical Effects of Pneumococcus and Meningococcus Infections.—Dr. Robt. B. Preble of Chicago took up a consideration of what might be called the specific effects of pneumococcus infections, with a comparison of these with certain phenomena due to the meningococcus infections, with a comparison of the complications seen in the two infections. Among these phenomena were considered the following: (1) The acuteness of the onset. The pneumococcus, whether in pneumonia, tonsillitis, etc., began its action so acutely that the individual could tell the day the onset began, even at times the hour or even the minute. (2) The development of leucocytosis. (3) The eruption of herpes, usually over the fifth nerve distribution. This phenomenon occurred with great frequency in pneumococcus infections, irrespective of the localization of the infection. He knew of no other affection which gave rise to this group of three phenomena. (4) The exceedingly low amount of chloride in the urine. Here were four phenomena which occurred together in only the pneumococcic and meningococcic infections. After referring to the epidemic and seasonal relation of the two, he spoke of the differences between the effects of the two infections. With pneumococcus infections they had learned to associate certain complications, such as arthritis, pleuritis, pericarditis, and endocarditis. He was convinced that in cases of endocarditis complicating pneumonia occurred as the result of a relatively low virulence, as shown by Rosenau, and he was inclined to believe that the meningococcus, was in fact but a pneumococcus with a low virulence. He asked whether it was possible that the miningococcus was the pneumococcus with its virulence lessened.

Dr., William Osler of England said there was a great similarity between these two infections, particularly when meningitis was alone considered. The source and origin were practically the same, yet the pneumococcic meningitis was almost uniformly fatal; in fact, Dr. Osler had never seen a case of pneumococcic meningitis recover. Another point he brought up was in regard to the distribution of the lesions; the meningococcic infection might be a spinal affair only, but this did not apply to the pneumococcic infection. An endocarditis was quite common as the result of a pneumococcic infection, yet it was very rare in cerebrospinal fever. However, there was no question about the great similarity between these two infections, and the two diseases should be sharply separated from each other. Dr. Osler had spoken of the meningococcus being a half-sister, and a very poor one at that, of the pneumococcus.

Dr. Henry Koplik of New York said that in young subjects there was a great similarity in pneumococcic and meningococcic meningitis, in the cerebral symptoms especially. He reported the case of a child who was brought to the hospital with a very obscure central process which the assistant thought to be a meningitis. After waiting two or three days the symptoms, which were identical with a meningococcic infection, cleared up, and a pneumonia developed very promptly. A point of value he believed was that given a pneumococcic infection of the lungs of severe type, with a complicating meningitis, or peritonitis, or endocarditis, it did not follow that the infection was a pneumococcic one; they had had several cases in which the streptococcic infection was the cause of the trouble.

Dr. E. Libman of New York said he had seen but one case of pneumococcic meningitis that recovered. With regard to the diminished virulency of the pneumococcus, their experiences did not correspond with those of Rosenau. In a study of twenty or thirty cases of long continued forms of endocarditis due to the presence of organisms in the blood of the pneumonic-streptococcic group, they believed that these organisms had become diminished in virulency through their long existence in the body. Personally he believed there was no relationship between the two organisms.

Dr. George M. Sternberg of Washington said that the pneumococcus was in reality a streptococcus; one found it as a diplococcus in the blood, especially in the liquid cultures, when it would be found in chains.

Dr. A. Jacobi of New York reported the case of a child, three or four years old, who was brought to the hospital with convulsions, one attack following another. There were contracted pupils, and the patient was unconscious. The pulse and respirations were frequent, and this directed attention to the lungs, and a beginning pneumonia was found. The symptoms continued. On the second day but little urine was passed; this, together with other

symptoms, made them believe that they were dealing with a general pneumococcic infection. On the fourth day the child took a favorable course. In the urine were eliminated large quantities of pneumococci and, at the same time, the brain symptoms disappeared. Here was a case of general pneumococcic infection which got well. Within a few weeks another case entered and this ran the same course. He was very much surprised at Dr. Osler's statement that these cases did not get well; Dr. Jacobi found there was a greater tendency for them to recover than to terminate fatally. Lumbar puncture in these cases was not done.

Dr. Osler said that he was referring to those cases of pneumonic infection with marked cerebral symptoms, with an actual meningitis which was determined by lumbar puncture. Cases of streptococcic and pneumococcic meningitis were almost uniformly fatal, but the meningococcic cases might recover.

Dr. L. F. Barker of Baltimore said that in his experience with the serum in the treatment of patients with pneumonia he was surprised at the large number of cases in which the pneumococcus was found in the blood, and many of these cases died of pneumococcic septicemia. The matter of meningism, as contrasted with meningitis, could not be too much emphasized.

Dr. Preble said that he had seen cases of pneumococcus meningitis recover; these cases were not diagnosed on their symptomatology, but on lumbar puncture, and they recovered with a typical crisis. With regard to the chloride output, he knew of no affection in which the chloride reached such a low point.

The Present Status of the Serum Treatment of Epidemic Cerebrospinal Meningitis.—Dr. Simon Flexner of New York said that two years had elapsed since the serum began to be used generally in the treatment of epidemic cerebrospinal meningitis in the human being, and up to this time about one thousand cases had been treated with the serum. They had collected between 800 and 900 cases which had been diagnosed bacteriologically, but the entire number had not as yet been subjected to analysis. His last careful analysis concerned 550 cases, and he considered the criteria of usefulness of the serum as based on the results obtained with this group of cases. The remaining cases he hoped to be able to analyze this coming summer, and to report upon them later. Dr. Flexner said he took his former position, that it was not fair to base any conclusions as to the value of this therapeutic method upon the results that had been observed at a time when an epidemic was not prevailing. The final test must come in the future and at a time when an epidemic existed, at a time when the serum can be administered at the beginning. Before the introduction of the serum the mortality in Great Britain was about the same as it was along the Atlantic coast, 75 per cent. After the introduction of the serum at Belfast the mortality there was less than 30 per cent., and the impression was gained by those who had followed this disease closely up to the time of the introduction of the serum that the character of the disease had suddenly changed. During the last two or three months in France, starting in Paris and one or two other points, there promised to be a very severe epidemic of cerebrospinal meningitis. When Calmette was in this country last year he took away with him about 100 bottles of the serum; now practically all the serum produced at the Rockefeller Institute for Medical Research was shipped to France. Calmette had so far reported 14 cases, occurring among soldiers in barracks, with 13 recoveries and one death; 3 patients living outside the barracks who were taken ill at that time, without the use of the serum, died. Dr. Flexner believed it was too early to state the true value of the serum in the treatment of cerebrospinal meningitis. At the Jefferson Barracks, Missouri, one soldier who was not suspected of having the disease died; a second soldier died; then they recognized the nature of the disease, used the serum, and five subsequent patients received the serum and recovered. In some cases, even before symptoms appeared, lumbar puncture was employed, a diagnosis made, the serum administered, and recovery ensued even before the patients considered themselves ill. In a town in Texas five cases occurred in rapid succession, four in one family, and all died. Susbequently five cases were given the serum treatment and all recovered. These were only small figures, but they were interesting. With regard to the manner of application of the serum, it should be administered so that it interfered with the development of the diplococcus, and the injections should be repeated frequently. There was a certain relationship between the amount of exudation and the number of organisms; it would therefore seem, so far as he was able to judge from the statistical evidence at hand, that there was produced a change in the nature of the disease, an abrupt termination and other indications of bacterial changes; therefore the serum was indicated in these cases. At the same time Dr. Flexner said that the value of this therapeutic measure could not be determined as yet, not until there occurred an outbreak of an epidemic, when cases could be diagnosed and treated in the beginning.

Dr. Abbott of Philadelphia emphasized the importance of removing an amount of cerebrospinal fluid equal to the amount of the serum to be injected.

Dr. Henry Koplik of New York believed that with the serum they had a weapon at least which would be effective against this scourge, and particularly in subjects below two years of age the results had been very gratifying.

A Systematic Comparison of Radiographs of Cadavers with Autopsy Findings in the Pathological and X-Ray Departments at the Boston City Hospital.—Dr. Francis H. Williams of Boston said that radiographs of cadavers might show differences in density, volume, and chemical composition, though in some cases they did not show as much as those taken in life, or as much as was shown by the fluoroscope in life. The interpretation of radiographs was difficult, but the errors made in their use for diagnostic purposes had been due to lack of training on the part of those who had employed this method or to failure to use the more important fluoroscopic examination with it, rather than to the method itself. A good radiograph might show much that was misinterpreted, or not interpreted at all. To assist in the correct interpretation of radiographs they should be studied systematically, and the findings obtained from them compared with the pathological conditions, whenever possible. Such comparisons had been made at the Boston City Hospital, and this communication presented examples of the work done jointly by the pathological and *x*-ray departments. The study showed conclusively the trustworthiness of the radiograph in certain directions; for example, the cardiac outlines, unless they were obscured by a very dense lung or a large amount of fluid in the thorax. The radiographic and the pathological findings taken together assisted in the correct interpretation of some parts of the negative. This method was useful in the training of those physicians who assumed the responsibility of giving an opinion based upon *x*-ray examinations in part.

Respiratory Variations of the Intrathoracic Pressure.—Drs. S. J. Meltzer and John Auer of New York reported some experimental investigations of the changes in pressure taking place within the intrathoracic cavity during the two phases of respiration. The pressure was studied in the esophagus in the anterior and posterior mediastinum and in the pleural cavities. The problem was to determine whether various parts of the lungs participated in the respiratory movements in a different degree.

Hyperplasia of the Hemolymph Nodes.—Dr. Alfred Scott Warthin of Ann Arbor, Mich., described the different forms of hyperplasia occurring in the hemolymph and hemal nodes, and the conditions under which such hyperplasias had been noted. From a histological standpoint hyperplasias of the lymph nodes fell into four classes. First, lymphoid hyperplasia; secondly, hyperplasia of the endothelial cells of the blood sinuses; thirdly, myeloid hyperplasia; fourthly, fibroid hyperplasia. The question of the hematoblastic function of the hemolymph nodes was gone into in detail, and cases were reported showing myeloid transformation of the hemolymph nodes in man.

Further Studies of the Disorder of Muscles Due to Intense Heat.—Dr. David L. Edsall of Philadelphia made some additional observations regarding the occupations in which this occurred, its frequency, and its economic influence in some of these occupations. The observations seemed to indicate that the trouble was due to the heat itself (and probably chiefly to the intense radiant heat), and not to light, gases, etc. Most of the physicians in the United States Navy had recognized the condition described, and one captain had said that he had been compelled to shut down to one-half speed because of the cramps of the muscles produced in the men. Iron and steel workers were very prone to this affection. This disease occurred in nearly all occupations in which was associated intense heat and hard muscular work. The degrees of heat the men worked in was sometimes astonishing; some firemen worked as long as two hours, sometimes even four hours, in a tempertaure 204 F. and not infrequently 180 or 190. One superintendent in an iron works observed the temperature in which men worked at 235 F.: in such a temperature a steak could be broiled. The men remained in this temperature from eight to ten minutes, although they were not working there. The degrees of severity of the condition varied enormously, but in general the attacks lasted but one or two hours, and were accompanied especially by cramps in the forearms, legs and especially in the abdominal muscles. There was an enormous output of creatinin, and chlorides were absent from the urine during the attack and for many days after the attack. There seemed to be a very severe protein destruction. A possible prevention was proper ventilation; also to supply the men who were exposed to this intense heat radiation with asbestos aprons. Enemata of saline solutions had also been advised by a naval surgeon.

A Small Epidemic of Jaundice with Symptoms of Gastrointestinal Catarrh.—Drs. L. F. Barker, Sladen, and Clough of Baltimore reported this epidemic.

The Effect of Cutting the Branch of the His Bundle Going to the Left Ventricle.—Drs. L. F. Barker, Hirschfelder, and Bond of Baltimore told of the methods devised for cutting the branch of His bundle, which went to the left ventricle. Hemisystole did not result.

A Comparative Study in the Serum Diagnosis of Syphilis.—Dr. Homer F. Swift of New York briefly discussed the Wassermann reaction; he also compared the Wassermann with the Bauer technique.

A Case of Severe Scarlatina Complicated with Gangrenous Diphtheria Treated Successfully without Medicine.—Dr. W. H. Thompson of New York reported the case of a girl, five years old, who was first attacked with scarlatina and on the seventh day developed diphtheria. When Dr. Thompson first saw her in consultation, the membrane had extended over the pharynx, uvula, and into the nose, and it had a very fetid odor. She was wholly unable to swallow. The further complications were abscesses in both ears, pneumonia and pleurisy on the left side, and persistent heart weakness, with a very intermittent pulse. She wholly recovered after very thorough douching of the throat with two gallons of hot water every two hours. This result Dr. Thompson regarded as in keeping with his recommendation to douch the throat in every case of scarlatina from the first onset of the symptoms so as to prevent invasion by streptococci which, in his opinion, was the main cause of the complications of both scarlatina and diphtheria.

The Cammidge Reaction in Experimental Lesions of the Pancreas.—Drs. John H. Musser, John Speese, and Edward H. Goodman presented this communication, and offered the following conclusions: (1) The Cammidge reaction was a constant feature in acute hemorrhagic pancreatitis in the mechanical injuries to the gland (crushing and partial extirpation) and in total extirpation. (2) In certain cases of the subacute type of pancreatitis the reaction was inconstant. (3) The nature of the phenylhydrazin compound was not definitely established. If it was a pentose, it was not derived from a pentose-yielding material of the pancreas. (4) A positive reaction was indicative of altered carbohydrate metabolism due to disturbances of the internal secretion of the pancreas.

The Value of the Wassermann Reaction in Cardiac and Vascular Disease.—Drs. Joseph Collins and B. Sachs of New York had collected a large number of cases of cardiac and vascular disease in order to test the value of the Wassermann reaction, with reference to the claim that the test was positive in many of these, and above all in aortic insufficiency. The results of these various tests tended to prove the great importance of syphilis as an etiological factor in diseases of the heart and blood vessels.

Some Observations on Adrenalin, Clinical and Experimental.—Dr. T. J. Halsey of New Orleans read this paper.

The Importance of Blood Cultures in the Study of Otitic Infections.—Drs. E. Libman and H. L. Celler of New York presented this paper and offered the following conclusions: (1) They had shown that negative results could be obtained, even though not frequently, in cases in which sinus thrombosis was present. The absence of bacteria in a doubtful case would make one hesitate to explore for any thrombus until the possibility of all intercurrent diseases had been excluded, or until the symptoms had become so severe as to justify an exploratory incision. (2) If the blood culture should be negative and the symptoms should persist in a given case, whether there was a sinus thrombosis or not, acute endocarditis could be excluded. In such cases it was advisable to take two blood cultures. In their experience in cases in which endocarditis was due to the ordinary streptococcus (and staphylococcus) the bacteria were always in the blood if two cultures were made. (3) As they had already stated several times, if there had been a sinus thrombosis and bacteria had been present in the blood and the jugular vein had been tied, a negative culture was not of value in showing that a general infection had been stopped. (4) Occasionally negative blood cultures had been of value in all cases with the clinical picture of rheumatism. It was very valuable in such cases to know that they were not dealing with an arthritis due to a general infection by ordinary bacteria.

Further Observations on the Influence of the Ductless Glands on the Pancreas.—Drs. D. L. Edsall, Ralph Pemberton, and J. Edwin Sweet presented this communication. They told of their previous observations that extracts of the suprarenal and pituitary bodies inhibited the flow of the pancreatic juice when excited by secretin; they had made an extension of these observations to the inhibition of the flow following the injection of hydrochloric acid into the duodenum. Similar effects were obtained from synthetic adrenalin. Their previous observations that adrenalin might lose its inhibitory powers while preserving its blood pressure raising qualities were corroborated. There was evidence of a greater pancreatic flow from secretin in thyroidectomized and parathyroidectomized dogs showing tetany, than in normal animals. Adrenalin exercised less inhibition on the pancreatic flow in

such dogs in whom active response to secretin could be obtained after repeated injections of adrenalin; thyroid and parathyroid glands apparently were necessary to the full action of adrenalin.

The Effects of the Injection of Bile Constituents on the Circulation.—Drs. John H. King and H. A. Stewart presented this paper.

The Relation of the Thyroid to Carbohydrate Metabolism.—Dr. John H. King of Baltimore presented this paper.

Studies on Isoagglutins and Isohemolysins.—Dr. W. L. Moss of Baltimore presented this paper.

Renal Suppuration in Typhoid Fever.—Dr. Charles F. Withington of Boston called attention to the occasional occurrence of miliary abscesses and pyelitis as local expressions of the typhoid septicemia. The organisms might be typhoid alone, or combined with others, the streptococcus, colon bacillus, etc. This might be the first expression of typhoid and so obscure the diagnosis. It might prolong the fever or it might occur late and be the cause of some relapses. It always aggraviated the prognosis. He reported cases from his own observation and from the literature. Acute symptoms referred to the upper abdominal quadrant had led to needless operation. Surgery was only useful if there was a closed pyonephrosis.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 15, 1909.

The President, Dr. John A. Wyeth, in the Chair.

This meeting was held under the auspices of the Section on Pediatrics.

Pathology of the Status Lymphaticus.—Dr. Aldred Scott Warthin of Ann Arbor addressed the members of the Academy on this subject, illustrating his remarks with lantern slides. An enlarged thymus played an important part as an etiological factor in cases of sudden death. The deaths that occurred from the mechanical obstruction caused by enlarged thymus glands presented rather peculiar symptoms. As early as the seventeenth century sudden deaths with enlarged thymus and lymphatic glands had been recognized. Dr. Warthin had seen a number of these cases. Until recently the minute anatomy had not been touched upon. Sudden death occurred during or immediately following anesthesia, after examinations, after going into water, etc. Some cases were associated with marked stridor, marked asthma, or with the administration of diphtheritic antitoxin. During the past four years ten per cent. of the cases dying in this sudden manner were autopsy cases; these did not include cases of Graves' disease showing enlarged thymus. The fact that an enlarged thymus was a constant feature in all these cases led him to look upon the thymus as an important thing to consider. The pathological findings caused him to look around for living cases, with the hope that a diagnosis might be made during life. In his own town he found two children with a peculiar stridor and he could state positively that they had enlarged thymus glands; the percussion area was large and definite and the *x*-ray picture was convincing. Some cases had been apparently cured under simple treatment; the treatment was pursued on the ground that there existed some chronic affection. However, the symptoms would disappear, sometimes to return again. In all the cases there was this enlargement of the thymus and, in the majority of the cases, more or less enlargement of lymphatic structures, not necessarily all, but sometimes one set, sometimes another. The lymphatic glands presented a rather uniform appearance microscopically. The one feature present in all cases was a hyperplasia of the thymus. Many lantern slides were used to illustrate Dr. Warthin's remarks.

The Clinical Features of Status Lymphaticus.—Dr. Emmett Holt said that he did not quite agree with what Dr. Warthin had said regarding the clinical features of this condition. His experience with status lymphaticus had been mostly with infants of from four to eighteen months of age. He had found the clinical manifestations different from those described by Dr. Warthin, as the following case illustrated. An infant, three months of age, weighing six pounds, had been very difficult to feed and had been under his observation for a month. The child seemed to be well except for the symptoms referable to the digestive tract and had gained two pounds in weight, when about ten o'clock one night the child vomited and seemed ill. At three o'clock the next morning the child was in collapse, with a temperature of 103° and respiration 100 per minute. There was intense prostration, moderate dyspnea, but no stridor. Thirteen hours after the appearance of the first symtoms the child died without having rallied from the state of collapse. At autopsy an acute congestion of the lungs with a beginning bronchopneumonia was found, the general lesions of status lymphaticus were also present together with an enormous thymus resembling the one Dr. Warthin had shown in the picture. Dr. Holt said that most of his cases had been of this type. These children were usually slightly rachitic, and were regarded as healthy even when under observation for some time and showed no symptoms referable to the thymus, but from apparently slight causes they suddenly developed most severe symptoms and death usually followed in from twelve to twenty-four hours. Bronchopneumonia was the associated condition which seemed most frequently to be the cause which precipitated the fatal attack. In several instances the exciting cause was the beginning of some acute infectious disease. The four symptoms usually present in the terminal stages of the disease were intense prostration, dyspnea and cyanosis, convulsions, and fever, which was often very high. The dyspnea was seldom of the obstructive type. In one case which was under observation for thirty-six hours he felt sure that he was dealing with an enlarged thymus, but he had found it impossible to map out the thymus by percussion. At autopsy an enlarged thymus was found. He believed that mapping out an enlarged thymus in infants was a very uncertain procedure. Children suffering from status lymphaticus had very feeble resistance and the slightest thing like the prick of a needle, anesthesia, acute indigestion, the beginning of some acute infection, seemed sufficient to disturb the delicate balance and to precipitate the fatal attack. He was of the opinion that the symptoms pointed rather to a toxic condition than to mechanical obstruction. It was often difficult to reconcile the clinical picture with the pathological findings. Status lymphaticus was not a very uncommon condition, one or two examples occurring in his experience in the course of a year. The condition was frequently, though not always, connected with rickets. He had not found the enlargement of the external glands to be as common in infants as in older children.

The Surgical Aspects of Status Lymphaticus.—Dr. Joseph A. Blake said he had hitherto held a view quite different from that set forth by Dr. Warthin. Some six or seven years ago he had the misfortune of meeting with eight cases of sudden death within one year at Roosevelt Hospital. These cases occurred either during or shortly after the administration of an anesthetic and were attributed to the status lymphaticus. In no instance were there symptoms of obstruction to respiration; the patients seemed to go into collapse and to die of heart failure. In one instance death occurred twenty-four hours after the administration of the anesthetic, the patient dying in coma. Necrosis of the liver might possibly have been the cause of death in this case, although at autopsy the signs of status lymphaticus were present. One patient died at the end of an operation for Graves' disease; after having stood

the operation well, the heart failed, respiration ceased, and death ensued within a few minutes. Several cases of so-called thymic asthma were recorded in the literature which seemed to have been cured by an operation that might be termed thymopexy. The thymus was stitched to the manubrium so as to relieve tracheal compression. It had been demonstrated that in intubating these cases to relieve pressure, the tubes would not pass the thymus unless they were extremely long. The questions as to whether operation should be performed in these cases and as to what anesthetic should be used were of interest. When only a minor operation was called for, as the removal of tonsils or adenoids, one should hesitate before operating, but as the condition of status lymphaticus was so difficult to diagnose it was almost impossible to refuse operation in cases that demanded it. Most of the deaths reported had occurred under the administration of chloroform. Three of the four deaths that had come under his observation were under ether narcosis. He preferred, however, to give ether and not chloroform as in his experience death had resulted from cardiac failure. Possibly some of the deaths attributed to the administration of chloroform might be due to the effects of chloroform on the liver.

Dr. A. Jacobi said that he believed that sudden death in cases of status lymphaticus was not due to that condition alone. Dr. Holt's case showed bronchopneumonia at autopsy. One should remember that not only were the blood vessels of the lungs enlarged in such cases, but those in the neighborhood as well. In speaking of the surgical aspects of these cases, Dr. Jacobi recalled an operation performed by Rehn at Frankfort-on-Main, in 1893 or 1894, in which the thymus was not removed but stitched to the anterior wall. There were a number of such cases now on record. Within the past two months he had seen an account of a case in which favorable results had been obtained by the removal of the entire organ. One should not lose sight of the fact that the space between the sternum and the vertebral column was very narrow, only 2.2 cm., and slight changes in the size of the blood vessels were liable to cause obstruction of respiration and to such an extent that death might occur. If in such cases the head of the child were bent forcibly backward or the child was lying in an uncomfortable position, the difficulty in respiration would be lessened by bending the head forward. Dr. Jacobi thought that one who saw these cases often enough would not have much difficulty in making a diagnosis. One could not detect the thymus with the baby lying on its back, but if the baby was turned over and raised gently the thymus could be found. Dullness behind the manubrium was quite characteristic of an enlarged thymus. The status lymphaticus might be the cause of difficulty in respiration, occasional convulsions and sudden death partly from hypertrophy of the thymus and partly from congestion. Laryngismus stridulus had seldom anything to do with enlarged thymus. A considerable amount of cranial and meningeal injection, as well as edema of the brain, was present in these cases; in some there was beginning hydrocephalus. If the rickets was successfully treated the patients recovered, but this took time. The prognosis depended upon the possibility of relieving the cerebral changes connected with rickets. Five or six weeks were usually required in order to get the baby in non-rachitic condition and until this was done one could not be sure that the baby would not die suddenly. The laryngismus did not, as a rule, result from the enlarged thymus, but from edema of the brain, which was connected with rachitic tabes. There were complications in most of these cases and it was necessary to improve the general condition of the child, to watch it carefully, and to keep the head well forward.

Dr. John A. Wyeth referred to an article published in the *Laryngoscope* by Roberts of California in which a series of seven cases of sudden death occurring in children who had been operated upon for adenoids was reported and, in which, at post mortem, status lymphaticus was demonstrated. Death, in these cases, occurred during the operation or immediately after. A series of thirty cases of status lymphaticus which ended fatally during narcosis was reviewed. In seventeen of these chloroform was the fatal agent; in six, ether; in five, chloroform and ether, mixed, and in two, nitrous oxide gas. Dr. Wyeth said that his personal experience with status lymphaticus was limited to one case. A boy received an injury to the ring finger from which infection, lymphangitis, and a metastatic abscess in the epitrochlear region at the elbow had resulted. There was no appreciable lymphatic enlargement in the neck or elsewhere. Chloroform was administered as least likely to cause nausea, the child having eaten a hearty meal within two hours. A single incision was made, the abscess cavity mopped out and the anesthetic discontinued. Whereupon the child gave a gasp, the pulse ceased at the wrist, and all efforts at resuscitation failed. The child had died from heart paralysis. At the autopsy by the coroner no mention was made of an enlarged thymus, but the glands of the mesentery were enlarged and soft. The physician who performed the autopsy stated that the death was due to chloroform, the patient suffering from status lymphaticus.

Dr. John Howland said that there was a division into two camps in regard to the cause of death in status lymphaticus, those who believed that pressure caused death and those who did not believe this. The great majority of pathologists had failed to find evidences of compression at autopsy. Friedleben, Paltauf and Richter expressly stated that they had never seen it. Dr. Bovaird had used the method that Dr. Warthin had insisted upon, namely, that of dissecting the trachea from above and splitting it before opening the thorax for many years at the Foundling Hospital and had never seen compression. During the past seven years Dr. Howland said that his experience had been similar. It was claimed that the congestion or edema responsible for the pressure disappeared after death. Theoretically it was impossible to conceive that a congested thymus could exert sufficient pressure to cause death in an individual who up to the very time of his demise showed no signs of dyspnea. The testimony of those who had seen children die suddenly was also conclusive. In the course of fifteen years Pott saw four children die of status lymphaticus while he was examining them. There was cyanosis, convulsive movements and gasping respiration, but in every instance the heart had stopped beating when he had examined it and attempts at respiration were continued for a time. Such was not the case with asphyxia. Escherich had had similar experience. There was lack of great and persistent cyanosis in children dying with symptoms that had lasted for several hours. The edema that one would expect from pressure on the great veins was also lacking. The dyspnea was not accompanied by the supraclavicular, suprasternal and epigastric retraction that would result if air were prevented from entering the lungs. The dyspnea came and went with great rapidity and death might occur without any whatever. In cases that had been operated on for thymus obstruction, the dyspnea had been constant and unremitting for periods of from a few weeks to two and one-half years. It seemed to him that evidence both anatomical and clinical of death from pressure was wanting. We were still without a satisfactory explanation for death in status lymphaticus.

Dr. James Ewing said that while in Vienna, in 1895, he had seen several cases of *"constitutio lymphatica"* at autopsy. In these cases the thymus was persistent or enlarged, the faucial, intestinal, and splenic lymphoid follicles were hyperplastic, the aorta was usually small, there were often signs of rachitis, and in the older subjects there was

a peculiar faminine type of physical development. These features were very striking and the condition was entirely new to him, not having been described at that time in American medical literature. Yet within a few months after returning from Vienna he had encountered two fatal cases, one in a young girl who died under ether narcosis, and the other in a parturient woman who died unexpectedly from a trivial hemorrhage. Status lymphaticus had now become a well recognized condition of great clinical significance in relation to sudden death. It was frequent enough to be kept constantly in mind, being found in from one to three per cent. of autopsies. It had been found by Ohlmacher in many cases of epilepsy. Hannseman had emphasized its importance in Graves' disease, and he himself had observed it in four of five fatal cases of that disease. It figured in most fatalities from short submersion in water, and was the chief underlying condition in fatalities under narcosis. Elser had recently shown that it was present in many cases of fulminant meningitis, an observation which was verified by Norris and in Germany, so that it must stand as an important predisposing cause of fatal meningitis. Dr. Warthin's contribution seemed important as furnishing evidence from the proliferation of endothelial cells in the lymph nodes that there was a toxic element in the condition, and his observation of a case of advanced atrophy of the abdominal lymph nodes was distinctly new. The chief point of debate was the etiology of status lymphaticus. Many had thought that in young subjects death must result from sudden compression of the trachea by the large thymus, and he was inclined to believe that in such subjects this might be an important consideration. The compression of the trachea or vagus could not figure in the majority of the cases. The disease was not one of young children but occurred in adults in whom there could be no question of death by pressure. An interesting point of view was that of Bartel, who held that the condition might have a definite relation to tuberculous intoxication. There was occasionally some histological resemblance of the hyperplastic lymph nodes to tuberculosis. An opinion largely held in France was that the enlarged thymus yielded an excess of internal secretion, with hyperthymization of the system. This theory was open to experimental study. Systematic investigation from these theoretical standpoints was, therefore, indicated. Careful clinical analysis of the cases was also discussed. Status lymphaticus was not always fatal, but must influence the course of many diseases. Yet one saw in clinical literature little reference to the part played by this condition in the so-called idiosyncrasies of disease.

Dr. Charles Norris said that he had never seen a single death either in the young or in adults from compression of the trachea as the result of status lymphaticus. Though his experience with children had been somewhat limited he had seen many cases of this condition among adults. It was conceivable that an enlarged thymus might compress the trachea, but it was inconceivable that the thymus could increase in size so suddenly through hyperemia. Dr. Norris said that he wished to emphasize the point that a clinical diagnosis of status lymphaticus could not be made out, but that a diagnosis could be made quite readily at autopsy. In his opinion patients did not die of status lymphaticus alone, but as they grew up they became more susceptible to infections of various kinds and this might account for sudden deaths attributed to status lymphaticus.

Dr. William P. Northrup said that he wished to remind the audience to what extent the trachea could be narrowed without causing symptoms. A child could breathe through the small calibre of an intubation tube; this seemed incredible in the first days of intubation. Dr. Northrup cited the case of a child, eight months old, whose tonsils and tongue were so swollen and whose adenoids were so congested that breathing was very difficult and the child was exhausted for want of sleep when nasal intubation was resorted to and the smallest sized drainage tubes were passed through the nostrils, past the swollen adenoids and tonsils to the larynx. The child then slept seven hours. These drainage tubes were barely large enough to admit the smallest probes. From this it would seem that an extreme enlargement of the thymus must be present in order to cause sudden death from compression of the trachea.

Dr. S. J. Meltzer said that he thought the sudden deaths in status lymphaticus were not respiratory deaths. The phenomena of asphyxia were so characteristic that there could be no doubt as to the cause of death; even a layman would state simply that the child suffocated. The descriptions of these deaths all indicated plainly that cardiac failure was the cause. However, sudden increase in the size of the thymus might have occasioned the cardiac failure. A normal heart might be arrested many times without serious consequences, but with hearts that had lost their stability this was not the case. Dr. Meltzer said that from experimental experience he knew that a single slight stimulus applied directly to the vagus would cause sudden and fatal stoppage of the heart. With a heart whose stability was lost a sudden enlargement of the thymus might occasionally be capable of exerting a pressure sufficiently strong to bring a heart to a fatal standstill. From this point of view one could accept Dr. Warthin's theory that a considerable amount of lymphoid material was being absorbed by the system and that these substances robbed the heart of its "factors of safety."

Dr. Charles G. Kerley related three cases of sudden death from status lymphaticus without any evidence of tracheal obstruction. In the first case the child died in convulsions; at post mortem a large thymus was found. The second case also had convulsions and died very suddenly without any evidence whatever of tracheal obstruction. In the third case the conditions were similar to those in the case reported by Dr. Holt: all inhibitory control seemed to be abolished and the child died from exhaustion as a result of the tremendous efforts at breathing. At autopsy an enlarged thymus was found.

Dr. Warthin, in closing the discussion, said that he did not know exactly what status lymphaticus meant aside from sudden death that did not seem to be associated with other things. There seemed to be danger of attributing all cases of sudden deaths to status lymphaticus. One should be very careful as to what he called the lymphatic struma. Dr. Warthin thought it meant an enlarged thymus. In the literature, especially in France and Germany, there seemed to be an increasing amount of evidence favoring the obstruction theory, pressure being on the vagus nerve, the recurrent laryngeal or the trachea. Pressure on nerves might, of course, play a part in causing sudden death. Intoxications might occur, but they were not the cause of death in these cases. The enlarged thymus might be the cause of intoxication and this in turn might be the cause of sudden death.

Stated Meeting, Held May 6, 1909.

The President, Dr. John A. Wyeth, in the Chair.

Acute Pulmonary Edema as a Terminal Event in Certain Forms of Epilepsy.—Dr. A. P. Ohlmacher of Detroit, Mich., presented this preliminary communication. This gave him an opportunity of bringing before the Academy a much belated report on certain phenomena in epilepsy which, so far as he had been able to determine, had received no general recognition. In fact, at the time the observations narrated occurred, during the period of his active connection with the Ohio Hospital for Epileptics, from 1897 to 1905, and his then close touch with the literature of epilepsy, he could find no record to indicate that

the syndrome acute pulmonary edema, epileptic seizures, status epilepticus, and sudden death in epileptics had been recognized. Acute edema of the lungs, even apart from any relation to epilepsy, was an uncommonly discussed clinical event. Riesman described the history of six personally observed cases of acute pulmonary edema, but nowhere in his study did he mention its association with epilepsy, nor with status lymphaticus. The acute serous inundation of the lungs which Dr. Ohlmacher described had been observed in epileptics under several types, as accompanying a single major fit with death soon succeeding, after a single attack of coma, and death after a longer interval, and after a series of fits not reaching status epilepticus, and as hastening status epilepticus to a lethal termination. There was also evidence, so far as postmortem observations went, that some of the not uncommon nocturnal fatalities (the "found-dead-in-bed" class of institutional records) in reality were instances of acute pulmonary edema after one or more epileptic attacks, rather than of mechanical asphyxia by bed clothing or otherwise, as was commonly believed. To illustrate the variations just alluded to, five typical cases had been selected from his notes and were described. Thorough investigation at autopsy precluded the existence of renal, cardiac, or cerebral disease as explaining the causation of edema; in each case also a negative result followed the search for foreign bodies in the air passages which might have induced a mechanical suffocation. As to the relative frequency of pulmonary edema in epileptics, the following statistics from the records of the Ohio Hospital for Epileptics would bear witness: In the years 1903, 1904, and 1905 there were a total of 203 deaths; of these, 41 followed a single epileptic attack, or were otherwise sudden. In this group of 41 edema of the lungs was noted, either as a terminal event, or was verified at autopsy in 13 cases. Again in the period above mentioned, 41 patients succumbed to status epilepticus, and here edema of the lungs was noted in 15 cases. That the syndrome acute edema of the lungs and epileptic attacks was truly a "terminal event" seemed evident from his recital; he had no record of a case in which pulmonary edema clearly manifested itself as a coincidence of grand mal or of status epilepticus that did not result in death. The full significance of acute pulmonary edema in epilepsy was at most conjectural, but with what his studies had disclosed as to the existence of a status lymphaticus in those cases they could suggestively recall the fact repeatedly emphasized by those who had occupied themselves with that peculiar morbid condition, viz., that a tendency to sudden and usually fatal edema, as of the larynx, lungs, or brain, was one of the outstanding peculiarities of the victims of the lymphatic constitution. Accordingly the observations recorded should tend in two directions—to emphasize the importance of acute edema of the lungs as a concurrence in epilepsy, and to further illustrate the kinship between certain types of epilepsy and status lymphaticus.

The Structural Side of Epilepsy.—Dr. E. E. Southard of Boston said that, although the analysis of his material was not complete, he could not withstand the temptation to draw a few conclusions. He had been especially interested in the nervous side of epilepsy, and there were an extraordinary number of cases in which there were found lesions of the kidneys, liver, and other organs. The nervous system was the trumpet through which sounds were emitted in this disease. The nervous mechanism might be normal in certain cases of epilepsy. In many cases of insanity the histological aspects of the brain were normal. In epilepsy there might be a possible, though not a definite, division made along the lines of heredity. All books on epilepsy dealt with heredity, and the more recent the book the larger the percentage of hereditary cases of this disease. The brain in those cases which showed some heredity of epilepsy in one or both parents was likely to be absolutely normal, so far as could be detected. With a technique relatively perfect they could say that a large number of epileptics which they had examined showed absolutely nothing in the brain that was at all significant, nothing in the shape of a lesion. In the past, cases in which no lesion could be found had been termed idiopathic epilepsy. Cases which showed more or less gross lesions microscopically were not regarded as idiopathic, but as being secondary to the lesion. The point he wished to make was that when they looked into heredity they found these so-called idiopathic cases. These hereditary cases of epilepsy were subjected to a great variety of diseases; they might even show lesions; epileptics were subject to other lesions. He wanted a careful study of the so-called idiopathic cases of epilepsy from the standpoint of heredity. Gower's figures dealt with about 2,400 cases, and in 1901 he showed that 973, or about 40 per cent., of these had a neuropathic heredity. In the statistics of 1881, 429 out of 1,218 cases showed a strong heredity, or 35 per cent. a neuropathic heredity. In 1901, 544 out of 1,182 cases, or 46 per cent., showed a strong heredity. There was a distinct advance in the number of cases of hereditary epilepsy found when there was a neuropathic background in the family. Gower's later statistics included only such cases in which they could get reliable accounts of the condition of both parents, statements by physicians, relatives, and employers; in these cases they found that the true percentage was not beyond 50 per cent. Dr. Southard said that he could find no data in literature upon which he could rely, and the cases that he had taken into consideration were examined very thoroughly and reliable biological results were given. Most of the cases of epilepsy with marked lesions of the nervous system were cases in which they could not demonstrate heredity. A few, however, showed epilepsy in some relative, but far the greater number of cases did not. The investigations carried on in those cases which presented no determinable lesion of the nervous system were of far more importance. In interpreting the data to which he had access in literature he had no difficulty; he found that there was a group of cases in which there could be shown definitely certain foci, tumors, infarctions, hemorrhages, all in the brain, and even spots of encephalitis, and among these the most striking cases were reported. In some the only lesion was a distinct kink or streak. There was a gliosis as the result of encephalitis which resembled somewhat the acute inflammation of a finger following an infection. The fact that cultures were negative did not mean that organisms were not present. In some cases there were spots in the brain which were erosions, the result of pressure of the nerve cells. In nine cases out of ten epileptic lesions were not found in the motor area; they were found particularly in the occipital lobe and the hippocampal gyrus. One case had been reported as occurring in the General Hospital in Boston in 1890, in which there was an aneurysm the size of an egg occupying the site of the anterior choroid artery. This aneurysm had produced the attacks of epilepsy. It was necessary to distinguish conditions or tissues underlying in the cerebral structures which promoted the spread of impulses; that spread was usually laterally. A number of instances were found in which an invasion of the gyrus would produce a condition of gliosis. In cases of hereditary epilepsy in which no lesion could be found he thought that the condition could probably be explained by conditions in the parent; in cases of hereditary epilepsy the habit should be considered. In general they should differentiate sharply between the acquired and hereditary forms of epilepsy. In the hereditary cases they would often find signs of organic disease in the nervous system either in life or after death. In the acquired cases they usually found an original focus, such as an infarction, hemorrhage, or tumor, which produced a spread of the epileptic impulses.

A Brief Review of the Broader Lines of Progress in the Treatment of Epilepsy During the Past Two Decades.—Dr. William P. Spratling of Baltimore presented this paper, which was read by title.

WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting Held April 12, 1909.

Dr. William Lindner in the Chair.

The Medical and Surgical Treatment of Erysipelas.—Dr. Adolph Bonner of Brooklyn read this paper. He said that erysipelas attacked individuals of robust constitution and also those predisposed to its invasion by diabetes, alcoholism, decreased resistance from previous illness, and mental anguish. He cited three cases that he had seen in which diabetes had not been suspected, but was disclosed upon urinary examination. Internal medication in erysipelas was not of a specific nature, but was symptomatic, being directed toward sustaining the heart, reducing the temperature, quieting the nervous system, caring for the stomach, intestines and kidneys, and seeking the source of the infection. The majority of cases ran a short acute course and did not show any marked constitutional disturbances. These cases needed little or no stimulation. The speaker employed whiskey in cases that did not show cerebral involvement, and in which there was no delirium. In the latter, caffeine had proven valuable as a cardiac stimulant. For high temperatures the tepid sponge bath of alcohol and water had been used, or if this was not sufficient, the warm pack. The use of the coal-tar products for this purpose had to be condemned. The sodium salts administered per rectum had been efficient in the treatment of restlessness and delirium. For gastric irritation functional rest had been employed, or if this had been inefficient, vomiting had been induced by means of large draughts of lukewarm water. Clearing of the intestinal tract with salines, and avoidance of milk when the temperature had been very high, with the administration of fair amounts of water, plain or acidulated, to lessen the concentration of the urine, in addition to the enforcement of physical rest, were all important elements in the treatment. The topical treatment had been quite varied. Ichthyol, either in ointment or in solution, had stood the test of time, and had been found efficacious in the milder types, especially when located on the face. Erysipelas of the scalp was best treated by first cutting the hair as close as possible. Shaving was an added irritating element. Alcohol in 25 or 50 per cent. solution, constantly applied, had given satisfactory results. The best remedy for local application was pure carbolic acid. This attacked the infectious process, which was superficially located. It was applied by means of a metal probe; the surface of the infected area, and especially its edge, were swabbed with the pure carbolic, and when the surface showed distinct whitish discolorations it was quickly sponged with pure alcohol, which was not discontinued until the whitish color disappeared. It was important that the edge of the infected area and an area at least half an inch outside of this should be thoroughly treated in this manner. This method had been tried in cases of severe type and long standing. If the process seemed to advance the application might be repeated in ten to twelve hours. Bier's hyperemic treatment had been also employed. Phlegmonous infection needed surgical treatment. In the severe type of cases that continued to grow worse in spite of any form of medical treatment, some measure was necessary to prevent the advance of the process.

Where Is the Appendix?—Dr. George I. Miller of New York read this paper. He said that for practical purposes the theoretical surveys of the anatomical landmarks of the appendix were generally useless. In the fifth week of fetal development the cecum was high up, and in close relation with the transverse portion of the large intestine. The later development of the ascending colon caused the cecum to descend. The apex of the cecum did not keep pace with the remainder in the course of further growth, with the result that the narrow tubular appendix vermiformis represented the oldest portion of the cecum. The text-book descriptions that the appendix lay in the right iliac fossa, with its base midway between the anterior superior spine and the umbilicus, or in the pelvis, or in the left iliac fossa, or near the spleen and beneath the diaphragm, were all diagrammatic and did not apply to pathological contortions or resulting destructions. In catarrhal appendicitis the three muscular bands of the colon easily led to the point of attachment of the appendix. Extensive and firm adhesions changed the scenery of the operative field, and the appendix was so completely buried in cicatricial tissue as to be scarcely recognized and only liberated with great care and considerable force. The appendix was sometimes adherent to the wall of the cecum, so that it could not be separated from it with safety, or it was similarly caught between a coil of intestine, with the result that separation from it would involve the risk of tearing the gut. Many appendices were blended in adhesions and apparently formed part of the fascia covering the right psoas muscle. The sloughed appendix was sometimes found floating in a localized abscess cavity, or it was fished out of a diffused pyoperitoneum. Sometimes the appendix that had been sloughed off migrated somewhere in the abdomen or was swallowed by the cecum and passed through the large intestine and out of the system. The appendix sometimes protruded through a slit in the mesoappendix, the former twisting on itself in passing through the slit. Instead of an appendix, there was found at times a tumor accompanied by suppuration and cellulitis, with the omentum as the main bulk of the mass, adherent and wrapped about the appendix, thickened and infiltrated with inflammatory products. Sometimes the omentum fell over a ruptured appendix and prevented leakage from it. In such cases the omentum was highly inflamed, infiltrated, and often pyogenic. Sometimes the appendix was a fibrous cord, very small and atrophied, and when fused to inflammatory products furnished the cases in which the appendix was not found. Sometimes an enveloping appendix, although not itself diseased, produced strangulation of a loop of bowel. The ovary or fallopian tube might be fused with the appendix into one indistinguishable mass; this occurred mostly on the right side, although the appendix had been found by Rochard drawn across the abdomen and adherent to the left tube. The appendix was always behind an enlarged uterus, whether the enlargement was due to physiological or pathological causes. In appendicitis complicating pregnancy the offending structure had been found at the lower end of the kidney. A strangulated appendix without perforation gave the appearance of a cyst in the right iliac fossa. The appendix, either gangrenous or not, had been found in the sac of various forms of hernia, such as umbilical femoral, or inguinal. A supposed suppurating inguinal adenitis had been found to be the sac of a femoral hernia. The presence of a fulminating appendicitis in an irriducible inguinal hernial sac gave symptoms simulating strangulation. In 3,054 hernias operated upon the appendix had been found in the pro-

portion of one in about fifty-three cases. The author had operated on a five months old infant, in which the appendix, cecum, and colon were all invaginated in the rectum and protruded partly through the anus. This was a rare form of intussusception. There was a case recorded by Bary, in which the perforated appendix was found in a collection of pus behind the obturator foramen. In nondescent of the cecum there was a corresponding abnormal situation of the appendix. Turner of Moscow, quoted by G. R. Fowler, in a study of 83 cadavers in which the appendix lay freely in the abdominal cavity, found that it was located in order of frequency, as follows: In the lesser pelvis, transversely on the psoas muscle toward the sacral promontory, freely upon the iliacus or upon the psoas, in the mesogastric region, with the commencement of the colon, lying transversely, upward upon the lateral surface of the descending colon, and in front of a right-sided sigmoid flexure. The appendix had been found in the quadratus lumborum muscle, an inch and a half above the right iliac crest; in contact with the under surface of the liver; behind the peritoneum, with no peritoneal covering, constituting a retroperitoneal hernia of the appendix; coiled on itself and embedded in cellular elements on the surface of the iliac fascia entirely outside of the peritoneal cavity; and in the scrotum, instead of the testicles. Cases had been reported in which no appendix was found. In considering the location of the appendix, one had to bear in mind, first, its position with regard to the cecum; second, its direction, and third, the relation it acquired to the neighboring peritoneum. In conclusion the speaker stated that where the appendix should be everyone knew, but where to find it was guesswork until the problem was solved by opening the abdomen.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF MONTANA.

April 6, 7, and 8, 1909.

ANATOMY.

1. Give the origin, insertion, and action of the following muscles: deltoid, latissimus dorsi, rectus femoris, and tibialis anticus.
2. Trace the arterial blood supply from the heart to the foot, naming the principal branches given off.
3. Give the origin, course, and distribution of the following nerves: seventh cranial, great sciatic, median.
4. Give classification of joints, with an example of each.
5. Name and describe the salivary glands.

PHYSIOLOGY.

1. Give the varied functions of the sympathetic nervous system.
2. How is normal body temperature regulated and sustained?
3. What is metabolism? What are its objects?
4. Give the mechanism of respiration. How is it regulated?
5. How is the heartbeat regulated and sustained?
6. Describe the digestion of a meal of beefsteak and potatoes.

Answer five questions.

MATERIA MEDICA.

1. What is the alkaloid of hyoscyamus? What is the dose of hyoscyamus? What is the dose of hyoscine hydrobromate for hypodermic use?
2. Give the average adult dose of the following: (1) liquor potassii arsenitis, (2) tinctura nucis vomicæ, (3) tinctura opii, (4) spiritus glyceritis nitratis, (5) oleum tiglii, (6) eserina, (7) hydrargyri chloridum corrosivum.
3. Mention the conditions which affect the dosage of medicines.
4. What are incompatibles in medicine, and what are the different kinds of incompatibles?
5. Name four efficient hypnotics and give source and dose of each.

THERAPEUTICS.

1. By what methods do antipyretics act? Give an example of one that acts by each method.
2. What are the physiological effects and medicinal uses of the preparations of belladonna?
3. State the condition of the venous system and that of the arterial system that indicate the use of digitalis, and what effect this drug has on the arterioles.
4. How do antagonists and antidotes differ? Illustrate.
5. Name three drugs used to accelerate the action of the heart, also three drugs used to retard its action, and state the dose of some preparation of each.

PRACTICE.

1. Differentiate cardiac hypertrophy from cardiac dilatation; organic from functional heart murmurs.
2. What are the causes and symptoms of dilatation of the stomach?
3. Give the causes and symptoms of ascites, and tell how to recognize by what disease it is produced.
4. If summoned to a middle-aged person discovered in a comatose condition, explain how to recognize upon what disease the condition depends and give treatment for the uremic type of coma.
5. Differentiate catarrhal from croupous pneumonia and give treatment for the former disease.

SURGERY.

1. Give symptoms, diagnosis, and treatment of strangulated inguinal hernia.
2. Give differential diagnosis between gallstone colic, appendicitis, and kidney colic.
3. Give symptoms, diagnosis, and treatment of acute empyema.
4. Give symptoms, diagnosis, and treatment of acute osteomyelitis.
5. Give symptoms, diagnosis, and treatment of fractures in general. Give differential diagnosis between fracture and dislocation.

DISEASES OF WOMEN AND CHILDREN.

1. Give the symptoms, diagnosis, and treatment of gonorrheal cystitis.
2. What are the indications for a complete hysterectomy?
3. Give the symptoms, diagnosis, and treatment of laryngeal diphtheria.
4. Differentiate scarlet fever, measles, and rötheln.
5. Give the varieties, symptoms, diagnosis, and treatment of stomatitis.

OBSTETRICS.

1. Give the differential diagnosis of the different kinds of convulsions which may arise in the puerperal state.
2. Give diagnosis of a transverse presentation and its causes and management.
3. Give the causes and treatment of post-partum hemorrhage.
4. Give the symptoms and treatment of an incomplete abortion.
5. Describe the third stage of labor and its management.

DISEASES OF THE NERVOUS SYSTEM.

1. Give the etiology, diagnosis, and treatment of chorea.
2. Differentiate neuritis from neuralgia.
3. What is aphasia? Describe its varieties.
4. Give the etiology, symptoms, and treatment of acute anterior poliomyelitis.
5. In what conditions is the patellar reflex increased, diminished, or absent?

DISEASES OF THE EYE AND EAR.

1. Give the diagnosis and treatment of gonorrheal ophthalmia.
2. Give the causes and sequelæ of suppurative middle-ear disease.
3. Give the etiology, diagnosis, and treatment of trachoma.
4. Give the symptoms and treatment of acute mastoiditis.
5. Give the diagnosis and treatment of corneal ulcer.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF MONTANA.

April 6, 7, and 8, 1909.

ANATOMY.

1. DELTOID. *Origin*: From the outer third of anterior border and upper surface of the clavicle, from the outer margin and upper surface of the acromion process, and from the lower edge of the spine of the scapula. *Insertion*: Into the deltoid impression on the middle of the outer side

of the shaft of the humerus. *Action*: It raises the arm from the side so as to bring it at right angles with the body; its anterior fibers draw the arm forward; its posterior fibers draw the arm backward.

Latissimus dorsi. *Origin*: From the spinous processes of lower six dorsal vertebræ, posterior layer of lumbar fascia, external lip of crest of ilium, and from the three or four lowest ribs. *Insertion*: Into the bicipital groove of the humerus. *Action*: It depresses the humerus, draws it backward, adducts it, and rotates it inward.

Rectus femoris. *Origin*: Two heads, one from the anterior inferior spine of the ilium; the other from groove above the brim of the acetabulum. *Insertion*: Into the patella, in common with the Vasti and Crureus. *Action*: It flexes the hip and extends the knee.

2. From the heart the blood flows into the arch of the aorta, thoracic aorta, abdominal aorta, common iliac, external iliac, femoral, popliteal, anterior tibial, and dorsalis pedis arteries.

Branches of the *arch of the aorta*: Innominate, left common carotid, and left subclavian. Of the *thoracic aorta*: Bronchial, œsophageal, pericardial, mediastinal, and intercostals. Of the *abdominal aorta*: Phrenic, celiac axis, superior mesenteric, suprarenal, renal, spermatic (or ovarian), inferior mesenteric, lumbar, and sacra media. Of the *external iliac*: Deep epigastric and deep circumflex iliac. Of the *femoral*: Superficial epigastric, superficial circumflex iliac, superficial external pudic, deep external pudic, profunda femoris, muscular, and anastomotica magna. Of the *popliteal*: Muscular, cutaneous, superior articulars, inferior articulars, and azygos. Of the *anterior tibial*: Anterior and posterior recurrents, internal and external malleolar, and muscular.

4. Classification of Joints. 1. *Diarthrodial*, or freely movable; as hip and knee. 2. *Amphiarthrodial*, or slightly movable; as symphysis pubis and joints between bodies of vertebræ. 3. *Synarthrodial*, or immovable; as ethmoid with vomer and parietal with frontal.

PHYSIOLOGY.

1. *Functions of the sympathetic nervous system*: "It may safely be said that the sympathetic system has, to a great extent, a controlling influence over the secretion of most of the glands, the lacrymal, the salivary, the sweat glands, the glands of the stomach and intestines, the liver, the kidney, etc.; that it presides over the circulation by regulating the caliber of the blood-vessels and the action of the heart; that it influences respiration; and, finally, that all involuntary muscles, those of the digestive apparatus, of the genitourinary system, of the hair follicles (pilomotor nerves), are under its control to such extent that, for instance, in certain mammalians the bladder still continues to fulfill its function for weeks after all the cerebrospinal motor nerves leading to it have been severed. In short, we find that all vegetative life of the organism is, to a greater or less extent, under the control of the sympathetic system. Therefore it may properly be called the vegetative nerve system *par excellence*."—(*Reference Handbook of the Medical Sciences.*)

2. The normal body temperature is *regulated* and *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost.

Heat is produced in the body by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord.

Heat is given off from the body, by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and fæces.

3. Metabolism is a name given to the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Anabolic or constructive, and (2) catabolic, or destructive.

The objects of metabolism, are: Nutrition and life, and the conservation of bodily energy.

MATERIA MEDICA.

1. The alkaloid of hyoscyamus is hyoscyamine.
The dose of hyoscyamus is gr. vij.
The dose of hyoscine hydrobromide for hypodermic use is gr. 1/150.

2. Average adult dose of: (1) Liquor potassii arsenitis, is ♏iij; (2) tinctura nucis vomicæ, is ♏x; (3) tinctura opii, is ♏viij; (4) spiritus glycerylis nitratis, is ♏j; (5) oleum tiglii, is ♏j; (6) eserina (sulphate or salicylate), is gr. 1/64; (7) hydrargyri chloridum corrosivum, is gr. 1/20.

3. The conditions which affect the dosage of medicines, are: Age, body weight, body temperature, drug habits, idiosyncrasy, method of administration, intervals between doses, cumulative action of drug, disease, and race.

4. Incompatibles are substances which, when combined or associated, undergo a more or less complete change. The different kinds of incompatibles are: Chemical, pharmaceutical, and therapeutic.

5.

FOUR EFFICIENT HYPNOTICS.	SOURCE.	DOSE.
Chloral hydrate.	Alcohol and chlorine.	gr. xv to xx.
Sulphonal.	Acetone and mercaptan.	gr. xv to xxv.
Trional.	Methylethylketone and mercaptan.	gr. xv to xxv.
Paraldehyde.	Acetic aldehyde and sulphuric acid.	♏xxx to ʒj.

THERAPEUTICS.

1. The following table (from Potter's *Materia Medica*) gives the chief temperature depressants, with their manner of action: Temperature depression may be done by five different actions working upon two principal lines, viz., by—

(*a*) *Lessening heat production, by*
- (1) diminishing tissue change.
- (2) reducing the circulation.

(*b*) *Promoting heat loss, by*
- (3) dilating cutaneous vessels, thus increasing heat radiation.
- (4) promoting perspiration—its evaporation lowering the temperature.
- (5) abstracting heat from the body.

The following list of antipyretics includes a few for each of the above named actions, to which the numbers refer in each case, viz.:

Quinine, 1.	Aconite, 2.	Alcohol, 1, 3,
Phenol, 1.	Nitrous ether, 3, 4.	Antimony, 2, 4.
Salicin, 1.	Acetanilid, 1, 4.	Cold bath, 5.
Digitalis, 2.	Phenacetin, 1, 4.	Cold drinks, 5.
	Antipyrin, 1, 4.	Wet pack, 5.

2. Belladonna and Its Preparations. *Physiological effects*: Anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall, stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

Medicinal uses: To relieve pain, relax spasm, check sweating, as a mydriatic, for night sweats, to check griping of purgatives; in asthma, to check fevers, in heart disease, shock and collapse, acute coryza, urinary incontinence, chordee, low delirium of fevers, mania, alcoholism; as an antigalactagogue, spasmodic cough.

4. *Antagonists* "are agents which directly oppose each other in some or all of their physiological actions, and therefore may be used, one against the other, in a case of poisoning by either, to *counteract* its effect upon the organism, after it has been absorbed, and when, therefore, the time for an antidote has passed. Antagonistic action takes place in the blood and tissues, and is applicable almost entirely to vegetable poisons."

Antidotes "are agents which act upon poisons in such a manner as to alter their composition, rendering them more or less innocuous and so *preventing* their toxic action being exerted upon the organism. Antidotal action takes place in the alimentary canal, upon such portion of the poison as is unabsorbed, and is applicable to vegetable as well as to mineral poisons."—(Potter's *Materia Medica.*)

5. *Three drugs used to accelerate the action of the heart*: (1) Ammonia; dose of aromatic spirits of ammonia, ♏xxx. (2) Camphor; dose of spirit of camphor, ♏xv. (3) Alcohol; dose of brandy, ʒi.

Three drugs used to retard the action of the heart: (1) Aconite; dose of tincture of aconite, ♏viij. (2) Digitalis; dose of tincture of digitalis, ♏xv. (3) Veratrum; dose of tincture of veratrum, ♏xv.

PRACTICE.

1. *Cardiac hypertrophy* is usually a conservative process; there is an increase in the muscular tissue of the heart; the cardiac area is enlarged; the precordium bulges; the heart

beat is slow and strong; the pulse strong and regular; the cardiac enlargement is chiefly downward and outward; the first sound is long, loud, and booming, and the second sound is accentuated.

Cardiac dilatation is generally a destructive process; the cavities of the heart are enlarged; the cardiac area is enlarged; the heart beat is weak and diffuse; the pulse is weak and irregular and rapid; the cardiac enlargement is outward and upward, and gives the heart a quadrangular outline; the first sound is short and weak; the second sound is also weak; there may be soft, systolic murmurs, and there are generally signs of venous engorgement.

Organic murmurs are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease.

Organic murmurs may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

2. Dilatation of the Stomach. *Causes*: Motor insufficiency of the stomach wall; obstruction of the pylorus by cancer, or cicatrix from ulcer; pressure on duodenum from without by tumors or adhesions; pyloric hypertrophy.

Symptoms: Dyspepsia; emaciation; thirst; constipation; pain, and vomiting at long intervals of large quantities of sour and fermenting fluid, which contains particles of food taken several days previously; yeast cells and sarcinæ may be present in the vomitus. The outline of the stomach may be seen to be enlarged; percussion and auscultation show enlargement also, and artificial inflation of the stomach may also show increased stomach area.

3. Ascites is *caused* by: Mechanical obstruction of the portal circulation; cardiac or pulmonary diseases obstructing the general venous circulation; disease of the peritoneum; diseases of the kidneys; anemia, debility, exposure to cold or wet; cancer, syphilis.

Symptoms: Generally of gradual onset; abdominal distention, sense of weight and fullness; dyspnea; gastro-intestinal disturbances; lineæ albicantes, presence of fluid may be detected by palpation, percussion, or aspiration. If due to heart or lung disease, ascites will occur elsewhere, and the legs are generally affected first; in hepatic disorders the abdominal distention is marked, and appears early; in renal disease, the abdominal fluid is generally small in amount.

4. In *alcoholic coma* the coma is not usually absolute; there may be an odor of alcohol on the breath, the patient can generally be aroused by shouting in his ear; there is no paralysis; the pupils are normal or dilated; respiration is practically normal; the pulse is first rapid and later feeble, and the skin cool.

In *uremic coma* the coma is deep; there may be a urinous odor to the breath; the urine is scanty and contains albumin; there is slow pulse, with high arterial tension; the pupils are usually small and equal; respiration is deep and may be quickened; the body temperature may be above normal or subnormal.

In *cerebral apoplexy* there is generally paralysis of the head and upper limbs, and in left-sided lesions there may be aphasia; the pulse is slow and full; the respirations are at first slow, regular, and stertorous, later on becoming of the Cheyne-Stokes type.

In *opium poisoning* the pupils are contracted, there is no sign of paralysis; both respirations and pulse are slow and full.

In *coma of epilepsy*: History of attack, with previous convulsion; the coma is of brief duration, and the unconsciousness gradually becomes less; there may be a bitten tongue or other scars.

5.

CROUPOUS PNEUMONIA.	CATARRHAL PNEUMONIA.
Generally a primary disase.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular.	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct, and there is a large area of consolidation.	Physical signs indistinct, and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

SURGERY.

2. In *gallstone colic*: The pain is in the region of the liver; it radiates to the right scapula and toward the umbilicus; chills and sweats are common; also vomiting, and sometimes symptoms of collapse and jaundice; calculi are found, if at all, in the feces.

In *appendicitis*: The pain is at first diffuse, but later becomes localized over the appendix in the right iliac fossa; nausea, vomiting, and constipation may be present; tenderness over the appendix and rigidity of the right rectus abdominis muscle are present; there is generally moderate fever.

In *kidney colic*: The pain is in the region of the affected kidney; it radiates down the thigh; there are intense rigors; retraction of the testicle may be present; also history of previous attacks or of calculi; the urine may be scanty, suppressed, or bloody.

3. Acute Empyema. *Symptoms*: Fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis.

Diagnosis is made by aspiration, showing the fluid to be pus.

Treatment: Aspiration, drainage, irrigation, resection of ribs (Estlander's operation) or resection of chest wall (Schede's operation).

4. *Osteomyelitis* is inflammation of the bone and marrow; the term is often used now for inflammation of bone.

It is *caused* by infection, the bacteria gaining entrance either through a wound, or by extension from neighboring tissues, or they may be brought by the blood.

Symptoms: Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia may be present.

It is to be *diagnosed* from (1) *Rheumatism*, in which more than one joint is affected and the tenderness is *in* the joint, and not *near* it. (2) *Tubercular arthritis*, in which the onset is slow and the trouble starts in the epiphysis rather than in the diaphysis. (3) *Cellulitis* in which the bone and periosteum are not affected, and in which there is always a wound.

In *osteomyelitis*, the *treatment* consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

5. The *general symptoms of fracture* are: History of injury, disability, pain, swelling, deformity, abnormal mobility, and crepitus.

The cardinal principles in the treatment of fractures are: Reduction, coaptation, immobilization, and suitable measures for promoting the nutrition of the part and for preventing adhesions in the neighboring joints and muscles. Compound fractures, in addition, demand: Asepis, removal of foreign matter or damaged tissues, stopping the hemorrhage, and measures to combat shock.

FRACTURE.	DISLOCATION.
1. Crepitus may be present.	1. Crepitus never present.
2. Preternatural mobility.	2. Rigidity rather than mobility.
3. Easily reduced—but	3. Difficult to reduce—but
4. Deformity more liable to recur after reduction.	4. Deformity less liable to recur after reduction.
5. The head of the bone is in its proper place.	5. The head of the bone is not in its proper place.
6. The socket containing the head of the bone is not empty.	6. The socket which should contain the head of the bone is empty.
7. When rotated the bone does not move as one piece.	7. When rotated the bone moves as one piece.

DISEASES OF WOMEN AND CHILDREN.

1. Gonorrheal Cystitis. *Symptoms*: Frequent micturition; pain; bladder irritability and tenesmus; the urine

is turbid and may contain blood, pus, or mucus; the gonococcus is present; the patient may also experience chills and fever.

Treatment includes: Rest in bed; administration of plenty of cold water or milk, diuretics, bland and mild foods, laxatives, hot sitz baths or vaginal douches, irrigation of the bladder with antiseptic solution, followed by solution of nitrate of silver.

2. The INDICATIONS FOR HYSTERECTOMY are given as follows: *For the abdominal operation*: All solid or cystic tumors of the uterus; cancer; uterine rupture during labor; certain conditions of puerperal sepsis; pregnancy complicated by pelvic deformity, cancer, or other serious obstacle to the passage of the child; uterine prolapse or inversion, and incidentally as a step in the removal of complicated suppurative conditions of the uterine appendages.

For the vaginal operation: Bilateral suppurative conditions of the appendages; prolapse, cancer, pregnancy with cancer before the sixth month; certain septic conditions of the uterus; certain rare conditions which may require the ablation of a small movable uterus.

For the combined operation: Cancer, certain complicated fibroids; failure to secure hemostasis from below.—(From *Reference Handbook of the Medical Sciences.*)

3. LARYNGEAL DIPHTHERIA. *Symptoms*: General malaise, chills, fever, sore throat, stiff neck, congestion of soft palate, whitish patches of membrane are formed. The fever may become very high; the membrane is adherent; reforms if stripped off, and contains the Klebs-Loeffler bacillus. Cough and dyspnea are present.

Diagnosis consists in a microscopical examination of the exudate, when the specific (Klebs-Loeffler) bacillus will be found.

Treatment: The patient should be isolated and put to bed; the atmosphere of the room should be kept moist; the diet must be nutritious and easily digested; diphtheria antitoxin should be administered as soon as possible; alcohol or strychnine are indicated; local applications, either hot or cold, will relieve the pain; mild antiseptic solutions are often used.

4.

	SCARLET FEVER.	MEASLES.	RÖTHELN.
Incubation	Twenty-four hours to four or five days.	Ten to twelve days.	Ten to seventeen days.
Prodromal stage	Twenty-four hours.	Three to four days.	Twenty-four hours.
Prodromal symptoms	Vomiting, sore throat, diarrhea, and headache; pulse very rapid, 140 to 160. The disease has an abrupt onset.	Sneezing, coryza, photophobia, bronchial catarrh, croupy cough, eruption of red points on soft palate, Koplik's spots.	May be absent, but never more than slight poorliness and coryza. The posterior cervical glands may be enlarged and tender. Vomiting is very rare. Pulse slow: rarely over 90.
Throat	Sore throat is pronounced.	Not complained of, as a rule.	Complained of, as a rule, and pain on swallowing may be considerable.
Rash	Is erythematous and punctiform. Face is simply flushed, and the circum-oral ring is pale and uninvaded.	Appears on the fourth or fifth day. Consists of red papules, which become darker in color, and show a marked tendency to coalesce and form patches. Seen first on the face, and groups of papules forming blotches appear on the body and limbs in a few hours.	Appears on the first and is most intense on the second day. Consists of rose-red papules, which are confluent on the face, but usually discrete on the limbs. Often fades from the face before it is fully developed on the body and limbs. In the scarlatinal form it is brighter and more punctiform.
Glands	Submaxillary glands swollen and tender; no swelling of posterior cervical glands. Leucocytosis is present, and may be marked.	Cervical glands not enlarged or tender. No leucocytosis.	Cervical glands considerably swollen and complained of, especially the posterior group. Submaxillary glands not affected. No leucocytosis.
Temperature	Generally reaches 103° F., and may be much higher.	Generally reaches 103° F., and may be higher. Remains elevated until the rash is fully developed.	Rarely above 100° F., and may be normal throughout
Desquamation	Usually free, scaly, and in flakes.	Branny	Absent or very slight.

—(Modified from *Aids to Diseases of Children.*)

DISEASES OF THE NERVOUS SYSTEM.

2. In *neuritis* the pain is continuous, is always worse after use of the nerve, and does not vary in situation; painful points are present; the nerve trunk is tender, and the pain can be increased proportionately with pressure; it is not limited to sensory nerves, and trophic disturbances, wasting, and alterations in the electrical reactions are very apt to appear.

In *neuralgia* the pain is paroxysmal and intermittent; it is independent of the use of the nerve; it may vary in situation; painful points are not often present; the nerve trunk is not particularly tender, and a light pressure along the nerve trunk may cause as much pain as a heavy pressure; neuralgia only affects sensory nerves, and wasting and trophic disturbances only rarely occur.

3. *Aphasia* is the inability to express ideas by either speech or writing. It is caused by lesions of the cortical centers, and is not due to lesions of the peripheral nerves or of the organs concerned in speech or writing.

In *otaxic aphasia* there is loss of speech, owing to lack of coördination of the muscles concerned in voice production. The patient knows what he wants to say, but he cannot utter the words.

In *sensory or amnesic aphasia* there is loss of word memory, which may or may not exist in connection with ataxic aphasia. The chief varieties are: (1) *Visual aphasia*, in which the patient can see, but cannot recognize or understand words written or printed. (2) *Auditory aphasia*, in which the patient hears the sound of spoken words, but they convey no meaning to him.

5. The *patella reflex* is nearly always *present* in health, and denotes a healthy condition of the entire reflex arc (tendon, afferent or sensory nerve, posterior roots and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself). It is *absent* when there is a lesion which affects any part of this reflex arc, such as is the case in locomotor ataxia, poliomyelitis, Landry's paralysis, neuritis, in apoplexy just after the shock, and in epilepsy following the convulsion, etc. It is *exaggerated* in: Hemiplegia, lateral sclerosis, general paresis, transverse myelitis, injuries to the spinal cord, hysteria, neurasthenia, tetanus, and strychnine poisoning.

DISEASES OF THE EYE AND EAR.

3. *Trachoma* is an inflammatory condition of the conjunctiva, accompanied by hypertrophy, granule formation, and subsequent cicatricial changes.

Etiology: It is caused by contagion from another eye, being transferred by means of the secretion.

Treatment "consists in an attempt to reduce the inflammatory symptoms and secretion, and to check and remove hypertrophy of the conjunctiva, thus shortening the duration and diminishing the liability to conjunctival cicatrization and to sequelæ. This is accomplished either by the use of certain irritating applications, or by mechanical (surgical) means.

Irritating applications: Sulphate of copper in the form of a crystal or pencil is the favorite local application. Nitrate of silver (one or two per cent. solution), glycerole

of tannin (five to twenty-five per cent.), and the alum stick are also employed.

Mechanical (surgical) treatment includes expression, grattage, excision, curetting, electrolysis, *x*-rays, and galvano-cautery."—(May's *Diseases of the Eye.*)

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	July 13
Arizona*	Ancil Martin, Phoenix	Phoenix	July 5
Arkansas*	F. T. Murphy, Brinkley	Little Rock	July 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	Aug. 3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	July 6

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Alabama.—After next July a diploma from a reputable medical college will be required of all candidates for the State Board medical examinations. Non-graduates are now admitted only in Arkansas, Massachusetts, Mississippi, and Tennessee.

Glycogen in the Sputum.—Pozzilli has made a study of the amount of glycogen in the sputum in various pulmonary diseases. In pneumonia he found that the glycogen content was only 0.05 to 0.06 per cent.; in early tuberculosis, 0.5 to 0.6 per cent., while in advanced tuberculosis it was increased to as high as 2.60 to 3.75 per cent. In acute and chronic bronchitis, when not of a tuberculous nature, it was entirely absent, while in two cases of post-pneumonic abscess it was only 0.05 per cent. He considers the estimation of the glycogen in the sputum to be of value in the diagnosis and prognosis of pulmonary tuberculosis.—*Gazzetta degli Ospedali.*

Results of Enlarged Tonsils and Adenoids.—W. D. Ludlum tabulates the results of these conditions as follows: (a) Mouth breathing, with poor respiratory development, irregular teeth, and poor nutrition; (b) nasal catarrh, coryza, and bronchitis; (c) otitis media and deafness; (d) liability to severe attacks of scarlet fever, diphtheria, and measles; (e) liability to tonsilitis; (f) liability to rheumatism; (g) liability to tuberculous infection; (h) night and day restlessness, inability to fix attention, and disorders of taste, smell, and speech; (j) recurrent cervical adenitis.—*Pediatrics.*

THE INADEQUACY OF THE SANATORIUM TREATMENT OF TUBERCULOSIS.

By MAURICE FISHBERG, M.D.,

NEW YORK.

The main result aimed at by the campaign of education waged during recent years against tuberculosis is the total eradication of the disease. The steady diminution in the number of persons who succumb to the disease in civilized countries may be taken as evidence that the diffusion of information as to the modes of infection and methods of prevention has borne fruits. We can to-day claim credit for having saved in almost every community in which the agitation has been carried as effectively as conditions permitted many lives which, had the people been kept in ignorance as to the causes of tuberculosis, would undoubtedly have succumbed to the scourge. There are to-day but few well-informed people who would deny these elementary facts evident to all who seek information on the subject.

Next in importance to our prophylactic achievements come the services we have rendered to those unfortunates who have been afflicted with the disease. Up to about thirty years ago the diagnosis of tuberculosis carried with it as much of a sentence of death as to-day the diagnosis of cancer. Conditions have changed in this regard. With the diagnosis of tuberculosis we can, in the vast majority of cases, inspire the patient with a hopeful outlook for the future, especially in cases which are recognized in their incipiency; and even in quite a large proportion of cases which are more or less advanced we can assure the patient that under proper treatment he may regain his health and efficiency.

In former years our prognosis in cases of tuberculosis was thus qualified: Provided the patient leaves for a more salutary climate he has good chances of recovery. Under the circumstances, all those unfortunates who could not afford to go to a mountainous region and sustain themselves for several months or years; and all those who were the breadwinners for their wives and children had to consider themselves doomed. Considering that most of the consumptives belong to just the class incapable of raising sufficient funds to sustain themselves far away from home and provide for those dependent on them during their long period of incapacity, the vast majority of consumptives were discouraged, seeing that for the lack of funds, their lives could not be saved. Those who have met with many consumptives know well that hopefulness is one of the most important factors in the promotion of recovery.

But the fetich of climate has recently been dispelled. It has been shown that tuberculosis in the vast majority of cases is just as curable in a lower as in a higher altitude; in a cold as in a warm climate, and there are indications that everything points in favor of the cold climate when compared with the results obtained in warm regions; that the average number of hours of sunshine in a given place is by no means a safe index as to its efficacy in the cure of tuberculosis. Indeed, the results obtained in sanatoria established in various places differing extremely in their geographical position and meterological conditions have been about the same. The proportion of cases discharged as apparently cured, improved, and unimproved are, on the average, about the same. All of this goes far to prove that neither altitude nor climate is essential in the successful cure of the disease. Slowly has this truism been diffused among the masses, and while a considerable proportion of consumptives are to-day clamoring for opportunities to go to a mountainous or southern climate, yet, just as many, perhaps even more, are satisfied that they can be cured in the neighborhood of their homes, provided they can succeed in gaining admission to a sanatorium. The long waiting lists of the state, municipal, and private sanatoria in the eastern and northern States attest to their popularity, which is excellent proof that the results obtained in them are about as good as those attained in the sanatoria in Colorado, Arizona, southern California, etc. Physicians meeting many consumptives will agree that after all the average patient is just as much impressed by the experience of his fellow sufferers as by the opinion of his medical adviser. Often the former has more weight than the latter. When thousands of consumptives are anxious to gain admission to the sanatoria in the near vicinity of the cities in which they live, it means that they have met with many who were in their plight but have been cured in these sanatoria. As a matter of fact, the consumptive fights shy when he is told that the only available place for him is the hospital for advanced cases which is found in almost every city. He balks because he has hardly met with any who have been cured in these institutions.

We have made a considerable step in advance in learning that tuberculosis is curable in every climate habitable by human beings, and by educating the laity that it is not absolutely essential for a consumptive to go far away from home to assure his recovery. I am, however, under the impression that we have not gone as far as the facts warrant in dispelling the commonly accepted, though ill-founded notions about the place in which a consumptive may hope for a cure. I refer to the sanatoria which have of late been considered as the only places where these unfortunates may be cured.* After the average patient is informed by his physician that a definite diagnosis of tuberculosis has been arrived at, he at once inquires as to which sanatorium is

the most suitable for his case. The patient is informed where and how to apply; examined by the admitting physician, and, when found suitable, placed on the list and told to wait for a vacant bed. How long he is likely to wait depends on many conditions. Only rarely his turn comes before the expiration of one month; often he has to wait for from one to three months, and I have known cases waiting for a longer period before the authorities have communicated the information that they are prepared to admit them provided on reexamination they are again found suitable cases.

How many cases which were found at the first examination "suitable," *i. e.* in the incipient stage of the disease, but on re-examination, after waiting for weeks or months, were found to be "too far advanced to be benefitted by a stay in the institution," we have means of knowing. I personally have met with many. Most physicians who see many consumptives have seen more. It is to be remembered that a patient concentrating all his hopes on the benefits to be dervied from the sanatorium treatment when admitted, makes up his mind that at home no salvation is to be expected. As a result, he does not take proper care of himself. Indeed, many sanatoria which theoretically do not admit any but incipient cases and which practically reject at the first examination nearly all who are moderately advanced, hardly get many incipients in the full sense of the word in case they have a long waiting list. The fact of the matter is that in a fair proportion of cases the disease progresses while one is waiting for admission and many have to be admitted for one reason or another. Especially is this the case with patients in whom the disease is active and progressive, characterized by fever, rapid loss of weight, anorexia, etc. But even those cases which do not display any extraordinary rapidity in the course of their malady often lose considerably while waiting for admission to a sanatorium, considering that they believe this the only place where a cure may be expected.

Curability of Tuberculosis Outside of Sanatoria. —It is, however, not true that the only place where a consumptive may expect a cure is a sanatorium. From materials gathered by many careful and reliable pathologists it is evident that many more consumptives are cured at home than in sanatoria. I refer here to the large number of persons who during life have not been known to suffer from tuberculosis but who are found to have tuberculous foci in various parts of the body when they come on the autopsy table. The first to make a special effort to ascertain the proportion of dead persons who present tuberculous foci was Nägeli[1] who in 1900 reported his careful dissections of 500 bodies in the Pathological Institute of Zurich. He found that 71 per cent presented pathological changes due to tuberculosis; and later when he was more careful in his investigation, even 84 per cent were found to have been tuberculous during life. It is interesting and instructive that noteworthy differences were found in this respect between adults and children. Among individuals under 18 years of age only 24 to 25 per cent of the cases dissected were tuberculous, and in nearly all cases the lesions were of a grave character and often led to a fatal termination. On the other hand, in individuals above 18 years of age, the proportion showing tuberculous lesions reached 97 to 98 per cent, and of these only 28 per cent died as a result of tuberculosis, while the rest showed tuberculous lesions which were either slowly progressing or altogether healed. These revelations when first published appeared incredible for two reasons: It was rather frightful to behold that nearly everybody over 20 suffers from tuberculosis during some period of life, and it was difficult to believe that such a large number of persons were affected with this disease and remained either ignorant of its existence or were cured without any special effort on their part. Many other pathologists were not slow to verify these observations. Harbitz[2] performed 558 autopsies in Christiania and found that among adults over 15 years of age, 69.2 per cent showed tuberculous lesions. Victor Scheel,[3] during 2,022 autopsies performed in the Pathological Institute in Copenhagen, found that in 487 (24 per cent) tuberculosis was the cause of death; in 1,092 (54.2 per cent) tuberculous lesions were found of which 55.6 per cent were healed, and among 39.7 per cent of those who succumbed to non-tuberculous diseases, healed lesions were elicited. This author even states that more careful dissection might have revealed more cases of tuberculosis. Burckhardt[4] found during 1,452 autopsies that 38 per cent of the children were tuberculous, of which 50 per cent proved fatal, while of the adults, 91 per cent showed tuberculous foci on the autopsy table. Lubarsch found while performing 792 autopsies that 82 per cent showed tuberculous lesions or evidences of healed tuberculosis; while among the persons over 16 years of age the percentage was 84. In a later communication by the same author, giving results of 1,820 autopsies, he shows that only 60.6 per cent of persons under 16 years of age were tuberculous, while of those above that age 69.1 per cent showed active or healed lesions of this disease. Adami and McCrea reported to the last International Tuberculosis Congress results of 1,000 autopsies made in Canada, showing that in 41.7 per cent evidences of past or present tuberculosis was found; 15.1 per cent were healed cases; 9.3 per cent, latent; 2.2. per cent, active, but slight, etc. In only 8.5 per cent was there active pulmonary phthisis. At the same congress Martha Wollstein reported results of 1,131 autopsies on children under 4 years of age in New York City. One hundred and eighty-five showed tuberculosis, and whereas 78 per cent of the autopsies were on infants less than 1 year old, tuberculosis affected 12 per cent at that age. During the second year of life 33 per cent of all who came to autopsy had tuberculosis, and of those between 2 and 4 years old, 34 per cent had tuberculous lesions.

These autopsy findings were criticised, pointing at the fact that Nägeli, Burckhardt and others have not been careful in their diagnosis of tuberculosis on the autopsy table; that they considered as tuberculous not only those lesions which are considered generally pathognomonic by pathologists, but that they have included all kinds of scars in the apices of the lungs, pleural adhesions, etc., without ascertaining whether the cause of these changes has actually been the tubercle bacillus. In fact, Necker,[5] who carefully investigated the problem in 600 autopsies in the Rudolph Hospital in Vienna, shows that 70.21 per cent had tuberculous foci beyond any doubt, which agrees with the percentage obtained by Lubarsch. But he also shows that 22.34 per cent of the persons who came to autopsy showed doubtful signs of tuberculosis during life. When these doubtful cases are added to the rest we have 92.55 per cent, a figure nearing the high pro-

portion found by Nägeli and Burckhardt is obtained. Moreover, it has been shown by Lubarsch that the healed lesions which consist of chalky nodules when inoculated in guinea pigs was followed by infection of the animals in 75 per cent of cases.[6]

From all these facts it is evident that a very large proportion of humanity had tuberculosis some time during their life. I believe a conclusion that around 70 per cent. of persons coming to autopsy show signs of tuberculosis is conservative. Fifty per cent of these died as a result of this disease, while the other half died from other causes and a large percentage of these latter class give ample evidence that the disease has been healed.

How have these persons been cured without undergoing a course of treatment at sanatoria? This is especially an interesting problem, considering that the vast majority of persons met with on the autopsy table are generally of the lower classes, socially and economically. It has indeed been argued by many that the frightful proportion of tuberculous found on the autopsy table does not hold good for humanity at large; that among those who are on a higher social and economic plane the percentage of tuberculous is much smaller, which may be true. This, of course, goes yet further to confirm our contention that tuberculosis is curable not only in sanatoria, but also in cities, in the homes of the poor, in their usual *milieu*, in poverty and privation. Moreover, while the sanatoria of to-day cure only a comparatively small number of consumptives, considering that there is only a limited number of these institutions available, it is evident that the number cured at home, with or without their knowing it, and with or without medical assistance, is much larger than is generally appreciated. How have these thousands, I may say millions, of people who have healed or inactive tuberculous foci in their bodies attained an arrest of their disease?

Inadequacy of the Available Sanatoria.—The figures given above are instructive when taken in connection with the sanatorium population of some countries. It is then evident that by far more consumptives are cured in their homes than in sanatoria. Germany is the home of the sanatorium. It is there that the institutions for the cure of tuberculosis have been developed and maintained to a much larger extent than in any other country. The state, the municipalities, insurance companies and private enterprise have all combined to establish sanatoria for the treatment of the disease. The latest published report[7] is to the effect that in the spring, 1908, there were 99 sanatoria for adult consumptives, comprising 6,500 beds for male and 4,039 for female patients. In addition to these there were also 36 private sanatoria with 2,175 beds. The total was consequently 12,714 beds for the treatment of adult consumptives. Even if to these be added the 18 institutions devoted to the treatment of tuberculous children which contain 837 beds; and also the 73 institutions in which scrofulous children as well as children predisposed to tuberculosis are cared for and which have available 6,843 beds (among the latter many institutions are only open for a few months during the summer) we have only 20,394 beds for the treatment of tuberculosis in sanatoria.

In the United States the number of available beds in sanatoria and hospitals for consumptives is even smaller in proportion to the population. According to the last Report of the National Association for the Study and Prevention of Tuberculosis[8] there were in August, 1908, 240 hospitals, sanatoria, and day camps in the United States. Altogether these institutions have 14,014 available beds. All those devoted to the cause of the cure and eradication of the disease point to the pitiable lack of provisions for the unfortunate consumptives and keep urging on the State as well as private enterprise and philanthropy the necessity of increasing the number of such institutions. Indeed, one who is convinced that sanatoria are at the present state of our knowledge the only available agents effective in the prevention and cure of this disease, is actually dismayed when contemplating the inadequacy of the provisions made for the hundreds of thousands afflicted with tuberculosis.

It is unfortunate that we do not know the exact number of persons sick with tuberculosis. In some countries the mortality rate is known more or less exactly. In Germany, where the registration of deaths is very rigorously enforced, it is known that around 120,000 persons die annually as a result of tuberculosis. Nobody knows the exact number of deaths in the United States. The registration of deaths, as well as of births, marriages, etc., is in many States not at all carried out in a manner as to give reliable information on the subject; and even in the few States and cities in which an effort in this direction has been made, the vital statistics leave much to be desired. But assuming that there occur annually 20 deaths from tuberculosis per 10,000 population, which is rather a low estimate, it appears that at least 175,000 persons die annually in the United States as a result of tuberculosis.

While all available statistics show conclusively that about one-seventh of humanity die from tuberculosis, it does not necessarily follow that one in seven living persons is afflicted with the active disease. There are good and valid reasons against the assumption of such a frightfully high morbidity, as was shown by Cornet[9] and others. But a safe computation of the morbidity rate may be made by multiplying the number of deaths by the average duration of the disease in an individual. Some authors have computed their cases and given figures which might prove valuable in this regard, if they all agreed. But they differ extremely. Dettweiler, Riebmayr, and others estimate the average duration of life of a consumptive as seven years; Weicker,[10] between five and six years, while some authors believe it to be much shorter, even less than two years. But when we again recall the autopsy findings given above we must concede that all those human beings in whom healed tuberculous foci are found after death must also be included when calculating the average duration of life of the consumptive. This undoubtedly raises the average. It is also a fact that acute miliary tuberculosis as well as galloping consumption which carry off the patient in the course of a few months are comparatively infrequent. We do not know how long it takes for a case of tuberculosis to heal spontaneously, but we can reasonably argue that the period must vary greatly according to the individual and the conditions under which he finds himself. Taking all these factors into consideration, it appears that six to seven years is a conservative estimate as to the average duration of the active stage of the disease.

On this basis there are in Germany over 800,000 and in the United States about 1,225,000 consump-

tives in the active stage of the disease, of which only one-seventh die annually, while the rest live on—cured, improved or unimproved. That the proportion of cured cases must be very high is beyond any question. About 50 per cent. of those showing tuberculous foci on the autopsy table have healed scars. The absolute number of such living persons nobody would venture to estimate beyond saying that it must be very large. And when we compare it with the comparatively small number who are able to receive sanatorium treatment, we are impressed with the fact that many more are cured out of than within sanatoria. It has in fact been said that the available sanatorium accommodations are like a drop of water on a red-hot stove.

A few more figures will not be amiss in this regard: We have shown that there were in Germany in 1898 only 12,714 beds in the sanatoria for the treatment of tuberculosis. The provisions made for children may be discarded because many are only available for a few months during the summer, while others are more devoted to prophylaxis than to the cure of the active disease; they admit cases suffering from conditions allied to tuberculosis, such as scrofula, anemia, children predisposed to tuberculosis, etc. In the United States only 14,014 beds were available during 1908, but then not all of these institutions were for curable or hopeful cases. Many are for advanced and incurable cases, and the day camps are included in the figures. If we estimate that seventy-five per cent. of these beds aspire to admit only incipient and curable cases (which like every ideal is rarely if ever achieved completely), we find that in Germany only about 9,500 and in the United States 10,500 beds are available for cases which, in the opinion of those having experience in sanatorium treatment, have a favorable outlook as regards an ultimate cure. The average stay in a sanatorium is quite short in Germany; four months will be as near the true figure as is possible to estimate from the available figures published in the annual reports of these sanatoria. In the United States it is much longer, about six months on the average. This would indicate that the number of consumptives that can be admitted and treated in the sanatoria in Germany is about 19,000, and in the United States, 21,000 annually. From these must be deducted those who were admitted in the moderately advanced and far advanced stages of the disease, cases admittedly as in the main incurable, and the best that can be expected is that after a prolonged stay in the institution they may be discharged with the "disease arrested," a term which covers a multitude of conditions. The bulk of these cases are, however, discharged as only "improved," "unimproved," while some few are even reported as having died in the sanatoria, after all the efforts of the medical superintendents to persuade those likely to have a fatal termination to leave the place because they are "not suitable cases and cannot expect to derive any benefit from the treatment." The proportion of cases discharged with the disease arrested, improved, unimproved or dead exceeds fifty per cent. in the best sanatoria, and in some institutions it reaches even seventy-five per cent. Even conceding that fifty per cent. of all the patients treated in sanatoria have been benefited to such an extent as to be discharged in the category of the "apparently cured," which is, to be sure, much above the real percentage, it appears that hardly more than 9,500 are cured annually in German and 10,500 in American sanatoria.

Compare these with that vast army of persons who have been cured in their own homes, with or without their knowing that they have ever had the disease, with or without medical dietetic, or climatic treatment, as is evidenced by the large number of persons who have healed tuberculous foci in their bodies. Even if only five per cent. of the population of the United States and Germany have had tuberculosis some time during their life there are over 4,000,000 persons in the United States and 3,000,000 in Germany who have somehow been cured of the disease. How insignificant the small number cured in sanatoria looks when compared with those just mentioned.

The Incipient and Hopeful Cases of Tuberculosis.—Most of the tuberculous lesions found during autopsies consist of small foci in the viscera, especially the lungs, which have undergone fibroid changes; some are quite extensive and show evidences of having undergone calcareous changes. These latter, had they been diagnosed during the life of the individual, while the tuberculous process was active, would have been considered moderately or even far advanced cases of consumption, and if referred to a sanatorium for treatment might have been rejected by the admitting physician after a careful examination as not "hopeful" cases; that the prognosis is very unfavorable and even under the most salutory treatment in sanatoria they cannot expect any good result. On the other hand we see daily many cases admitted to sanatoria in the incipient stage of the disease, kept under treatment for months, occasionally for years and finally discharged as only "improved," or even "unimproved."

It is only the incipient case which is favorably received in sanatoria. As a *conditio sine qua non* they must be cases in which both the physical and rational signs point to but slight local and constitutional involvement; cases in which the lesion is limited to one apex or apices in the form of a small infiltration and especially displaying no constitutional disturbances, such as fever, gastric derangement, rapid loss of weight, albuminuria, etc. It is only with such cases that the sanatoria expect to achieve the highest proportion of cures. That just these cases are the ones that stand good chances of cure without the sanatorium, at a lesser personal and public expense, we will see later. But it must be mentioned that this attempt of selection of incipient cases has often been cerried to extremes. Many cases of anemia and debility, slight catarrhal inflammation of the bronchi in which the expiratory murmur is somewhat prolonged, or showing defective resonance at an apex due to adhesions and retractions of the pleura following a pneumonia or pleurisy in former years, are thus diagnosed as tuberculosis. Some such cases may show these physical signs because of a real tuberculous lesion in former years which has healed, but at the time when referred to the sanatorium they complain of some general debility and their physician on careful examination discovers a prolonged expiratory murmur at the apex, some dullness, etc. Without waiting for developments, without watching the course of the disease, the patient, especially if he happens to be financially well off or has friends willing to help him, is sent in a hurry to a sanatorium where he is cured within a few months. The small number of persons admitted to sanatoria and discharged within a few weeks or months (I know of one case which was kept at a well-known sanatorium for eight months and then discharged as never having

had tuberculosis) as nontuberculous is by no means an index of the extent to which the eagerness for real "incipient" cases for sanatoria has been carried. A yet larger number have not taken their medical advisers seriously. I often meet persons who have been examined by admitting physicians of sanatoria, found to be proper cases and placed on the waiting lists. When after the lapse of a few weeks or months a bed was found for them and they were informed that they might report for admission, they for some reason did not go. They find themselves in excellent health for years later. While in many cases of this kind the diagnosis was probably wrong, but most of them did show tubercle bacilli in their sputum. In the latter class the patients were cured at home in their usual environment. Had the sanatorium not been overcrowded and admitted them immediately after the first examination, the credit of saving their lives would have been due to the sanatoria. To these must be added those cases which on the first examination by the admitting physician are considered as "incipients," but on subsequent examinations, after the lapse of a few weeks or months are not found to be showing any positive signs of the disease. I recall another experience some years ago while looking up for the Health Department of this city cases of tuberculosis reported some three or more years before. A very large proportion of cases could not be found at all owing to the frequency with which the tenement population moves about. But the most remarkable among those found were many who stated that they were perfectly well, excepting for a slight "cold" a few years ago, when their physician sent their sputum to the Health Department laboratory for a microscopical examination. It appears that tubercle bacilli were found in their sputum and they were registered as cases of tuberculosis. These cases did not go to sanatoria, still they recovered at home. Every physician of experience knows of such cases. These cases are to be considered in connection with the fairly large number of incipient cases of tuberculosis in which the constitutional and objective signs and symptoms are not very definite and no tubercle bacilli are discovered in the sputum, which are admitted to sanatoria, and there, after repeated examinations, no bacilli can be found. When such cases are finally discharged as cured we may logically suspect that some of them never suffered from tuberculosis, while some others could have been cured at home just as well.

Many sanatoria admit also moderately advanced cases of tuberculosis and, unwilling as most are to admit far advanced cases, still it appears from their reports that nearly all have them in larger or smaller proportions. The results they obtain in these cases are noteworthy. Of course several factors are to be considered. In the first place most of those who show any signs of progressive disease after admission go back home seeing that they can expect no relief in the institution. Many of those who leave within the first two months after admission are of this class. Those who show no inclination to leave of their own violition are persuaded by the medical superintendent to do so, inasmuch as they can expect no relief, they are told that they are not suitable cases for the climate, etc. But the majority of those who remain for a full course of treatment are finally discharged as improved, and some even as apparently cured. This is to be expected considering the rigid process of selection which has been carried out; the strict elimination of all active and progressive cases which I just mentioned. I see daily moderately and even far advanced cases of tuberculosis in the tenement houses of New York City who show tendencies to keep alive in spite of the vicious surroundings in which they find themselves. I often meet with cases showing positive signs of cavities in the lungs which keep on working in sweatshops. They often report that they feel much better, that their cough has ameliorated, their strength and vitality much improved, and they insist on keeping on at work. I have met with cases which were sent home from sanatoria because the disease was rather progressive and a speedy fatal termination could be expected, but which improved at home after returning to their overcrowded tenements. Of course they are exceptional cases, but they go far to demonstrate that tuberculosis is curable under all circumstances.

A moderately advanced case is considered one in which the local lesion is moderate in extent, showing no evidence of destruction of tissue or disseminated fibroid deposits, and having no serious complications such as emaciation due to rapid loss of weight, fever, gastric disturbances, albuminuria, etc. These are just the cases that stand good chances of improvement at home, especially if they take good care of themselves; and this improvement is procurable at home at a much lower cost to themselves and the community as we shall soon see. It must be borne in mind that according to our present knowledge of the course of this disease it is not necessarily the duration of the disease, nor the severity of the symptoms manifesting themselves at a given time, that is of prime importance in formulating the prognosis of tuberculosis. The ultimate issue of the average case depends much more on the specific protective powers of the individual. These protective forces of the body are as yet but little understood, but we do know that the tubercle bacilli when implanted in some individuals they get the upper hand in a comparatively short time, as is the case with miliary tuberculosis. In such cases the resisting powers are at a minimum and no treatment at home or in the sanatorium is of any avail. In other cases in which these forces are abundant and effective, the bacilli are sooner or later destroyed, the tissues which they succeeded to disintegrate are repaired by either fibrosis or calcification and the body recuperates not much the worse for the experience. In such individuals the specific protective forces are at their highest potentiality. Midway between these two extremes there are individuals in whom the resisting powers are equal to the occasion, meeting the enemy as he comes, but unable to completely annihilate him. These are the chronic cases which run a slow, variable course; often passing periods in which the disease has the upper hand, followed by periods when the patient is apparently or actually improving both as regards his general condition as well as regards the local pathological process. It is from this class of cases that the majority of the discharges from sanatoria are recruited with the labels "diseased arrested," "improved," etc., implying that the constitutional symptoms have abated or have entirely disappeared, the cough and expectoration, with or without bacilli may or may not be present, the physical signs are stationary, unchanged, or retrogressive, etc. Even the "apparently cured" cases are mostly of this class—the only difference being that

these ameliorations have been observed for a period of three or more months and bacilli are not found in the sputum. Hardly 20 per cent. of all admissions to the best conducted sanatoria are discharged as apparently cured, while between 60 and 75 per cent. are only improved, or with the disease arrested after undergoing a course of treatment in these institutions. That the prognosis of these cases after they leave the sanatoria is not excellent we shall soon see.

The Results Attained in Sanatoria.—From the strictly medical standpoint we can consider a favorable result in a given case of tuberculosis when the cure consists in the disappearance of all the subjective symptoms, as well as the objective physical signs of the local pathological process; the latter, of course, to be replaced by signs of fibrosis or calcification of the tubercular lesion. Owing, however, to the recent conception of tuberculosis as a social disease, which is just considering the great havoc it works in our social and economic structure by removing hundreds of thousands of persons in the prime of life, and incapacitating many more, the sanatoria often look favorably at results even when they can by no means be considered cures in the strict medical sense of the word. Thus we have to-day two views concerning what constitutes a cure of tuberculosis, the medical, and the social. To the former nothing short of a complete disappearance of the clinical symptoms, both subjective and objective can be accepted as a cure; while the latter is satisfied with an amelioration of the clinical picture, with regaining for the patient of sufficient strength so that he can again perform his social functions, supporting himself and those dependent on him by resuming his work. Most of the German popular sanatoria have this aim in view, considering that they have been subsidized and supported by the compulsory workingmen's insurance and invalidity funds. Most of the cases of tuberculosis are given three months' treatment in these institutions and then sent back to their homes with the expectation that they will be able to resume work. A consumptive who, after a course of treatment is able to earn one-third of the standard wage at his trade is considered a success, and if this capacity to earn one-third of the standard wage keeps on for more than two years, it is put down as a lasting success ("Dauererfolg"). It appears from statistics published by these sanatoria that between 33 and 40 per cent. of all those who have been treated in these institutions, most of which were incipient cases, have shown the success was lasting, and continued at work two years after discharge. The rest, 60 to 67 per cent., either died or suffered relapse of the disease. The most recent statistics published treat of 16,489 cases of tuberculosis treated in German sanatoria during 1902. An investigation at the end of 1906, *i. e.* five years after discharge, revealed the following results: [11]On the whole 42 per cent. were found to be in condition to work and earn at least one-third the standard wage; 20 per cent. were either dead or, when alive, were invalids; and 15 per cent. were again under treatment. It must, however, be mentioned in this connection that the fate of only 9,713 patients was thus ascertained. What became of the other 6,776 is not stated. What picture the ultimate results would have shown had we the exact statistics of all the cases, I do not venture to suggest. It is reasonable to presume that it is harder to trace the later history of a dead man than that of a living one.

But it must be emphasized that nearly all these cases were in the incipient stage when admitted to the sanatoria, a selected class, each of which had a more or less favorable prognosis; that such cases often recover under any kind of treatment often even in spite of the lack of any kind of treatment as was already shown. Then it must be recalled that the natural life of a consumptive has been ascertained to be between six and seven years. Of incipient cases showing no tendency to present acute symptoms, the average duration of life must be even longer. Moreover, the favorable ultimate results are not given in these statistics from the medical standpoint, *i. e.* success does not necessarily imply that the local lesion has been healed. It only means that the individual is able to earn at least one-third of the standard wage. We all know that the term "able to work" is at best very elastic and can be stretched to cover a multitude of conditions. It may mean that the patient is anxious to keep on working irrespective whether his physical condition warrants it or not: inability to work may mean unwillingness due to inherent laziness or to habits acquired during the sojourn in the sanatorium. Physicians coming in contact with many consumptives know how difficult it is often to convince a cured patient that he may resume work, while others cannot be convinced that it is absolutely imperative for them to abstain from any physical exertion. Whether these two classes are of about equal frequency so as to offset each other in statistical material covering 10,000 cases, it is impossible to state. It is also important to know the kind of work the patient is capable of accomplishing after a cure has been attained. Does he resume work at his trade, or is he compelled to change his vocation owing to physical incapacity, or for fear of relapse of the disease? The vast majority of workers at dangerous trades, such as stone cutters, cigar makers, printers, furriers, tailors, etc., should not resume work at their former trades if they want to make sure of keeping well. Such persons must try to make themselves useful in some other occupation after their discharge from sanatoria. On the other hand, persons skilled in less dangerous trades may resume work with impunity. Until we have statistics which take all these factors into consideration we are not in a position to properly estimate the value of any method of treatment from the social and economic standpoint.

There are hardly any statistics available treating of the results of investigations of later histories of consumptives after they have left sanatoria, taking as a criterion of lasting success the condition of their lungs, the objective evidence of health or disease. The few papers that appeared on the subject treat of very few cases and cannot be considered conclusive of anything. The best and most thorough study of the duration of life of patients discharged from sanatoria has been made by Lawrason Brown, of the Adirondack Cottage Sanatorium at Saranac Lake.[12] With indefatigable zeal Dr. Brown has followed up the cases discharged from that institution during the years 1885 to 1906, sending letters of inquiry to them since 1902. He thus succeeded to reach a fairly large proportion of former patients. In his last publication Brown assumes that the ultimate test of the economic value of sanatorium treatment of pulmonary tuberculosis is to be found in a comparison of the death rates of patients treated with that of the general population. He finds that those who were discharged

"apparently cured" have a death rate at first twice, later about three times that of the general population, but this rate is somewhat reduced after eight or ten years. In 47 cases the cause of death was ascertained and in 33 of these, or 70 per cent., it was due to tuberculosis, confirming that the cure was only "apparent." The death rate of those who were discharged with the disease arrested was much higher than that of the preceding class: It was four times that of the general population at the end of the first year, and ten times at the end of the third year. A slight decrease in the mortality was observed during the subsequent years, which is undoubtedly due to the severe process of elimination during the first five years. This is confirmed by the mortality rates of those who were discharged with the disease active, among whom it is very high, forty times that of the general population during the first year, thirty times during the second year, and twenty times during the third and fourth years; it then begins to fall and becomes about the same as the mortality among the patients in whom the disease has been arrested during the stay in the sanatorium—at the end of eight or ten years, evidently as a result of the fact that most of those in whom the resisting forces have been at a minimum have previously succumbed.

These statistics are the best that have been published on the subject. They are the most carefully collected and compiled and are of peculiar value because they deal with quite a large number of patients treated in one institution, uniformly observed, classified by one standard and followed up, as far as possible for over twenty years; peculiarities which are unique and not available in any other report on ultimate results of sanatorium treatment. But here, just as was the case with the German statistics quoted above, the comparison with the general population is not at all satisfactory. We could not expect anything but a higher rate of mortality among those who have had consumption and were cured or had the disease arrested. It by no means gives us an estimate of the value of sanatorium treatment as compared with other methods of treatment. Such a study could only be made by comparing a number of tuberculous persons, divided into similar groups, incipient, moderately, and far advanced. One half the number of patients to be treated in sanatoria and the other by any other method. Consumptives can no more be compared with the general population as regards death rates than with typhoid fever cases. Such a study is as yet not available, excepting that soon to be mentioned. That many are cured outside of sanatoria has already been shown by the autopsy findings of Nägeli, Buckhardt, Adami, and others above mentioned. That many active and far advances cases survive for long periods of years, we all know. I know patients with large tuberculous cavities in their lungs holding on to life for more than ten years, and I have met with many who keep on working in sweatshops in New York City. They have periods of complete disability, followed by periods of comparative well being. Dr. Brown's statistics confirm this. Some of the advanced cases discharged from the sanatorium with the disease still active were traced alive eighteen years later.

It must also be borne in mind that the majority of the patients of the Adirondack Cottage Sanatorium belong to the so-called middle class, persons who use their brains rather than their muscles to earn their living. In this class of people the prognosis of tuberculosis is more favorable than in the working class, because after their discharge from the sanatoria they may engage in some occupation which does not favor a relapse of the disease, which is not often the case among the less favored working class. Thus among 2,000 cases treated, according to a personal communication from Dr. Brown, I find that only 25 were before admission dressmakers, 8 printers, 3 tailors, 7 machinists, etc. The bulk was made up of clerks, students, teachers, merchants, and professional persons generally. It is questionable whether the results shown in the favorable death rate after discharge would have been the same in case the bulk of the patients had been workers at trades which are considered dangerous. Moreover, it is a question whether society is *economically* the gainer by the prolongation of life of consumptive artizans or laborers who after an expensive stay in the institutions are discharged with the disease arrested or apparently cured and especially when only improved and are warned that they must not again engage in their previous occupations for fear of a relapse of the disease. He returns an invalid after discharge, as is often the case, to his friends and relatives who are not only burdened with his support, but are also exposed to infection. When we bear in mind that such results are attained only at a considerable cost, as will soon be evident, the question of the economic gain by society stands out more prominently, and it has been stated that sanatoria for the poor, who make up the majority of the patients in the civilized world, are not economically a success for just this reason.

The Economics of Sanatoria.—The economic problem presented by tuberculosis is important mainly because it is a disease of the masses, of that large mass of artizans and laborers who depend on their muscles for a living. A case of consumption in the breadwinner of a family means that all those dependent on him are left without resources for support; a case of this disease in his wife or child taxes his limited income to an unbearable degree. While the comparatively few rich and well-to-do consumptives can take care of themselves, the poor and a larger proportion of the middle class must be cared for by the community in case they are infected by this disease. They have a just claim on society which is responsible for permitting conditions favoring the spread of a disease which is known to be contagious but preventable. It is therefore important to inquire whether the community can undertake to provide places in sanatoria for all the consumptives who are in need of treatment.

As has already been shown we do not know the exact number of consumptives in any country. It would, to be sure, be incorrect to assume that from seventy to ninety per cent. of the people over twenty years of age are tuberculous and must be under treatment because autopsies have shown that such a percentage have tuberculous foci in their bodies. In a very large proportion of these the lesions have been more or less perfectly healed and they are none the worse as regards their physical capacity to work for a living, nor are they a menace to those around them because they do not scatter the seeds of the disease as do the active cases. But even taking the lowest estimate of the probable morbidity from tuberculosis, that about seven times the annual number of deaths due to this disease, we find that there are about 1,225,000 cases of active tuberculosis in the United States. Assuming that all

these ought to be taken care of in sanatoria, what would be the expense to the States, municipalities, and philanthropists to provide places for them in institutions?

It has been the experience of the existing sanatoria that it is required an initial outlay of about $1,000 for each bed when an institution of this kind is built and equipped. In Germany the outlay is not much smaller. This would imply that an investment of $1,225,000,000 would be necessary to provide for the 1,225,000 consumptives in this country. That this is not the maximum number of beds will be realized when we consider that once we undertake to keep the patients there till cured, the number to be cared for will not diminish, but increase, because many are not cured in a year and will have to be kept longer, thus swelling the number of cases annually, unless such a wholesale segregation shall ultimately reduce the number of new cases. After this initial outlay there would be necessary funds for maintenance, including food, salaries, repairs, and replacements, interest on investment, etc. The experience of existing institutions shows that this amounts to about one dollar per day per patient. The expenditure for maintenance would thus amount to about $450,000,000 annually. Knowing the difficulties encountered while attempts are being made to raise money for a good cause, it is questionable whether such an amount of money can be raised in this country and then repeated annually.

Judging from present results hardly 30 per cent. of the hopeful, *i. e.* incipient cases are discharged apparently cured after a prolonged sojourn in the sanatoria. The rest would have to be kept for years in the institutions in an improved or even aggravated condition or discharged as invalids, not to speak of those who will die. It is thus evident that only about 367,000 would be apparently cured annually at an expense of $450,000,000, or of over $1,200 per case on the average. That this is a conservative estimate will be realized when we recall that the experience of modern sanatoria is only based on hopeful and incipient cases which constitute the majority of their favored clientèle. But if provisions were made for all the active cases of consumption the percentage of incipient cases would undoubtedly be smaller among those admitted during the first few years, and the percentage of cures correspondingly smaller, much lower than 30 per cent., and the cost per patient cured much higher on the average.

Of course from the standpoint of humanity and charity nothing ought to be too much or too expensive when the problem is the saving of human life, the regeneration of the invalid and bring him back to a condition capable of self support. No one will deny this primary principle of humanity. But it must also be borne in mind that all available facts tend to show that similar results can also be obtained at a much lower cost by non-institutional treatment. In addition to the facts detailed above showing that many more tuberculous persons are being cured in their homes than in sanatoria I can quote some statistics proving that the results obtained in the treatment of tuberculosis in dispensaries were not much different than those obtained in sanatoria. Hammer[13] finds that against the 74 per cent. of patients treated successfully (from the social and economic standpoint, *i. e.* ability to work), 69 per cent. of those treated at home showed similar salutary results, a very slight difference in favor of the sanatoria. Complete success (from the medical standpoint) was obtained in 35 per cent. of sanatorium patients and 52 per cent. of the patients otherwise treated; while a medium success was evident in 38.6 per cent. of sanatorium and 16.6 per cent. of the other patients. In other words, those treated at home gave on the whole better economic and lasting results. Even the length of time these patients were able to work after the treatment was longer than those treated at home. Hammer's conclusion of his study is to the effect that sanatoria show no results worth mentioning. Ambrosins[14] arrives to a similar conclusion.

In a recent paper on the subject Karl Croissant[15] also compares results obtained in the treatment of 407 cases in the sanatorium and 166 cases treated in the poliklinik of Heidelberg. As is usual in Germany he lays more stress on social and economic results than on medical success. In general he finds that 77.3 per cent. of those treated in sanatoria for more than six weeks showed a lasting success, as against only 53 per cent. of those treated in the poliklinik. But it must be borne in mind that the former were nearly all incipient cases, displaying no tendency to run a rapid and progressive course; while among the latter there was a large proportion of advanced cases which no sanatorium would admit. It appears also that if the incipient cases alone are considered, those who were treated in the poliklinik fared much better than those who underwent a course of sanatorium treatment. The capacity for work was better and of longer duration among those treated at the dispensary than those treated in sanatoria. This Croissant explains as due to the care and anxiety with which the former sanatoria inmates take note of all insignificant disturbances in their health, and more often consult a physician, or stop working, for trivial reasons. It is interesting that of the cases in the first stage of the disease 89.6 per cent. of the sanatoria patients and 82.5 per cent. of those treated at home were able to work, although the former class were, on the whole, in better physical condition—78 out of 244 were not at all disabled before admission to the institution. Even the mortality rate of the dispensary patients was lower than of those who underwent a course of institutional treatment. On the whole, Croissant shows that as regards lasting results there is no difference between the sanatorium patients and the others.

While figures like those just quoted go far to show that dispensaries give quite good results, perhaps as good as those obtained in sanatoria, yet it must be agreed that they are not conclusive because they are based on very small numbers of observations. It is a deplorable fact that we lack data on the results of home treatment of tuberculosis. If such data were collected and published they might prove quite instructive and perhaps revolutionize our present views on the treatment of this disease. Let us hope that the large number of tuberculosis dispensaries which have of late been organized will in the near future give us their experiences. Meanwhile the average physician and with him his patients believe that the only place where a consumptive may expect a cure is an institution. But provisions for all those in need of treatment has not been made, nor is it likely to be done within the next generation or two considering the heavy initial outlay as well as the enormous sums necessary for their maintenance, and the great difficulties en-

countered while attempting to raise money for the purpose. That they are not economically an investment which society can consider excellent has been shown when speaking of the small percentage of cases that are actually cured in these institutions. Even Cornet,[16] one of the first who championed the cause of sanatoria, has this to say: "The literature of the subject (of sanatoria) is often careless in its statistics. One author calculates that 13 per cent. of recoveries means a saving of more than 100,000 lives; another widely read author is satisfied with 80,000. Such data are without foundation, and as the future proves them false they can only injure the cause." In the United States we have recently been treated to greater exaggerations as to the fabulous sums to be gained by the State through the saving of certain number of lives and restoring many more to self support by the provision of a sufficient number of sanatoria for consumptives. But "the establishment of these institutions is only a half-measure," says Cornet, "the enormous outlay of money useless, the success only apparent, if we do not also give heed to the immediate future of the patient, if we do not improve the conditions of the home, do not relieve him of a part of his responsibility toward his family, and supply him for some time with a less injurious occupation and keep him busy, if possible in the open air—requirements it is easier to enumerate than to fulfil."

Indeed, all those interested in the problem of the prevention and cure of tuberculosis are to-day so much taken up with the problem of sanatoria that everything else that may do much toward this end is more or less neglected. It is noteworthy that while those admitted to a sanatorium cost the community on the average seven dollars weekly, the thousands who receive treatment in dispensaries are expected to be cured by imbibing all the nasty mixtures that can be forced on them. No serious effort has been made to give dispensary patients sick with tuberculosis sufficient food, better and more sanitary homes, etc. This could be done at a much lower cost than in sanatoria, and everything points to as much success as in institutional treatment. At any rate a serious effort in this direction ought to be made and the results carefully studied and recorded.

Many consumptives are able to do more or less work for their support. To be sure those who have fever, rapid loss of weight, debility, anorexia, etc., cannot work. But these are just the cases in which the sanatoria do not expect any brilliant results. But a large proportion of cases run a slow, chronic course, rarely have fever, excepting for some intercurrent disturbance, and maintain their physique in a fairly good condition. Such patients, if their vocation is not of a dangerous character, may continue at work and earn their living. In fact in many of the better sanatoria the patients are made to work, especially the last two or three months of their sojourn in the institution. I personally know of many consumptives who have kept on working for years while their disease was in a quiescent stage, and the work did not aggravate their condition. It is my conviction, based on close observation, that in most of these cases a breakdown manifests itself only through some intercurrent affection, mainly influenza, pneumonia, etc. But if these individuals are taken to sanatoria they become a burden on the community, and those dependent on them are also thrown on charitable societies for support. Moreover many of these cases are practically incurable from the medical standpoint. They are just the class that supplies most of those who are discharged in the category of "improved," or at most "disease arrested," and this can be attained at home in the majority of cases at a much lower cost. Of course those who pursue occupations involving work in close and dusty mills and factories cannot under any circumstances remain at their trades. But the sanatorium is hardly a remedy—after their discharge they must not reenter their workshop. They must change their occupation no matter where and how treated.

In the large American commercial and industrial centers the municipal and State sanatoria are impracticable for another important reason: The cosmopolitan character of the population is by no means conducive to the promotion of friendly intercourse between the patients. Many intelligent patients have told me that, while they liked the treatment accorded them by the authorities, they could not bear some of their fellow patients of other nationalities, and they had to leave the institution before their time expired and against the advice of the medical superintendent.

There are reasons why even sanatoria having a homogeneous class of patients should often lose their patients prematurely. Institutional life is at best distasteful to the average American who is not used to submit to a system of regimentation and bureaucracy essential for discipline. In addition to this is often added the care, worry, and anxiety about the poverty and misery of those left at home without a breadwinner, who are not slow in communicating their troubles to the patient. A little improvement in the condition of the patient is sufficient for him to decide that he has regained enough strength to resume work and provide for his family. I often meet with such cases. It is true they soon discover that they were mistaken, but it is often too late.

These and many other reasons are responsible for the fact that between 15 and 30 per cent. of the patients of sanatoria leave the institution within three months after admission. The result is that between 15 and 30 per cent. of the money invested in the attempts to cure these patients has actually been wasted.

The Preventive Function of the Sanatoria.—Many who agree that the ultimate success of sanatorium treatment has been overestimated, and is at best rather expensive considering that lasting results are obtainable in only quite a small proportion of cases, still insist that they are the best available prophylactic measure we possess. Because the isolation of a number of consumptives, who otherwise might prove a source of infection to their fellow men, prevents them from spreading the disease, the sanatoria are worth all the labor and money invested in them. Moreover, some have shown that since the establishment of sanatoria in some countries the death rate from tuberculosis has decreased, which is not the case in countries where these institutions are scarce or altogether lacking.

Statisticians have shown that it is often dangerous to draw parallel illustration when studying vital phenomena. By the use of concomitants many absurd propositions may easily be proved. It can, for instance, be satisfactorily demonstrated and substantiated by facts and figures that crime increases in every community in which the religious and moral forces increase; that during the past fifty years the number of negroes has increased in Boston and as

a result the birth rate of the native white population of that city has decreased; that during the last twenty years, since horse cars have been disappearing from the streets of the cities there was a notable increase in the number of cases operated upon for appendicitis; and many other absurdities. Persons not adept in the art of avoiding irrelevant evidence are apt to take for granted conclusions based on reasoning from concomitants whose reciprocal influence is nil. Similarly it has often been shown that the mortality from tuberculosis has been decreasing within recent years, and concomitantly the number of sanatoria has increased. The relation of cause and effect was apparently evident, especially since isolation has been such a great factor in the prevention of other contagious diseases. In a recent paper by one of the best English demographers analogies are drawn between tuberculosis and other contagious diseases showing that leprosy, the plague, typhus, typhoid, and yellow fever, etc., have been banished from civilized countries only by rigid isolation of all those afflicted with the disease.[17] The inference is evident: The only sure method to pursue in our attempts to rid humanity of tuberculosis is to build more sanatoria for incipient cases and hospitals for advanced cases, and to forcibly segregate all those unfortunates in whom traces of the disease is discovered.

Here is not the place to test the statement that all the contagious and infectious diseases have been banished by isolation. We all know to-day that leprosy is not as contagious as was once thought. In many hospitals in the United States lepers are permitted to mingle with other patients, still there is hardly a record of a case of disease acquired in this country. The plague disappeared from Medieval Europe not because those affected were rigidly isolated; in fact, there was hardly anything of the kind attempted on a large scale in those days. Prayers could be proven to have been more effective than isolation because they were more often used in the attempts to banish the plague. It is true that to-day the plague is kept out of Europe and America by isolation of any stray cases that happen to be imported, but it must be emphasized that it is an acute disease and only rarely is a case introduced into a civilized country. In the case of acute contagious diseases which are common among us, such as measles, scarlet fever, diphtheria, etc., isolation alone proves ineffective in our attempts to completely eradicate the disease. We see this with diseases which only attack men—measles and scarlet fever are not known in the lower animals. But tuberculosis is widespread in the animal kingdom, and isolation of those human beings that are affected by the tubercle bacillus will yet leave this parasite in the lower animals, from which infection may spread.

As a matter of fact, the tuberculosis mortality began to decline in Germany years before introduction of sanatoria, and in France, where sanatoria are scarce even to-day, yet earlier. In that country the decline in the tuberculosis mortality manifested itself as far back as the sixth decade of the nineteenth century and, with the exception of war periods, the decrease has been quite regular and steady. That the decrease in England cannot be attributed solely to the few hospitals for consumptives opened many years ago will be agreed by every one who knows that a few isolated cases of a contagious disease are insignificant when tens of thousands of cases are permitted to mingle with the people generally. In a recent report by the medical department of the British Local Government Board on "Sanatoria for Consumptives and Certain Other Aspects of the Tuberculosis Question," by Dr. Timbrell Bulstrode, it is shown that sanatoria in England and Wales have not produced any perceptible affect upon the rate of decline of the tuberculosis mortality. The same is true of any other country. The recent diminution in the tuberculosis mortality may not be due to the diminution in the rates of morbidity. Indeed, it has not been proven that the rates of morbidity have decreased in recent years. A higher rate of recovery of those affected with the disease may be the cause of the lower mortality. Which of these two factors was predominant in this regard is impossible to say as long as we do not know the rates of morbidity, past and present. One thing is certain: Tuberculosis finds its victims mostly among those who live in close, overcrowded homes, work in factories and mills in which the air is laden with organic and inorganic dust and cannot maintain their general nutrition in proper shape owing to poverty. Within the last fifty years the economic condition of the western workmen has been greatly ameliorated; their homes have been improved, wages increased, hours of work diminished, and they can afford to live on better kind of nourishment than the workmen of the first half of the nineteenth century. In addition to this must also be mentioned the sanitary reforms in the modern cities which have been inaugurated within the last fifty years; State factory inspection which is quite rigid in Western Europe, and the abolition of child labor, etc. It cannot be denied that these were great factors in reducing the spread of tuberculosis, minimizing the chances of infection and increasing the power of resistance of the average individual. Those attacked by the tubercle bacillus stand more chances of recovery than formerly when hygienic and sanitary surroundings were primitive.

That the sanatoria are not very efficient in reducing the spread of tuberculosis is also evident from the following facts: Considering how widespread this disease is, the small number isolated in institutions is rather small to be effective in the checking its spread. We may just imagine that among a thousand cases of plague twenty-five are isolated and the rest permitted to mingle with the general population. Moreover, sanatoria do not isolate the most dangerous cases, the far advanced, with cavities in the lungs expectorating profusely secretions containing millions of virulent bacilli. These are just the class which are invariably refused admission to sanatoria, and are permitted to remain in their homes, boarding, and lodging houses, hotels, railway sleepers, public buildings, etc., and to thus spread the disease broadcast, even if they are careful about the fate of their fellow man, which is not always the case. The incipient, mostly of so-called closed cases, which are the least dangerous are the class isolated in sanatoria.

It has been pointed as one social service rendered by sanatoria which is undoubtedly important. I refer here to hygienic drill which the patients in these institutions are subjected. It is said that no amount of police prohibition of indiscriminate expectoration, even when enforced rigorously; no popular lectures and tracts on the prevention of tuberculosis can be expected to achieve such salutary results as the regular hygienic drill to which patients in sanatoria are subjected for months, will achieve. But we all know how evenescent these acquired habits are often. Just fancy the differ-

ences between the sanatorium and the home of the average artizan and laborer; the differences in the accommodations and opportunities of personal cleanliness are of such magnitude as to obliterate any desire to lead a hygienic life. Many an intelligent, though poor, consumptive told me that he finds it impossible to continue at home all the sanitary habits he practised in the sanatorium. And I agreed with him, knowing that he has no bath, no douche, no room for himself, no window in his sleeping room; in fact he is compelled to share his room with one or more persons of different ages; that he must work in a dusty factory or mill, etc. The extreme difference in the environment of the sanatorium with its extravagant buildings, equipment and service, as compared with the accommodations which the average artizan or laborer finds in his home in the tenement house only emphasize the futility of attempting to maintain that standard of hygiene in which he was drilled in the sanatorium. Under the circumstances the patient discharged from a sanatorium and instructed to follow certain rules of healthy life, whether willing or unwilling, is compelled to abandon sooner or later these personal habits which lead to the maintenance of health and prevention of the spread of disease. Physicians practising among the poorer portions of the population, from which the majority of the consumptives are recruited, see these cases often.

When we consider the investment made by the community in such cases, we realize that there was an extravagant waste of labor and money. A patient remaining about four months in a sanatorium at an average cost of one dollar per day and discharged with the disease arrested or even apparently cured is in danger of relapse as soon as he returns to his home. The just mentioned sum by no means gives the exact sum invested in the arrest or apparent cure of the case. To this must be added the value of the initial investment, averaging about $1,000 per bed, as well as the money invested on maintenance of patients who have, for one reason or another, left within three months after admission, and those who have been kept for many months and yet discharged as with the disease unimproved, or dead.

Would not the same amount invested in the building of better dwellings for those of limited means bring better results? It has been demonstrated that sanitary tenements, built with a view of maintaining health and preventing the spread of disease, can be erected with an investment not higher than that invested in a sanatorium, and the cost of maintainance can be derived from the rents. In fact fair returns may be had on the capital invested. Tuberculous people living in good homes can be treated in dispensaries and the ultimate results could be about the same as those obtained in sanatoria, as is evident from the reports of Hammer, Croissant, and others detailed above. The advantages of this sort of treatment can be realized when it is considered that all the hygienic and sanitary instruction given by the physician to his patient can be followed when the patient lives in a room for himself and must not share his bed with another person; when he has a bath tub which he can use at any time; when he has sufficient light, fresh air in his home equal to that available in sanatoria. Moreover, those who are in a condition to work, and who do work in the better sort of sanatoria, could work and support themselves and their families.

Summary and Conclusion.—It is a deplorable fact that the average consumptive and often his medical adviser look upon the sanatorium as the only place where he may be cured of his disease. Those patients who for some reason cannot gain admission to sanatoria consider themselves doomed, lose courage, and often fail to make any attempt to submit to treatment at home. The available sanatoria are overcrowded and patients have to wait for months before accommodations can be found for them in existing institution. Considering the large number of living consumptives and the enoromous sum of money necessary to invest for the equipment and maintenance of sanatoria, it is hardly to be hoped that in the near future the number of beds will be increased to such an extent as to accommodate all those who are in need of institutional treatment.

It is well known that many more consumptives are being cured at home than in sanatoria. Autopsy findings show that about 70 per cent. of humanity have had tuberculosis sometime during their lives. It is also established that the majority of these have been cured of the disease. Even conceding that the well-to-do, who only rarely come to autopsy, would not show such a large proportion of tuberculous, it argues in favor of the curability of consumption among the poor in their homes, in their usual *milieu*.

The sanatoria admit only incipient cases, which display no constitutional symptoms, such as fever, rapid loss of weight, etc. These are just the cases that are under proper care getting along well at home, at a much lower cost to the patient and the community. Acute cases, as well as active cases with fever, emaciation anorexia, albuminuria, etc., are not doing well in either place. The low mortality rates in sanatoria is in a measure due to the fact that all unfavorable cases are persuaded to leave for home.

The ultimate results of sanatorium treatment are not as good as some authors would lead us to believe. The German sanatoria show results that about forty per cent. of all the cases are able to work and earn at least one-third of the standard wage at the expiration of five years after discharge. Considering that the average duration of life of the consumptive is about seven years and that the sanatoria admit only incipient cases, it is a question whether forty per cent. of a given number of incipient cases treated at home would not show similar results. According to Hammer and Croissant the results obtained in the treatment of consumptives in dispensaries are about the same, and from the standpoint of the duration of the favorable results, even better. The excellent results obtained by Trudeau and reported by Brown are not conclusive. They by no means prove that the mortality of the sanatorium patients is lower than that of the patients who are cared for at home. It is not fair to compare the death rates of consumptives with those of the general population when testing one method of treatment with another. The only conclusive method of comparing results of treatment is to elicit the mortality of sanatorium patients as compared with results obtained in home treatment, but such a study has not yet been made on a large scale.

Economically sanatoria are expensive. The initial outlay for building and equipment, which amounts to about $1,000 per bed, and maintenance which amounts to about one dollar per day per pa-

tient, precludes at present the hope of building and maintaining a sufficient number of sanatoria to provide for all consumptives in any country. The fact that there are indications that the results obtained in dispensaries are not below those obtained in institutions, and at a much lower rate of expense, urges that we must turn our attention to the home treatment of tuberculosis.

The prophylactic results of sanatoria are of negligible value, considering that they admit the incipients and refuse the most dangerous, the advanced cases.

THE TREATMENT OF SYPHILIS AND PARASYPHILIS OF THE NERVOUS SYSTEM.

By D'ORSAY HECHT, M.D.,

CHICAGO, ILL.

ASSISTANT PROFESSOR OF NERVOUS AND MENTAL DISEASES, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL; CONSULTING NEUROLOGIST TO THE COOK COUNTY INSTITUTIONS FOR THE INSANE AT DUNNING, ILL.; ATTENDING NEUROLOGIST TO THE MICHAEL REESE HOSPITAL AND ST. ELIZABETH'S HOSPITAL.

The relation of syphilis to the occurrence of nervous disease has ever given rise to extensive and intensive study. To ponder all its vast and various aspects would mean to commit one's self to a task truly herculean, and fitting neither the title nor the purpose of these remarks. One may be pardoned, however, focusing the attention, by way of introduction, upon a few bare yet basic facts, which, when categorically discussed, may assist to an intelligent conception of the therapy in syphilitic and parasyphilitic affections of the nervous system. The first of these to require reemphasis is that syphilis of the nervous system is never, or hardly ever, syphilis of nerve tissue. The specific lesion of the nervous system, be it understood, is presumably microbic in origin, essentially neoplastic in type, attacking primarily the vascular and interstitial structures, and only secondarily encroaching upon the nerve cell and fiber, disturbing its function and eventually destroying it, through local tissue death. By the term "neoplastic" it is not intended to convey the idea, erroneously held by many, that all or nearly all the specific lesions are veritable tumor masses, gummata, syphilomata, of more than appreciable size. On the contrary, the term includes, or, better said, implies, simple inflammations, cellular infiltrates, exudates, and the smallest of nodular or gummy excrescences. An allusion to cerebral syphilis, for instance, should not conjure up the sole image of a large, solitary tumor, except when other factors in the variant pathology of lues have been dismissed as untenable or improbable. The artery that supplies nerve tissue proper, the neuroglia that supports it, the membrane that shields it, play rôles not to be despised in the causation of nerve cell necrosis. Stating it somewhat differently:—The morbid processes underlying the polymorphous symptomatology of syphilis of the nervous system in order of their importance and frequency are: (1) Syphilitic arteritis; (2) syphilitic meningitis (inclusive of cranial nerves); (3) gummata. Syphilis of the nerves may be said to occur, but it is rare—very rare, indeed. Just what determines that the nervous system should become involved, and which part of it, we have no way of knowing, but in view of its protozoan etiology the explanation is at hand that (1) the spirochete elaborates a virus of variable toxicity, this virus having a special affinity for nerve structures, or (2) the nerve tissues of certain individuals have a lessened resistance for certain neurotoxins in the virus.

Of all the organic systems, the nervous system pays the heaviest tribute to the "tertiary" period of syphilis, and this assertion brings me to the point of referring briefly to the misconception by not a few of the word "tertiary." Be it observed that the word "tertiary" bears no relation to the time interval between the acquisition of chancre and the later manifestations of the disease; it merely emphasizes the kind of lesion. Those lesions of syphilis which are local, and as such destructive of tissue, are properly called tertiary. It matters not at all whether syphilis of the brain or cord follows the chancre as early as eight weeks, or as late as twenty years—it yet remains a "tertiary" phase of the disease. It is quite true that clinical experience has taught neurologists to believe that a majority of the cases of nervous syphilis are destined to occur within three to five years from the date of primary infection, with the incidence steadily decreasing after that, but such a chronological criterion need not render a diagnosis doubtful when made at even a much later period.

These relations clear, it may be said in summary that, when disease of the nervous system has its origin in syphilis, is in its pathology of the nature of syphilis, amenable and responsive to the therapy of syphilis, then we are justified in postulating syphilis of the nervous system.

And what constitutes parasyphilis? When nerve elements proper—that is, cells and fibers—undergo degeneration *ab initio*, a considerable period of time after syphilitic infection has occurred, as is indeed the case, we are disposed to regard that process as parasyphilitic.

The parasyphilitic diseases, so designated by Fournier, chief of which are tabes, general paresis, and a combination of the two, tabo-paresis, are in all probability induced in some manner by syphilis, but reveal a pathology unlike that of nerve syphilis, and are not prone to succumb to specific therapy in the sense that does syphilis. I do not, however, share in the belief that the pathology is totally dissimilar to that of syphilis, or that specific treatment is wholly contraindicated, for I am familiar with the occurrence of tertiary lesions in frank tabes and paresis, and have in certain cases, particularly of the former, noted the good effect of specific treatment—but of this I shall say more presently.

In the light of recent investigations and contributions to the syphilis problem, there is good cause to predict that the etiological and therapeutic position of the disease will be greatly strengthened by the discovery of the *Spirochæta pallida* by Schaudinn and Hoffmann, and the serodiagnostic reaction of Wassermann. The well-nigh constant demonstration of the former in the lesions of syphilis and the invariable positive reaction of the latter in individuals acknowledging to earlier infection would seem to have placed these newer criteria well beyond the sphere of speculation and doubt. That the *Spirochæta pallida* appears not only in the virus of the primary sore papule and gumma, but has been demonstrated by Hoffmann on the inner wall of a cerebral vessel showing syphilitic arteritis is a point worthy of note, not without its direct bearing upon treatment.

Because of its field of application in syphlis of the nervous system, merely a word in passing about the Wassermann test, which aims to ascertain the solubility or insolubility of suspect blood when admixed in a test tube with an already prepared serum formula. If the suspect blood is soluble, it means that syphilis of reaction is absent; if the blood remain insoluble, it means that syphilis of reaction is present; in other words, solubility means a negative and insolubility a positive test.

In some of the cases of nerve syphilis and parasyphilis recently under my care, and in others observed by my colleagues, this test was made, and with the laboratory kept in ignorance of the clinical diagnosis and patients' confession of syphilis, it in every instance returned a verdict of "positive." From the literature recording to date a vast number of cases in which the test has been used to confirm antecedent syphilis, one gains the impression that we may be called upon to revise again our present notions of syphilis toxins and parasyphilis. The fact that the Wassermann test has been positive in 70 per cent. of tabes cases and 90 per cent. of general paresis lends force to the argument presented some time ago by Lesser, Bose, and others, that the late manifestations of degeneration of the nervous system caused by the virus of syphilis may rightfully be construed as a fourth stage of syphilis. Many of the results with antisyphilitic remedies would seem to negative this contention, but, on the other hand, some of the experiences with mercury and iodides in checking the progress of these diseases would tend to support the view.

The test is surely full of promise where it is desirable, and even imperative, to make the early diagnosis in a doubtful case and institute prompt treatment.

Nowhere are we more in need of this direction than in cases of latent or denied syphilis presenting symptoms suggestive of brain tumor or brain syphilis. The therapeutic test for so long applied with watchful expectancy to make the diagnosis in these cases will then fall into disuse.

Treatment.—In the matter of treating nerve syphilis and parasyphilis we encounter a diversity of opinion that is but the natural sequence of a lack of fuller information all along the line of etiology and pathology. It may be well first to allude to some well established facts concerning several methods of treatment, obtrude some personal experiences, and conclude with a résumé that is in consonance with the best and latest knowledge we have acquired.

If, for the purpose of completeness, I refer to a positive prophylaxis against syphilis of the nervous system, I must of necessity mean the accomplishment of an ideal prophylaxis against the primary sore, with the aid in one form or another of an antisyphilitic vaccine. Whereas this seems far from realization, yet the experiments of Metchnikoff and Roux are indicative of a scientific preoccupation in this direction. Mention of their work seems in place here also, because of the calomel ointment (calomel, one part, to lanolin, three parts), which they advocate as a lubricant prophylactic to be applied to the genitalia immediately or within an hour after suspicious intercourse. The authors remark that in their experiments this remedy has afforded immunity against primary infection, and accordingly it has been issued to the army by the Secretary of War in France as a prophylactic measure against venereal disease.

The initial lesion once acquired, nothing short of a prompt, efficient, and sufficiently long continued course of mercury and iodides is indicated; when well accomplished, such a course of specific treatment will in the majority of cases be of avail in preventing the dire tertiary consequences to the nervous system. This, I think, none may doubt, since it has been estimated from very large and convincing statistics that when *properly* treated perhaps 90 per cent. of the cases get well and remain so. A retrospect of the cases which the neurologist is privileged to see forces the conclusion, however, that the cases have been treated either imperfectly, improperly, or not at all.

What constitutes, from the neurological viewpoint, the best treatment in these cases?

Extremely urgent instances aside, I think it is the consensus of opinion among neurologists that the inunction method, the *Schmierkur* of the Germans, has on the whole given the best satisfaction in nerve syphilis. It may be inferior to the oral, hypodermic, or intravenous method in point of rapidity and cleanliness, but it fulfills most of the demands made upon it in most of the cases, is simple of application, less prone to produce salivation, and obviates gastrointestinal distress. I believe that to have the unguentum hydrargyri dispensed in an exact dosage in wax papers, with written instructions to the patient for its use, contributes greatly toward the efficiency of the method. It has been my custom to prescribe unguentum hydrargyri, ℥ss to ℥i, to be rubbed nightly by the patients themselves when they are able; and the specifications call for one thorough rubbing on a different non-hairy,

flexor surface each night for five nights, this to be followed by a warm, cleansing bath on the sixth, a rest on the seventh, and then a fresh series of five rubbings on successive nights, with interruptions of bath and rest as before. The number of such series required is variable, four having sufficed in some of my cases, and eight in others. In private practice I have found most of the patients very ill at ease over the denial of daily baths, and after making concessions have come to believe that a short cleansing bath in the morning is no serious infraction upon the technique. In two of the considerable number of cases in my records I met with nonabsorbing skins, which no amount of rubbing could affect, and, after a brief trial, resort was had to deep injections. What I have said of the official unguentum hydrargyri applies to the vasogen preparations containing from 25 to 33 per cent. of mercury. Occasionally one meets with circumstances where it is desirable to suppress the real facts surrounding a case of lues, as in the congenital types of the disease, and here antispecifics in agreeable disguise may be given in the form of colloid calomel, used as calemelol salve or unguentum Heyden, which contains an additional 2 per cent. of free mercury (Abt).

When resorption from skin surfaces has proven slow, I suggest that the site of inunction be previously prepared by cleansing with soap and warm water, then alcohol or ether, and complete this toilet by the application of a tight flannel bandage over the part rubbed.

With these qualifications the endermic administration of mercury has given me most gratifying results. The symptoms of brain syphilis will appear less ominous, I think, if we appreciate that mercury in large enough doses constitutes the remedy *par excellence*. It is mercury that annihilates the *Spirochæta pallida*, and if, as has been demonstrated, this protozoan may reside in the cerebral vessel-walls of the syphilitic, then it is the mercurials that are cardinally indicated and iodides become but the essential adjuncts in the therapeutic scheme. So much depends upon the pathology in each case that generalizations as to the degree of recovery are quite difficult to formulate. The area of softening in the brain resulting from the complete occlusion of a cerebral terminal artery is not likely to be irrigated back to life, nor will the brain cells compressed in a patch of scar tissue, reminiscent of a destructive gumma, derive sustenance and potentiality from all the mercury and iodides that can be safely borne.

Small wonder then that our disappointments are not few. The lesson to be learned from this class of cases is that treatment should not only be adequate, but timely. There are types of brain syphilis which carry a patient to dissolution in spite of the most ideal therapeutic premises, but happily they are rare. In cerebral lesions the results of treatment are sometimes marvellous, but more or less complete failures are quite more numerous than cures. In spinal syphilis the proportion of failures is far greater than the successes.

When it seems necessary to get quick and complete control of a syphilitic lesion, initiated, for instance, by a single convulsive (epileptiform) seizure, the inunction treatment may well be waived in behalf of the more rapid administration of mercury by the deep intramuscular injection. I have no hesitancy in stating a preference for this method at *critical* periods in the disease. When it is intended to establish reservoirs of mercury in the deep muscular tissues from which slow resorption takes place, the insoluble preparations, such as calomel and the salicylate of mercury suspended in sterile oil or lanolin are used. It is maintained by Gottheil, who is the most ardent advocate of insoluble mercurials in this country, that they are free from danger, painless, and of greater convenience to the patient because of longer periods intervening between injections. The controversy that has been waged in dermatological circles concerning the advantages or disadvantages of the soluble *versus* the insoluble mercurials need not receive extended mention here, but I have found that the injection of insoluble mercurials in several cases caused quite as much pain as is experienced with the soluble corrosive sublimate. The dangers arising from the depots of mercury located in the deep tissues seem to me very real ones, and for this reason I have been content to use exclusively hypodermics of corrosive sublimate in doses varying from 1/12 to 1/4 grain injected every second or third day. Soreness in the gluteal muscle masses is quite sure to follow, but at its worst it is transitory. The danger of thrombosis or embolism by penetrating a vessel is not great in these regions, but the remote possibility of so serious an accident should lead to great precaution in the technique, which it is needless to add includes rigid asepsis.

The vast majority of syphilitic cases in this country are subjected to the oral administration of mercurials, perhaps because it is convenient and favors concealment of the patient's disease. This method, with its tendency to produce gastrointestinal disturbance, stomatitis, and diarrhea, is not free from serious objections, and in neurological practice is the least dependable and therefore the least favored of all the accepted methods. If, for a particular reason, it seems indicated, the protiodide, gr. 1/8 to 1/3, or the hydrargyrum tannicum oxydulatum (Lustgarten), grs. 2 to 4 in pill form, may be given after meals.

Of recent years intravenous injections of mercury have been suggested, and one can understand how, in these severer, rampant, and fulminating types of the disease, they would act with great promptness and certainty, but the risk of thrombophlebitis and embolism, in my opinion, outweighs all considerations in their favor. I concede their place in therapy, but have not as yet availed myself of their use.

In the ambition to check and control nerve syphilis, mercury in any of its forms will surely do harm if given injudiciously, meaning in doses either too large or too long continued. The dangers of chronic mercurialism require no emphasis here, but I have so frequently seen flagrant neglect of the teeth, gums, and mouth, that it seems pertinent to reiterate the necessity of mouth washes, tooth powders, and gargles three times daily after eating, to preserve oral cleanliness and prevent stomatitis.

In treating syphilis of the nervous system, it has been customary to administer the iodides conjointly with mercury, but the neurologist with experience will, I think, ascribe his good results to the use of mercury and not iodides. This, however, is not equivalent to saying that the iodides do no good, for in truth they are of inestimable value, and the best evidence of this fact is the disposition on the part of American neurologists to give massive doses, from two hundred to four hundred grains daily. On the Continent small doses of from thirty to

sixty grains daily are advocated, but it has always seemed ridiculous to me to be prejudiced by the size of a dose alone. It has been my principle to give enough, plenty, and then some more if that did not suffice. There has been a good deal of fastidiousness in the matter of iodide administration, in which, at one time or another, we all have been guilty of participation. I have noted the best results with the saturated solution of potassium iodine in ascending doses from fifteen to as high as one hundred drops, three times daily, given after meals, well diluted in water, Vichy or Seltzer, or milk. Sodium iodide has found favor in nerve syphilis, and is said to contain more iodide, be less irritating to the stomach, and less prone to produce iodism. Iodism, except in idiosyncratic individuals, is best prevented by large dilutions of the drug in milk or aërated water; and especially where three to four hundred grains constitute the daily dose, it is well to dissolve the entire amount in a quart or more, to be taken in divided doses during the twenty-four hours, thus avoiding gastric distress and other ill-effects. Iodonucleoid, a preparation containing 23 per cent. iodine, is a pharmaceutical refinement of iodide possessed of great merit, and may at any time be given in a dosage of from five, twenty, and even sixty grains, three times daily, for a long period of time without giving rise, except in very rare instances, to gastric distress or other familiar signs of iodism. I have given it repeatedly in doses of sixty to one hundred grains, three and four times daily, without apparent ill-effect, whereas ten drop doses of the saturated solution for the same patient were not at all well tolerated. Iodalbin in similar doses is very readily assimilated, and tends to act with good effect. It is advisable to reduce an excessively large dosage after a month, and then continue for eight to ten weeks with fifteen grains two or three times daily, as the condition may demand. Warm baths, copious water-drinking, and free catharsis will keep the elimination at the point necessary to prevent iodism. When the first energetic treatment has done all that could be expected of it, patients should be encouraged to take a course of iodide and mercury every six months for five years, and some specific treatment is indicated for a short period every year for the rest of their lives. It is a mistake to think that the exhibition of antispecifics in syphilis puts an end to the medical obligations toward a case, for we not infrequently encounter states of malnutrition, even cachexia, and profound anemias which require the most careful and judicious employment of rest, diet, hydrotherapy, fresh air, and alterative tonic treatment. In the past few years the French have treated cases of both primary syphilis and syphilis of the nervous system with atoxyl, an arsenical preparation used subcutaneously in doses of about one-half to two grains, two and three times daily. There is a great diversity of opinion as to the utility of this alterative remedy. I have resorted to its use in cases of anemia, neurasthenia, and in a few instances of nerve syphilis, but am not at all convinced of its superiority to other arsenical preparations, such as sodium cacodylate or the liquor arsenicalis.

Germane to any discussion of parasyphilis, and in keeping with the limits of this paper, I think it well to outline only a few of the essentials in the treatment of the two affections, tabes dorsalis and general paresis. In a prefatory way I might say that the very slow progress and tendency to spontaneous remission in tabes dorsalis makes it impractical and well-nigh impossible to suggest a therapy for certain "stages," such as the preataxic, ataxic, paralytic, and so forth, which are merely convenient and now obsolete descriptive terms. It should be appreciated that from the very first this disease is incurable, progressive, often remaining stationary for a long time in the benign and milder forms, and yet capable of marked improvement following the exhibition of diverse reasonable therapeutic measures employed singly or in such combination as to meet the requirements of each case. There should be no hesitancy, however, in acknowledging that, on the whole, only a minority of the cases are influenced in their course or arrested in their development.

Recognizing tabes as a late sequel of syphilis, it is only natural and logical to ask, Will the prompt and energetic treatment of the antecedent syphilis diminish the liability to tabes? Only the most extensive and exhaustive inquiry can establish the precedent for opinion on this point. Two quotations are worthy of mention. Neisser (*Deutsche med. Woch.*, 1902) has tabulated 445 cases of tabes; 254 (57 per cent.) had received no primary antiluetic treatment; 18 (¼ per cent.) were adequately treated, and 173 (39 per cent.) inadequately. Schuster (*Deutsche med. Woch.*, Dec., 1907), in a critical analysis of his own cases and those of others, arrives at quite opposite conclusions, maintaining that (1) the clinical average of tabes and paresis is identical, whether antecedent syphilis has been treated with mercury or not; (2) the metasyphilitic nerve sequelæ do not appear later in the patients treated with mercury than in those untreated; (3) the beneficial influence of antispecific therapy for the prevention of parasyphilitic nerve lesions is thus far not convincingly proven.

In our present state of knowledge extreme pro and con views will continue to enliven the pages of our literature on this subject, but from such sources as Erb, Fournier, Neisser, and Lerdde, I borrow the confirmation to my own observations of more than one hundred tabetics, and venture the opinion, firstly, that adequate antisyphilitic therapy does greatly diminish the liability to greater tabes; and, secondly, that all forms of syphilis, especially the milder ones, those treated either indifferently or not at all, should and must be held in higher therapeutic regard.

The diagnosis of tabes once established, neurologists are again confronted with the question as to the propriety of antispecific treatment, and again are reminded of an ardent controversy that has been carried on for many years and is still *sub judice*.

Many neurologists of experience accept as valuable the administration of mercury and iodides in tabes; by some they are liberally discounted, and by others again absolutely discredited. I recall cases, and they were nearly always the ones in which the interval between lues and tabes was short (at or under five years), that showed marked improvement shortly after and even during the exhibition of mercurials. Ataxia was greatly benefited, incontinence checked, pains controlled, vision improved, optic atrophy retarded, and the charted fields of vision restored to near normal. A second group of cases has been wholly unresponsive, and a third I have thought were made distinctly worse by specifics. For this therapeutic variability there is, so far as I know, no adequate explanation, but it prompts a belief not inconsistent with pathological facts, that the early cases presented tissue changes

of nerve syphilis together with those of tabes, and these were favorably influenced by therapy. The cases in which treatment was badly borne and wholly without benefit were those well advanced, of long standing, associated with emaciation, cachexia, or grave anemia. From out the increasing mass of contentions, I derive some comfort from the following attitude: In tabes (1) antispecifics should be resorted to in the early cases and early in these cases, for then they are capable of doing good; (2) antispecifics are inert in many cases and positively harmful in others; (3) the plan of specific treatment is much the same as that heretofore mentioned, and contemplates the use of both mercury and iodides.

Mindful of the undue length of this paper, I shall, with your permission, not touch upon the care of the bladder, the control of lancinating pains, the crises, and so forth, but pass on to a moment's reflection of ataxia. This most important and distressing symptom of tabes has for years received careful consideration and study, chiefly from Fraenkel, of Heiden, who finally was able to formulate a plan of treatment for the incoördination now known as Fraenkel's reeducation method, which postulates the "necessity of learning by systematic practice coördinated and proper movements in place of ataxic ones." A perfect system of graduated exercises, first simple and later more complicated, is performed every day for five minutes, with a rest period of five minutes following. Patients are directed to intelligently and perseveringly practice certain movements and steps in many directions until they can do them correctly and with satisfaction and comfort to themselves. For the bed-ridden patients exercises of flexion, extension, abduction and adduction should be performed in the prone position, with deliberation and exactness. Such practice results in a most gratifying improvement of gait and station in patients who for several years may have been utterly helpless. I have had occasion to observe the most astonishing feats of locomotion even after a few months of these exercises, but the conviction has grown upon me that strict adherence by the patient to the highly complicated plan of Fraenkel is not essential, for I have seen most marked improvement follow my simpler suggestion that exercises be done in a hop-scotch, chalked out on the bedroom floor. A pattern parquet floor will suffice, and the seams in the carpet or cracks in the sidewalk will answer the purpose, provided the maneuvers are planned to meet the requirements of each case, and the proper patience is observed in their execution. The inference to be drawn, then, is that the principle of the Fraenkel treatment is an excellent one, but unvarying obedience to a single formulated plan or system of exercises is not necessary for the attainment of good coördination.

A factor contributing not a little to ataxia of the lower extremities is hypotonia, which, when present in the musculature of the foot, tends to destroy its long arch and give rise to pronation. A correction of the faulty mechanism of the foot by a shoe modified to meet the individual requirements has in three of my cases, together with the Fraenkel exercises, offered the most favorable treatment for marked incoördination. Before leaving this topic, I desire to emphasize that in cases presenting ataxia of very acute onset and rapid progress, attended with great weakness and debility—the so-called acute tabes—it would be most reprehensible to suggest anything but absolutely bed-rest and quiet.

It is sometimes very difficult to decide whether or not a patient should know his true condition, and be apprised of it in terms of locomotor ataxia or tabes. In being too blunt in letting a patient know the truth of his plight, the physician sometimes commits a grievous error. Much will depend upon the temperament of the patient, but in any event he may be told that he has some chronic spinal disorder, capable of control and relief by judicious and careful treatment. Unpleasant psychic shocks are more than most tabetics can gracefully bear. It is indicated in this, as in all severe chronic conditions, to practice a mental therapy by virtue of which the patient may remain hopeful, encouraged, and stimulated to activity and obedience in the matter of taking proper care of self. This is no idle play of words, but an attempt to admonish the therapeutist in a matter of which he is either wilfully neglectful or wofully ill-advised. I know of tabes cases in which a swift and sudden decline could be attributed to no other cause half so readily as to psychotherapeutic indifference and disregard, and I know of others again whose every advance and gain was merely the reflection of a well-thought-out plan of mental support and suggestion. A patient should be made to change his occupation, if that were necessary or desirable, and should not want for the constant direction and supervision of his working and resting hours. The psychic side of the tabetic must never be lost sight of.

The certainty with which the prediction of dissolution can be made in general paresis would seem to make any references to the effect or non-effect of treatment quite superfluous, but the causal relation to syphilis again brings to mind a few points of the controversial order worthy of passing comment. More difficult even than in tabes is it to say that this or that case of paresis has improved under treatment for syphilis. But the same reason that prompts my use of mercury and iodides in the early stages of tabes in the hope of influencing pathological changes of active syphilis inclines me to their administration in the incipient stage of paresis. I think that all alienists can record a few instances of long remissions in paresis which at first thought are ascribed to specifics, but in not a few marked improvement is the result of all measures except those of specifics. The tendency to discountenance the importance of syphilis in subsequently developing paresis is best seen in the efforts of the Scottish school (and in this country by the researches of O'Brien) to identify a diphtheroid bacillus and mixed toxic infection as the cause, and then raise the question of serum treatment. The investigations thus far presented are interesting, but, in my opinion, far from convincing.

I think I need not dwell upon the necessity for isolation, institutional régime with its approved methods of nursing, hydrotherapy, exercise, and feeding. Those who have seen the mental, moral, and physical degeneration of the paretic progress steadily to the point of total oblivion will unhesitatingly acknowledge the rôle of the sanitarium and asylum in the life of these unfortunates.

In having brought this topic of perennial interest to your notice, I have sought to do little more than assemble in the light of latter-day research, the larger facts and broader opinions, and thus make them the targets for discussion. To epitomize: (1) Syphilis and parasyphilis of the nervous system continue to stand in direct and indirect causal relation to primary syphilis, although their nasological position is very likely to undergo revision of the

Schaudinn discovery and serodiagnostic values of to-day stand the test of time and further development; (2) the therapeutic position, it is hoped, will also share in this signal advance, but in the expectant interval it is well to insist that neither a routine nor a haphazard administration of antispecifics is commendable; (3) treatment to be intelligent must meet the requirements of each case with due regard for the many collateral, chiefly supportive measures; (4) antispecifics, when indicated in these conditions, mean mercury and iodides; (5) in the vast majority of the cases occurring in neurological practice, mercury by inunction is the method of choice; (6) the Fraenkel exercise treatment for the ataxia of tabes loses none of its efficiency if a departure is taken from the original complex plan to a simpler one.

CONCEALED APPENDIX.

By AUGUSTIN H. GOELET, M.D.,

NEW YORK.

It has occurred in two cases where I have opened the abdomen for interval appendectomy to find the appendix apparently absent, the head of the colon being as smooth as the palm of the hand and no visible evidence of there ever having been an appendix. Such a condition is very puzzling to the surgeon when encountered in a patient that has never been submitted to operation before, and had it not been for the experience of the first case I should never have found the appendix in the second.

By "concealed appendix" I do not mean those cases where the appendix is bound down by adhesions as ordinarily encountered, but in the two cases referred to there was positively no evidence of adhesions or visible thickening of the wall of the gut. The only way the appendix was eventually detected was by palpation of the wall of the gut between the thumb and finger, which revealed a slightly increased thickness at one point. The appendix was then dissected out of the wall of the gut in which it was imbedded. It was apparently causing no trouble, but when examined after removal it was found to be in a state of chronic inflammation.

I can best illustrate this somewhat unusual condition by briefly relating the two cases referred to:

Case I. Mr. B., æt. 25 years, had his first attack of appendicitis some three or four years before the operation. He was laid up in bed for a week and had recovered sufficiently for his physician to permit him to return to business. At the end of his first day at business he had a chill followed by considerable rise of temperature and renewed tenderness over the appendix. I was asked to see him. I arranged to have him moved to a suitable place for operation, but the following day the temperature and other symptoms subsided and the operation was postponed. I did not see him again for three or four years after when, becoming nervous over the death of a friend who died from a neglected appendicitis, he again consulted me. He stated at this time that he repeatedly had reminders of his previous trouble by pain in the region of the appendix caused particularly by exertion, as upon going up several flights of stairs, or running. The pain thus induced would continue sometimes for a considerable time after.

Operation was advised and readily consented to. The head of the colon was perfectly smooth and there was no appendix visible, nor were there any adhesions in the vicinity. But by picking up the wall of the caput coli and rolling it between the fingers it was found to be thicker at one point, though the surface was perfectly smooth there as elsewhere. Careful dissection succeeded in isolating the appendix from the wall of the gut and it was removed. The raw surface thus exposed was covered over by approximating the peritoneal margins of the gut and turning it in.

The appendix was shrunken in size and the lumen of the distal end was obliterated, while the proximal end showed inflammatory changes. The patient made a good recovery and has had no further trouble.

Case II. Miss J., æt. seventeen, while traveling in Spain with her mother, had a severe attack of appendicitis, but her mother would not consent to operation there in a strange country by strange surgeons in whom she had no confidence. She recovered and was brought home, her mother intending to have an interval operation done as soon as convenient. But the young lady regained her health rapidly and the appendix was causing no trouble, so operation was postponed on this account and on account of her studies.

However, during August of last year, three years after the attack, she was seized suddenly with sharp pain in the region of the appendix, accompanied by some tenderness, but there was no rise of temperature. She admitted having had pain in the same location from time to time during the past year, but was afraid to mention it because she dreaded the operation. Operation was then decided upon and was done August 4, 1908.

Upon exposing the caput coli there was no evidence of an appendix, the surface was perfectly smooth everywhere and there were no adhesions. Careful examination of the wall of the gut, however, by rolling it between the thumb and finger, detected slight thickening at one point. This was the appendix imbedded in the wall of the gut, the surface above and around it being as smooth as every other part of the gut wall, apparently covered completely by peritoneum.

The appendix was enucleated by dissection and removed, the raw surface being covered over as in the other case by approximation of the peritoneal margins over it.

The appendix was small and contracted, but showed evidence of chronic inflammatory changes. The patient made a good recovery and has had no trouble since.

SOME CORONER'S CASES.

By PHILIP F. O'HANLON, M.D.,

NEW YORK

To resume, as it were, the cases that can be classed as very interesting to the profession, cases that the general practitioner or even the hospital interne seldom see, let me give the history of one occurring at the New York Hospital on my tour of duty in the week of April 4, 1909:

Case I. Francis Devine, a lad of eighteen years, was playing with an umbrella, such as one sees on the big city watering carts in the summer season. In some manner not definite the rib of the umbrella entered his mouth, cut the base of his tongue on the left side, and lacerated the left internal carotid artery. He began to bleed. An ambulance was called for, but when the doctor arrived at the scene the boy had stopped bleeding. The patient was taken to the hospital, however, as he had a

large swelling over the clavicle extending up into the neck. An operation for the injury was begun. A most remarkable state of affairs was at once displayed, viz., a plugging of the distal and approximal end of the artery by a thrombus. The carotid was tied, and the patient put to bed, where, after a few hours, he died. At autopsy it was found that the thrombotic condition was manifest in the Sylvian artery and that the center of the temporal lobe had undergone softening all within a period of a few hours.

Case II. An old man was crossing on the avenue of one of the busy parts of the city. He stepped out from behind a wagon and in doing so got right in front of an oncoming automobile, which hit him. He was taken to the Roosevelt Hospital and soon after died. The autopsy of the body of the man showed no evidence of any violence whatever, no scalp wound, no swelling even of the scalp, yet, when the top of the skull was removed, it was found that he had sustained no less than ten distinct fractures of the base.

Case III. A man was taken ill on the Bowery, near Grand street. He fell to the pavement, an ambulance was sent for, and the surgeon pronounced him dead of heart trouble. No one claiming the body, it was sent to the Morgue, and autopsy showed that the real cause of death was carbolic acid. The peculiar thing about this, outside of the diagnosis, was the lack of any external signs of the burn or stain of the acid. I afterward learned that the man had taken the acid in a glass of beer only a few moments before he fell on the street.

Case IV. I had a most peculiar case of attempted abortion. A young girl, one of the chorus of a Broadway production, called in a "doctor," to whom she confided the fact that she could not well become a mother in the busy season of the year, and that she would need relief. The operation was most astounding in that the "operator" curetted the entire placenta away, and the girl died of a profuse hemorrhage. The case being reported to the Coroner's office, I was assigned to it and the autopsy showed that the placenta had been removed, but a five-months baby was found *in utero*. How the man did it was, and is to this day, to me a puzzle. The medical men on the jury, and it was made up of some very good citizens, turned the prisoner out on the ground, so one of them said to me afterward, that the "operator was too ignorant to have been guilty of a criminal intent."

Case V. A man working in a stable was kicked in the stomach by a horse. He was carried home and a doctor was sent for, who on arriving put a plaster over the seat of violence. In three days the man died. The autopsy showed that he had sustained a rupture of the intestines. This case is interesting in that it shows the unreliability of plasters when the hoof of a horse strikes the human abdomen, and also the uselessness of calling on any old kind of a doctor.

One of the few causes of sudden death recorded at the Board of Health by others than Coroner's physicians is edema of the larynx, and this is by no means an unusual terminating factor. In many cases of "police arrests for alcoholism" and where men are found dead in the cells the autopsy reveals the almost entire closure of the glottis. We also come in contact with a condition which we call "postural asphyxia." This is one oftentimes encountered in men who are found seated in chairs in the back rooms of saloons with the head bent forward on the chest and the collar pressing on the larynx, which slowly but surely causes asphyxia.

121 West Ninety-fifth Street.

REPORT OF A CASE OF HYDROPHOBIA.

By JOHN F. ANDERSON, M.D.,

WASHINGTON, D. C.

PASSED ASSISTANT SURGEON AND ASSISTANT DIRECTOR HYGIENIC LABORATORY, U. S. PUBLIC HEALTH AND MARINE HOSPITAL SERVICE,

AND

JOSEPH GOLDBERGER, M.D.,

WASHINGTON, D. C.

PASSED ASSISTANT SURGEON, U. S. PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.

T. B., colored, male, age 11, residence Alexandria, Va. Bitten on August 1, 1908, on the web of hand and foot; both bites were very slight and healed rapidly without treatment. The dog was a family pet and was noticed to be not well for a short time before biting the boy and died in less than a week afterward. After biting the boy the dog bit a neighbor's dog, and the latter died about three weeks later. Both dogs were buried without any examination having been made for rabies.

The boy was taken sick on Monday morning, October 12, or sixty-two days after being bitten, and rapidly developed the characteristic symptoms of hydrophobia. The first symptom noted by himself and family was sore throat, for which he was treated by the family doctor. This symptom rapidly increased and by the next morning there was marked spasm of the muscles of the pharynx and neck, attended with profuse salivation.

The attending physician, Dr. Penn, made a diagnosis of hydrophobia and requested us to see the case with him. When seen by us the patient was in a partial stupor, but could easily be aroused and could answer questions. There was a very free flow of a frothy saliva, which he expelled with a peculiar sound. He had, at rather short intervals, convulsions with some opisthotonos and marked respiratory spasm. We confirmed the diagnosis of hydrophobia.

The boy's condition rapidly grew worse and he died on the third day after the onset of illness. We were unable to obtain an autopsy.

Noninfectious Disease of the Adnexa.—H. Roulland states that noninfectious disease of the adnexa is deserving of greater attention than is usually given to it. We have under this head active and passive congestions, adhesions, hemorrhages, cysts, scleroses, and painful conditions that cause great suffering. The causes of these conditions are found by the author in the periodic congestions to which these organs are subjected, the displacements of which the uterus is susceptible, and the metritis and salpingitis that occur aside from infectious inflammatory conditions.—*La Gynécologie.*

Undialyzable Constituents of the Urine in Pregnant Women in Normal and Pathological Conditions.—M. Savare has examined the undialyzable residue of the urine, which is in considerable quantity in normal and pathological conditions in pregnant women, and has injected the residue into animals to ascertain whether it has toxic properties. He finds that there are contained in the urine of women who are in a pathological condition while pregnant, especially when attacked by eclampsia, elements that are markedly toxic to the experiment animals, causing them to have stupor and convulsions, and killing two out of ten animals injected. The relation to the causation of eclampsia of these toxic elements is not as yet clearly defined, but should be further studied, since it may prove a fruitful field of observation.—*Annali di Ostetricia e Ginecologia.*

New York, June 12, 1909.

VENEREAL DISEASES IN INFANCY.

THERE are probably no patients who receive so little human sympathy from the average physician as do those suffering from the various ailments classed as venereal diseases. When the patient is an unmarried male adult there is a general feeling that he is having a punishment that fits his crime, and when married, if he has contracted the disease from other than his legal life mate, sympathy is usually entirely lacking to the sufferer and is extended to the innocent person who may become a victim of his loss of self-control. When, however, the patient is a young child, especially a girl, the situation is changed, and one feels most sincere sympathy for the little patient. Venereal infection among young girls, especially girl babies, has until recent years been considered rather as a medical curiosity. That it is in reality a common disease of infancy is shown by the large literature which has appeared in recent years on gonococcus vaginitis in the infant.

The mode of infection in these cases has been a source of much worry to pediatrists, especially to the house staffs of the children's hospitals in which, with every possible precaution, the admission of one infected infant will ofttimes cause an epidemic involving every girl baby in a ward. The source of infection outside of the hospital is more easily explained and can often be traced directly to a urethritis in the father, or a vaginitis in the mother or sister, or to the attendance at school or a day nursery in which the infection may be spread by the common use of bedding, towels, or clothes. Besides these accidental modes of infection, however, there are at times cases in which even young infants acquire the disease from a diseased man in a manner similar to the common mode of infection among adults. That this may be much more commonly the case than is usually supposed is suggested by Flora Pollack in an article in the *Johns Hopkins Hospital Bulletin* for May, 1909. In this paper she reports one hundred and eighty-seven cases in children below the age of sixteen treated in the woman's venereal department of the Johns Hopkins Hospital Dispensary, and states her belief that the infection in these cases is never accidental. The writer draws attention to the characteristic lesions of the infant hymen after rupture, and points out that carunculæ are never formed, these being merely serrations on the free border with little or no bleeding. The ruptured hymen in the young child, she says, is characteristic, and when it has once been seen will always thereafter be recognized. It is on the strength of this testimony that she bases her conviction regarding the mode of infection in young girls.

The infecting individuals, the author believes, should be divided into two classes, the sadists, or sexual perverts, and the "infectionists." This second class has its origin in the very common superstition that a person infected with either syphilis or gonorrhea may get rid of it by infecting another, and preferably an untouched virgin. Such a superstition may well account for the otherwise inexplicable brutality of certain of the cases which come to one's notice in pediatric clinics and appear in the juvenile courts, cases which two years ago aroused such a fury in the East Side of New York that a man offering a child a piece of candy in the street did so at the risk of his life. If this false belief is the source of the infection in any considerable number of the cases active steps should be taken to prevent it. For the perverts, who indulge in the act in moments of excitement and as a result of a disordered brain, the State hospitals would seem to be the proper abode. As to dealing with the "infectionists," those who in cold blood willfully infect a young child in order to relieve their own ills, long terms in the penitentiary would seem to be indicated. However, the incarceration of the criminal, who is rarely apprehended, is but a poor method of protecting the child, and if such a superstition prevails among the lower classes, as Pollack suggests, a campaign of education should be taken up to eradicate this dangerous belief. It might be well to make it a routine practice in the genitourinary clinics to inquire of each patient whether he had ever been indoctrinated with this villainous superstition and to emphasize that the putting of its teachings into practice would not cure but aggravate his own disease.

How widespread such a belief may be we are unable to say, or what proportion of cases of venereal infection among infants is caused by the sadists and the "infectionists" we do not know. Valuable however as is Pollack's paper, we are sure that she is in error in believing that all, or even the majority, of cases of vaginitis in infants are due to direct infection from a man in the natural way. Those who have worked much in children's clinics continually see cases of vaginitis in young girls in which the condition of the hymen precludes positively any sexual act. Then again the frequency of the spread of the disease in hospitals and its common occurrence in the day nurseries suggest that gonococcus vaginitis is transmitted not only by direct contact, but indirectly as well. However, if only a small proportion of the cases belong to the classes of which Pollack speaks, the frequency of the disease in the large cities (the author estimates that there are 800 children under fifteen years of age infected annually in Baltimore alone) makes her communication one of exceptional interest and value.

TYPHOID BACILLURIA.

There are two great factors in the prevention of the spread of such an infectious disease as typhoid fever—one dealing with the sanitary and hygienic measures to be devised for the protection of our food and water supply from the organisms causing the disease, the other concerned with the cure and such management of the individual patient as to make of him a source of least possible danger to others. The latter factor used to be considered from the standpoint of isolation during the actual disease alone, but recently the discovery of the fact that the convalescent or cured patient may harbor and distribute virulent organisms for a long time after his sickness has compelled a reconsideration of the whole matter. One phase of the danger existing in many convalescent or cured patients, namely, typhoid bacilluria, is very instructively discussed by Karl Connell in the *American Journal of the Medical Sciences* for May, 1909. The author's studies have shown that typhoid bacilli are present in the urine in about one-quarter of all typhoid patients, occurring in enormous numbers about the time the temperature falls to normal and continuing for several weeks after this time. This phenomenon is in most cases unaccompanied by any subjective symptoms, the appearance of the bacilli being simply a part of the process of elimination of the organisms from the body for which they are no longer virulent. This very absence of symptoms makes the presence of the bacilli dangerous for others, for many precautions against the spread of the disease are sure to be related during convalescence or after the patient has quite recovered.

There is no doubt, however, that these bacilli are virulent for other persons and it seems imperative to treat the bacilluria in order to limit the spread of the disease. Connell reviews the numerous methods proposed with this purpose in view, and concludes that the best treatment is the use of hexamethylenamine. Ten to thirty grains a day of this drug for the week preceding and the two weeks following the fall to normal temperature seems quite sufficient to control the bacilluria in most cases. Often, however, the bladder itself is infected and the resulting lesion is best treated by daily irrigations with weak silver nitrate solutions or with other antiseptics. In rare cases chronic ulcerative inflammation of the bladder cystotomy and drainage may be required. Hexamethylenamine has proved to be quite a safe drug, though vesical tenesmus and pain over the kidneys with the appearance of blood in the urine may be produced by using large doses. Smaller doses, however, may be safely continued for a very long time until the desired effect on the urine has been obtained.

DELAYED CHLOROFORM POISONING.

It is well known that administration of chloroform as an anesthetic carries with it certain dangers involving parenchymatous changes in the liver. In a number of fatalities on the operative table, subsequent autopsy has shown hepatic degeneration simulating acute yellow atrophy. The possibility of such an outcome has deterred many surgeons from allowing the use of chloroform in their operative work although no other contraindication presented itself. Writing in the *Archiv für Gynäkologie*, Vol. 68, No. 1, A. Sippel, under caption of "A Typical Clinical Picture of Tardy Death from Chloroform," reports a case of his own, and reviews the forty articles he has found in the literature. He notes that in nearly all reported cases marked interference with the systemic blood current was brought about by the surgical procedure, and believes that certain toxins were thus produced which had a special injurious action on the hepatic parenchyma.

Sippel's case was that of a young woman, seemingly healthy, save for some tendency to chlorosis, who inhaled about sixty grams of chloroform given by a skilled anesthetist. No other anesthetic was combined with the chloroform. All went well until the following day when the patient became restless, vomited, and showed the evidences of circulatory disturbance by a soft rapid pulse. The abdomen was flat and not sensitive, save in the liver region where some tenderness was elicited. The eyes were slightly jaundiced. There was much albumin in the urine, and the patient manifested the stupor of eclampsia. Vomiting, jaundice, and failing heart became more pronounced and the woman died within sixty-eight hours after the abdominal section. Autopsy showed marked fatty degeneration of the liver without peritonitis or other evidences of inflammation or of infection at the site of operation.

It seems important in all cases in which chloroform is about to be administered to make not only the ordinary uranalysis for albumin, sugar, and casts, but also to determine the amount of urea, and to make an estimation of the proper glycogenic capacity of the liver, inasmuch as glycogen is such an important factor in burning up fat. To this end, Sippel holds, carbohydrates should be supplied long enough before the surgical attack to insure ample production of glycogen when most needed, that is to say when the liver is trying to throw off the excess of chloroform plus any toxic agent present in the blood as the result of the lesion. Rosenfeld's brilliant researches on the glycogenic function of the liver and its importance to the life and health of the individual are of great practical value and should always be kept in mind in general surgical work which is not of the acute emergency type.

Marriage by the Subjects of Cardiac Disease.

The question of the legal regulation of marriage in cases of hereditary disease, of insanity, or other form of disability is one of the live questions of the day. It would seem that an intelligent public would be trusted to handle such a matter, since it is a question of the health of their descendants. Unfortunately, the public is neither well-informed on the subject of heredity nor willing to be so informed by the family physician, when it becomes a question of the selection of a life partner. The contracting parties are much more interested in matters of the heart concerning themselves than

in the health of their offspring. They have a blind confidence that fate will not mete out to them the ills that have come to others, and that a gracious Providence will make an exception of their particular descendants, and they feel much concern when the very evils that the family physician could have predicted befall their children. Louis Rénon, in the *Gazette des Hôpitaux*, for March 18, 1909, takes up the question of whether persons who have cardiac disease should be prohibited from marrying. He says that the question differs with the sex of the person. There is practically no danger to the man in most forms of cardiac disease, since the regulation of his life by marriage is rather of benefit to his heart condition. The question of the probable inheritance by the children of his disease depends on the form of disease, cardiac sclerosis, interstitial nephritis, and aortic disease being frequently inherited. Cardiac valvular troubles are probably not inherited. The mother is the parent whose cardiac condition is subjected to extra strain by pregnancy, labor, the puerperal state, and lactation. There is danger that the fetus will die during pregnancy or labor, or survive with a cardiac difficulty. The dangers to the mother are of two kinds: cardiac insufficiency, and acute pulmonary edema. Cardiac insufficiency is manifested toward the end of the first half of pregnancy by dyspnea, violent palpitation, and repeated hemoptysis. Acute pulmonary edema occurs toward the end of pregnancy or during labor, is accompanied by asystole, and ends in death before delivery. In severe cases of heart disease and in young subjects marriage should be forbidden. Changes in arterial tension give an important indication, hypertension or hypotension both being unfavorable conditions if continuous. In all other cases the woman may go on to a successful end of pregnancy. A cardiac should not marry another cardiac, nor a near relative. The social position of the woman is important, since if she is able to lead an easy life the prognosis is better than in a working woman. Precautions should be taken in case of such marriages during pregnancy to protect the mother against extra strain. Her nutrition and the kidney condition should be carefully watched, and from the end of the fourth month of pregnancy the patient should have rest and avoid all fatigue. A slow labor should be hastened by version or forceps. Thus, Rénon says, we may hope to conduct the pregnancy to a successful issue.

Dangers of the Bier Treatment.

Since the first publication by Bier of his method of treating acute and chronic inflammation by passive hyperemia this therapeutic agent has received many adherents. As frequently happens, however, in other cases, the results obtained by the author of the method and those specially trained by him are not always equaled by others who attempt the procedure without sufficient practical experience. In an article in the *Deutsche medizinische Wochenschrift* for May 13, 1909, Arthur Schaefer shows that there may be danger in artificial hyperemia even when it is properly induced. The author has had extensive experience with the method, and his early scepticism due to failures was replaced by enthusiastic support after a visit to the Bonn clinic, where he learned to use the apparatus properly. He however reports a case as an example of one of the dangers of the method. The case was that of a man who, following an injury, had a severe phlegmon of the arm. The application of the bandage was followed by immediate relief of pain and fall of temperature. However, the marked edema caused by the pressure concealed for several days the presence of a periosteal abscess which was thus allowed to advance much farther than it otherwise would have done. After incision and continued hyperemia the wound slowly healed, but a radial paralysis developed. The author, thinking that the pressure of the bandage might be causing this, removed it, but a sudden exacerbation of pain compelled him to apply it again in a few days. The paralysis progressing, an exploratory incision was made over the radial nerve. It was found that the paralysis was not due to pressure but to a neuritis and the firm adhesion of the nerve to the site of the old periostitis. The author believes that if he had removed the compression at the first signs of paralysis, and had not been led astray by the relief of pain, he might have prevented, or at least arrested, the progress of the trouble. This case shows that artificial hyperemia is not the panacea which some seem to consider it. Bier himself urges great care in diagnosis and selection of cases for treatment, and this cannot be too strongly insisted upon. The treatment is certainly of value and can be applied in a private office or in an out-patient department as well as in the hospital wards, factors which make it of great practical use. Enthusiasm, however, should not be allowed to carry one to the extent of carelessness. Passive hyperemia is an important and valuable therapeutic aid, but, like every other good thing, it is capable of much harm if improperly used.

News of the Week.

New York Death Rate.—For the week ending May 29, there were 1,333 deaths in New York, two less than in the corresponding week of last year, the rate being 15.23 per 1,000, as against 15.75 for 1908. There was a slight decrease in the mortality among infants, and in the deaths from pneumonia and pulmonary tuberculosis. For the week ending June 5, the showing was less favorable, there being an increase of 183 deaths for the week, as compared with the corresponding week a year ago. The total of deaths for the week was 1,405, with a death rate per thousand of 16.06. The diseases showing increases are measles, diphtheria, heart disease, pneumonia, and tuberculosis.

Cholera in St. Petersburg.—On June 5, twelve positive and five suspected cases of cholera were reported in St. Petersburg. The outbreak is ascribed to carelessness in drinking water from the River Neva without first boiling it.

Investigating Plague.—Dr. Grubbs of the American Quarantine Service at Porto Rico, and Assistant Surgeon W. H. Kellogg of the U. S. Public Health and Marine Hospital Service have gone to La Guayra to investigate the bubonic plague conditions in Venezuela.

Pollution of New York Bay.—The Government of the United States has petitioned the Supreme Court for a perpetual injunction restraining the Bronx River Sewage Commission of New York from permitting the discharge of the sewage from the district comprising the valley of the Bronx River into the Hudson River. The petition recites that the Bronx Valley sewer as at present planned will allow the discharge of the sewage of a region, which

in a short time is expected to have a population of 850,000, into the Hudson River, "untreated, and without screening, clarification, or sedimentation." The plan has been opposed by a number of associations interested in the protection of the waters of New York, and is condemned by the State Commissioner of Health. A similar petition was filed a short time ago by the State of New York against the State of New Jersey in the case of the disposal of the sewage from the Passaic Valley.

New Tuberculosis Hospital.—The Central Federation of Labor of Brooklyn has made application to the State Commissioner of Health for permission to construct and operate a hospital for the treatment of cases of tuberculosis in Suffolk County. The Commission held a public hearing on June 11, the local health officers and the Board of Supervisors of the county being in attendance.

Philadelphia Hospital for Contagious Diseases.—The new Philadelphia Hospital for Contagious Diseases, erected on the outskirts of the city, on a 58-acre plot of ground, at a cost of $1,583,800, was opened on June 1. It consists of an administration building, storehouse, nurses' home, exit building, refectory building, building for private patients, four public ward buildings, receiving and observation ward building, all connected by an open corridor. These buildings, exclusive of the administration and storehouse buildings, are intended for the accommodation of scarlet fever patients. It is contemplated in the near future to erect a further group of buildings on the same general plan for the accommodation of diphtheria patients. There are besides six buildings intended for isolation, and it is contemplated building six more of the same kind in connection with the diphtheria group. There is now also a building intended for smallpox patients, but for the present it will be devoted to diphtheria patients. When the buildings for the latter are erected, this building will be used for measles patients. There is in addition a power plant, laundry, employees' kitchen and dining-room buildings, garage, and stables.

Farm at Bellevue.—A garden plot has been opened on the grounds of Bellevue Hospital for the tuberculosis patients who spend their days on the old ferryboat Southfield, anchored in the East River. The patients are to be allowed to raise vegetables of various sorts. Twenty smaller plots will also give the children an opportunity to raise flowers.

Gifts to Charities.—The will of the late Mrs. Margaret J. P. Graves, who during her lifetime had made generous gifts to the hospitals of New York, bequeaths to St. Vincent's Hospital, $25,000; to the New York and Mt. Sinai Hospitals, $10,000 each; to the Presbyterian Hospital, $10,000 for general purposes and $10,000 for the maintenance of an emergency ward; to the New York Infirmary for Women and Children, $10,000; to St. Luke's Hospital, $20,000 to be used for work under the direction of the medical board, and $10,000 for the care and treatment of crippled children; to the Society for the Relief of the Ruptured and Crippled, $10,000. Mrs. Graves was the donor of the Margaret J. Plant Pavilion for private patients at St. Luke's Hospital.

A number of institutions benefit under the will of the late Mr. F. J. Walgering of New York. $5,000 each being left to St. Francis' Hospital, St. Joseph's Hospital for Consumptives, St. Vincent's Hospital, Presbyterian Hospital, German Hospital, St. Catherine's Hospital, Brooklyn, and St. Gabriel's Sanitarium at Paul Smith's.

The will of the late Sebastian Lawrence of New London, Conn., sets aside $100,000 for the erection of a free hospital in that city, and $400,000 as an endowment fund for its support.

By the will of the late John G. Brill of Philadelphia, the sum of $5,000 is bequeathed to the White Haven Sanatorium for Tuberculosis Patients.

By the will of the late Lizzie D. Chidester of Philadelphia, the sum of $3,000 is bequeathed to the Wills Eye Hospital.

Vital Statistics in France.—During 1908 there were in France 46,441 more births than deaths. These figures are in marked contrast to the statistics for 1907, when the excess of deaths over births was 19,892, a result which caused the most pessimistic predictions as to the future of the French race. In 1908, as compared to 1907, there was a decrease in deaths amounting to 48,266, while births increased 18,067.

The Rockefeller Institute for Medical Research.—At a meeting of the board of directors of this institute, held on May 29, the following promotions and appointments were made: *Associate,* Paul A. Lewis (Pathology); *Assistant,* F. Peyton Rous (Pathology); *Scholar,* Angelia M. Courtney (Chemistry).

Columbia Bestows Degrees.—The commencement exercises of Columbia University were held on June 2, in the gymnasium, over eleven hundred students receiving degrees. The College of Physicians and Surgeons graduated eighty students, to whom the Hippocratic oath was administered by Prof. John G. Curtis. The Alumni Association Fellowship in Anatomy was awarded to Dr. Herman von W. Schulte, and that in Physiology to Dr. Daniel R. Lucas. The Alonzo Clark Scholarship was awarded to Dr. Augustus B. Wadsworth of the Department of Bacteriology, the Proudfit Fellowship to Dr. Edwards A. Park, and the Cartwright Prize of the Alumni Association to Dr. Samuel O. Mast.

New York University.—Seventy-four students were graduated from the University and Bellevue Hospital Medical College, the medical department of New York University, on June 2. The University also conferred the honorary degree of Doctor of Laws on Dr. Hermann M. Biggs, Professor of Clinical Medicine in the University and General Medical Officer of the Board of Health of the City of New York.

Graduation of Nurses.—The graduating exercises of the Provident Hospital and Training School for Nurses was held June 3. Seven nurses received diplomas. President George H. Webster delivered an address on the work of the year.

The Chicago College of Physicians and Surgeons Alumni Association held its annual meeting June 4, at which the following officers were elected: *President,* Dr. C. E. Humiston; *First Vice-president,* Dr. C. W. Harrison; *Second Vice-President,* Dr. Jeffrey Fleming; *Secretary,* Dr. P. H. Holmes.

Hospital Schools.—The Department of War will maintain three hospital schools during the coming summer, one at Sparta, Wis., from July 15 to 23, another at Antietam, Md., and a third at San Francisco.

The International Congress of Applied Chemistry which has been in session in London has

accepted the invitation presented by Ambassador Reid to hold its next convention in Washington. The date will be May, 1912.

American Gastroenterological Association.—At the twelfth annual meeting of this society, held at Atlantic City, June 7 and 8, 1909, the following officers were elected for the ensuing year: *President,* Dr. Julius Friedenwald, Baltimore; *First Vice-President,* Dr. W. B. Cannon, Boston; *Second Vice-President,* Dr. John A. Lichty, Pittsburg; *Secretary and Treasurer,* Dr. Charles D. Aaron, Detroit.

American Dermatological Association.—At the thirty-third annual meeting of this society, held in Philadelphia on June 3 to 5, 1909, the following officers were elected for the ensuing year: *President,* Dr. William Allen Pusey, Chicago; *Vice-President,* Dr. Grover William Wende, Buffalo; *Secretary and Treasurer,* Dr. James M. Winfield, Brooklyn. The next meeting of the Association is to be held in Washington, D. C., in May, 1910.

The Connecticut State Medical Association concluded its 117th annual meeting at Hartford on May 26 and 27, by the election of the following officers: *President,* Dr. Samuel D. Gilbert, New Haven; *Vice Presidents,* Dr. Decodore R. Parker, Williamantic; Dr. William J. Tracey, Norwalk; *Secretary,* Dr. Walter R. Steiner, Hartford; *Treasurer,* Dr. Joseph H. Townsend, New Haven; *Committee on Scientific Work,* Dr. George Blumer, New Haven; Dr. F. W. Wright, Bridgeport, and Dr. Walter R. Steiner, Hartford.

The American Pediatric Society, at its twenty-first annual meeting in Lenox, Mass., on May 28, elected the following officers: *President,* Dr. D. L. Edsall of Philadelphia; *First Vice-President,* Dr. E. W. Saunders of St. Louis; *Second Vice-President,* Dr. D. J. Milton Miller of Atlantic City; *Secretary,* Dr. Samuel S. Adams of Washington, D. C.; *Treasurer,* Dr. Charles H. Dunn of Boston; *Editor,* Dr. L. E. La Fétra of New York.

The Kansas State Medical Society held its forty-third annual meeting at Wilson during the third week of May. Topeka was selected as the place of meeting for next year, and officers were elected as follows: *President,* Dr. O. J. Furst, Peabody; *First Vice-President,* Dr. T. F. Foncanon, Emporia; *Second Vice-President,* Dr. Walthall, Parsons; *Third Vice-President,* Dr. J. P. Kaster, Topeka; *Treasurer,* Dr. L. H. Munn, Topeka; *Secretary,* Dr. C. S. Huffman, Columbus.

The Nebraska Homeopathic Medical Society, at its annual meeting in Omaha, on May 20, elected the following officers: *President,* Dr. F. A. Marsh of Seward; *First Vice-President,* Dr. F. F. Teal of Omaha; *Second Vice-President,* Dr. W. K. Foote of Omaha; *Corresponding Secretary,* Dr. F. S. Whitman of Omaha; *Recording Secretary,* Dr. R. C. Bowie of Table Rock; *Treasurer,* Dr. O. S. Wood of Omaha.

The Tennessee Medical and Surgical Association closed its annual meeting at Jackson on May 21. The elections for the ensuing year resulted as follows: *President,* Dr. Frank Jones of Memphis; *Vice-President,* Dr. S. A. Walker of Trenton; *Secretary,* Dr. I. A. McSwain of Paris.

The Portland (Ore.) City and County Medical Society, at its meeting on May 19, elected the following officers for the ensuing year: *President,* Dr. Alan Welch Smith; *Vice-President,* Dr. A. E. Rockey; *Secretary,* Dr. George S. Whiteside; *Treasurer,* Dr. S. H. Sheldon; *Board of Councillors,* Dr. J. A. Pettit, Dr. Ben Norden, and Dr. L. H. Hamilton.

The Davison County (S. D.) Medical Society, at its annual meeting at Michell, on May 25, elected Dr. C. A. Howard of Ethan, *President,* and Dr. E. F. Reamer of Michell *Secretary and Treasurer.*

Jefferson Medical College Alumni.—The New England Association of the graduates of this college held their fourth annual meeting and banquet in Hartford, Conn., on May 26, and elected the following officers: *President,* Dr. A. S. McKnight of Fall River, Mass; *Vice-President,* Dr. John T. Farrell of Providence, R. I.; *Secretary,* Dr. A. MacOdrum of Cambridge, Mass.; *Treasurer,* Dr. W. N. Thompson of Hartford.

Sir Charles Wyndham, the English actor who is playing a brief engagement in New York at the present time, was graduated as a physician, and served, it is said, as assistant surgeon in the Federal Army during the Civil War.

Mrs. Anna Eliza Hubbard, a widely known nurse during the Civil War, died recently at her home in Chicago, aged eighty-five years. Mrs. Hubbard was appointed a special agent to inspect hospitals, by the New York State government, and served throughout the war.

Obituary Notes.—Dr. Henry C. Keenan of Brooklyn, N. Y., died on June 1, in the Cumberland Street Hospital from the effect of injuries received by being thrown from his carriage. While on his way to make a professional call the horse which he was driving became frightened at a passing automobile and overturned the carriage. Dr. Keenan, who was thirty-six years old, was graduated from the College of Physicians and Surgeons, New York, in 1895. He was a member of the Brooklyn Gynecological Society, the Brooklyn Pathological Society, the Brooklyn Medical Society, the Alumni of St. Mary's Hospital, and the State and county societies. Dr. Keenan was also assistant gynecologist to St. Mary's Hospital and to St. Mary's Female Hospital.

Dr. Durell Shepard of West Haven, Conn., died on May 17, at his home, aged seventy-seven years. Dr. Shepard was graduated from Yale Medical School in 1864, and had practiced in West Haven for forty-three years. He was a veteran of the Civil War, and a member of the American Medical Association and the State and County Medical societies.

Dr. Arthur B. Smith of Chelsea, Vt., died after a brief illness at his home on May 17, aged fifty-seven years. Dr. Smith was graduated from Dartmouth Medical College in 1874, and had practised in Vermont since that time.

Dr. Floriman J. Taylor of Pittsfield, Me., died after a short illness on May 24, aged fifty-four years. Dr. Taylor was graduated from the Rush Medical College of Chicago in 1881, and was for some time on the Board of United States Pension Examining Surgeons for Somerset County.

Dr. Charles Ellery Stedman of Brookline, Mass., died at his home on May 24, aged seventy-eight years. Dr. Stedman was graduated from the Harvard Medical School in 1855, and from 1861 to 1865 served as assistant surgeon in the United States Navy. He was a member of the Massachusetts Medical Society, the Dorchester Medical Club, and the Boston Obstetrical Society.

Correspondence.

CHLOROFORM ANESTHESIA.

To the Editor of the Medical Record:

Sir:—I have read with much interest the "Administration of Anesthetics," by Dr. H. J. Boldt, in your issue of May 29. It is one of the most practical and satisfactory papers that I have ever read on that subsubject, which certainly is one of vast importance to the patient and to those who operate. He says: The "detail of the methods of administering, etc., is, I believe, understood, at least in theory, by every physician." This may correct as to theory, but it is certainly not as to practice, as regards chloroform. The best way to give chloroform is beyond question the drop method, if this method is understood. I have never seen it practised properly, as I view it, and during my professional life I have seen many good operators, at home and abroad. It requires more than an Esmarch's inhaler and a drop bottle to properly use the "drop method." The inhaler must be placed and held properly and the anesthetic dropped properly.

Text books advise the operator to pour the anesthetic on the inhaler, and then gradually approach this to the face, or, the inhaler being on the face, to pour a number of drops on the mask, then stop awhile, and resume again, and so on irregularly. Thus given, the dose is irregular, the amount of vapor inhaled is irregular and uncertain, consequently the effects produced must be irregular and uncertain.

How can the dose be regulated, and the amount of vapor inhaled be regulated, and the amount of air always be sufficient and regular? By covering an Esmarch inhaler with two to four thicknesses of gauze and putting it well down over the nose and mouth, in a fixed position, and keeping it there. It will be found that normal breathing is easy, for air is sufficient. That is first. Now we want to fill that sufficient amount of air with enough anesthetic vapor to anesthetize the patient. This is done by dropping, slowly at first, regularly and rhythmically, drop by drop, the anesthetic on the place where the bars of the inhaler cross, and nowhere else on the inhaler, because this will give a fixed point from which evaporation takes place to mix with the inspired air. The amount of vapor the patient receives is thus regulated by the slowness or rapidity of the dropping, and the dropping is slow or fast, as the effect on the patient is produced, which can be gauged nicely if carefully and cautiously watched and dropped, for we know how much we drop and can be reasonably sure of how much the patient inhales; for the source of air supply is sufficient and fixed, the source of vapor supply is always from the same point, and the dosage is regulated by the drops that are given. If there is reason for suspending the anesthesia, remove the mask entirely, and to resume it begin again as at first. To do this requires the constant, continuous and undivided attention of the anesthetist.

I have always used chloroform, and think it the best of all anesthetics, and this opinion is based on the experience that a fairly active surgical practice in a village has brought me. I have never had any accidents. They may come.

My environment has made necessary many different anesthetists. All anesthetics are dangerous. Every anesthesia is accompanied with danger. It is always a source of anxiety. In college I was taught to give a hypodermic of ¼ gr. morphine before many anesthesias, and after the operation, if a major one. I have nearly always followed this practice. Of late I have added to the morphine 1-100 hyoscine hydrobromate (never more than one dose) half an hour before the operation, and I have thought with benefit in helping to a quieter anesthesia and requiring less of the anesthetic.

T. M. McIntosh, M.D.

Thomasville, Ga.

To the Editor of the Medical Record:

Sir:—In Dr. H. J. Boldt's paper on the administration of anesthetics in the Medical Record for May 29, he mentions several deaths occurring on the table where preliminary morphine and scopalamine anesthesia was used. Where chloroform is used, morphine is dangerous, as it renders the respiratory center less irritable, and chloroform kills by respiratory failure. Previous to ether, morphine is not dangerous; in fact, gives a smoother narcosis, with less ether. Dr. Boldt's remarks on leaving the cornea alone, that the anesthetist should tend strictly to his business and not watch the operation, and that alcohol is too near a relative of ether to be used as a stimulant in too deep ether narcosis, should be emphasized.

If the anesthetic, whether it be ether, chloroform, the A.C.E. mixture, or what not, that is most suited to each case is used, the danger will be much less, for there can be no routine choice for every case.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RADIUM AT THE ROYAL SOCIETY OF MEDICINE—QUESTIONS AS TO UTERINE CANCER—MEDICAL SOCIETY OF LONDON, ANNUAL MEETING—ST. BARTHOLOMEW'S PATHOLOGICAL LABORATORIES—OBITUARY.

London, May 21, 1909.

There was a crowded meeting last evening at the Royal Society of Medicine to hear Dr. Louis Wickham, of the Paris Radium Institute, deliver an address on the treatment of cancer and other diseases by means of radium. The Lord Mayor was present as a visitor and Dr. Radcliffe Crocker occupied the chair. Dr. Wickham said that mostly when the curative property of radium was mentioned there arose in the mind of inquirers the idea of cauterization or burning with inflammatory reaction and destruction of tissues. He had found these effects were followed by repair; hence radium was a very valuable therapeutic agent. From this standpoint it had a far greater sphere of usefulness than many supposed. Dr. Wickham showed on lantern slides the results of some experiments in Paris hospitals. One pictured the four stages of treatment in a case of cancer on the face, which was cured in thirty-five days. Respecting mammary cancer, he submitted an epitome of results obtained by his co-workers and himself.

In replying to a cordial vote of thanks, the lecturer said it was very pleasant to think that the advance made in the study of radium was in a larger measure due to the interest shown and the support given by England's great King.

On Friday last there was a good exhibition, including some radium cases, in the Clinical Section of the society. Dr. T. S. Wilson showed three colored projection drawings of the brain, illustrating the relation of its internal structures to the convolutions. They had been prepared by photographing serial sections, cut through a hardened brain and afterward drawing them to scale. The design was to assist surgeons in cerebral operations, the idea being to show the parts as if the brain were transparent.

Dr. Finzi showed a case of inoperable scirrhus cancer of the breast under treatment by radium. The growth appeared eight years ago and three years ago the breast was removed, but the tumor recurred. It was improved by x-rays, but then neglected, with the result of rapid growth. Radium (bromide) was begun March 10; the tube method for 53 hours, the position of the tube being altered once. On March 12 it was used in the axilla for 41 hours. April 2 the tumor had almost disappeared; but one nodule remained, and the treatment was resumed on April 29 for 26 hours.

Dr. Finzi also showed a case of epithelioma of the lower lip, which started as a pimple fifteen or sixteen years ago. The last eight or ten months growth increased. There were enlarged glands under the jaw, larger on left side. Radium was begun March 21. Epilation was noticed on April 29 about the neck, and on the left side of upper lip on May 5. There is now improvement both in the growth and the glands. Dr. Watson testified that this growth had got smaller, as proved by careful measurements, and that operation would now cause less mutilation than would have been the case when the patient was admitted to the hospital. Mr. Godlee asked whether the tube plan was better than the applications spread out. Dr. A. H. Pirie said radium lost power if spread out too much. Mr. Pearce Gould said both cases were chronic and the severity in the second seemed greater than the exhibitor supposed. There seemed no actual cicatrization of the ulcer. Dr. Shaw said under the microscope there was no change in the cancer cells, but an in-

crease in the round-celled exudation, and no true scar formation on the surface. Mr. W. G. Spencer hoped epithelioma of the tongue would not be subjected to radium. He had seen a case in Paris which developed large cystic glands, encapsulated by malignant growth, and in his opinion so made much worse. Dr. Finzi, replying to the remarks reported above, said the tube was necessary for deep structures, but not for cutaneous cases. Decrease in the growth was certain and could not be due to less blood supply, as the opposite state was present. True cicatrization was not produced by radium, but a film was formed and under that healing took place.

Questions connected with uterine cancer have for a long time been anxiously discussed by gynecologists and obstetricians, as well as by the societies devoted to these subjects. At the 1907 meeting at Exeter the Section of the British Medical Association proposed a committee to consider the best means of promoting the earlier recognition of the disease, and the suggestion was further approved at last year's meeting at Sheffield. In anticipation of the approaching meeting a report of the committee has been prepared, which takes the form of an appeal to practitioners and another to midwives and nurses, and these appeals have been widely distrubted. The latter is naturally the more simple and may possibly be the more effectual, though it will have to meet much prejudice, especially among the more ignorant women. It starts by telling them with the emphasis of italics that cancer of the womb can be cured by operation when recognized early and reminds them that they often hear of some ailment before the doctor. It adds that cancer may occur at any age, in a woman who looks quite well and who may have no pain, discharge, or bleeding. At the same time it urges any nurse or midwife who is told of any irregular bleeding or discharge, slight or abundant, at any age, should insist on the doctor being informed without any delay, so that he may make an examination betimes and perhaps a valuable life be consequently saved.

The address to medical practitioners is a much more elaborate document and emphasizes their duties in a positive—not to say dogmatic—manner. But as the recommendations express the views of acknowledged experts, they are sure to be received with the consideration due to the importance of the subject. The curability of uterine cancer by operation in the early stage is the first point and the possibility of success in cases formerly thought inoperable has been shown since the adoption of the abdominal route. It is hoped that the number of cases seeking advice too late will be less and less as the knowledge of surgical resources becomes wider spread. The document asserts that the disease is at first local and often curable; that operation is the only satisfactory treatment and the earlier done the better the prospect and the risk is slight; that it is a grave error to omit physical examination in a case of suspicion and unjustifiable to delay or to treat by medicine in order to observe, as a diagnosis can be and ought to be cleared up in a few days. The symptomatology, types, position, mode of examination, and microscopical investigation are laid down. If the conclusion should be favorable, the patient will be reassured. Otherwise operation should be urged, its details being left to the operator. To sum up, the distinct duty of the practitioner is in every suspicious case to inform the patient of the necessity of examination, to make a definite diagnosis without any delay and if cancer be present to urge immediate operation.

The Conversazione of the Medical Society of London on Monday evening was very successful, as it usually is, and there was a large gathering of eminent men. Mr. C. B. Lockwood received the guests at the society's rooms in this, the 136th, session of the old institution. After the reception the annual oration was delivered by Dr. H. D. Rolleston of St. George's Hospital. He discussed pretty fully the branches of medical practice and intimated that the time was come for a somewhat different division of work. At present the physician, when he had formed a diagnosis, in many cases had to transfer the patient to a surgeon to treat him. It could very well be argued that this was absurd. On the other hand, it might be said that this was the natural development toward specialism. Be that as it may, the orator held that specialism would be more marked in the future and urged the importance of a thorough education in all departments before confining oneself to a specialty.

The orator also had something to say [illegible] more clinical kind. He spoke of diseases due to treatment, instancing the dermatitis of *x*-rays and its analogy to sunburn, Kaposi's disease, and squamous-celled carcinomata. The pathological effects of horse serum were equally interesting, for though they were usually trivial they are in rare cases serious, and have in fact been fatal in eighteen or nineteen recorded cases. Hypersensitiveness in connection with the injections of various vaccines was also cited and regarded as an important factor underlying the reaction of the several tuberculin tests. The idiosyncrasies displayed by some persons in regard to diet might be related to these manifestations.

St. Bartholomew's Hospital is passing through something like a financial crisis. This you may say is too often the case with hospitals. Barts, however, has a special claim on the city—from its position and also from its history—a claim which the city magnates have never been slow to admit. So again on Friday last the Lord Mayor laid before them the needs of their hospital and read a letter from the Prince of Wales, who as president had written to express his anxiety that some step should be taken in the matter. The debt stands at present at about £170,000 and the expenditure exceeds the income by some £12,000. The Convalescent Home costs only about £3,000 a year, so that its closure would not restore the balance. The Masters and Wardens of the city companies who had responded to the Lord Mayor's invitation to be present promised to put the case before their several courts. The Mercer's company had already promised £500.

Just a week previously the Lord Mayor opened the new Pathological Building, six stories high, which is equipped with all that is necessary to all branches of pathological investigation. The funds for this have been chiefly supplied by the friends of the school, but some supporters of the hospital have also assisted. Besides the accommodation for research, provision is made to facilitate the work of coroners and juries and the visits of friends of the deceased, as well as a mortuary for preserving the bodies, and of course a complete post-mortem department. There is also a communication with the museum, library, school, and out-patient department. A pathological clerk is appointed for each member of the hospital staff and every one of these clerks is provided with accommodation for his work separately from his colleagues, so that the clinical work for the staff will always be available and other investigations can be carried out without interruption. The provision for tutorial instruction is also complete.

Dr. Percy Boulton died on the 15th inst after a long illness, in his sixty-eighth year. He was M.D. Edin. 1862 and practised for a time in the provinces, but came to London in 1865. In 1878 he joined the College of Physicians. He was physician to the Samaritan Hospital for about thirty years and on resignation was elected consulting physician. He was an active member of the Obstetrical Society and for six or seven years editor of their Transactions. He was vice-president 1890-92. His contributions were mostly to the society, but he also edited an edition of Tanner's Index.

The death is announced at Las Palmas of Dr. Edward George Whittle, aged fifty-nine, who practised many years at Brighton and was president of the Medical Society there and surgeon to the Alexandra Hospital for Children. He was M.D. London and F.R.C.S. Eng.

Lieutenant-Colonel James Wilson, of the R.A.M.C. (retired) died on the 15th inst in his seventy-fourth year.

OUR LETTER FROM THE PHILIPPINES

(From Our Regular Correspondent.)

THE SANITATION OF MANILA—LEPER SEGREGATION—SMALLPOX—FILIPINA NURSES—NEW LEGISLATION—THE PLAGUE.

Manila, P. I., April 10, 1909.

THE conclusions of the Manila Merchants' Association, based upon evidence which they collected, that the unsanitary conditions which the local health officials have repeatedly brought to the attention of the Municipal Board for the purpose of having them corrected, were largely responsible for much of the cholera that has been present in Manila during the past few

years, had a most decided effect upon public opinion, and no doubt induced the Governor-General of the Islands to appoint a committee for the purpose of studying and making recommendations upon the following points:

1. The location and extent of residence districts of the city of Manila which are swampy in character or overflowed during the rainy season.

2. The cost of draining such districts, or if that be impracticable, the cost of raising them to a level which will make them sanitary and fit for residence purposes.

3. The location and extent of areas which are so unsanitary as to make it inadvisable that they should continue to be occupied for residence purposes until they are drained or filled in.

4. The cutting of streets and alleys through congested unsanitary areas, and providing sanitary sites for nipa shack dwellers forced out of the strong material districts; and

5. Whether the expense of the draining or the filling in of swampy, overflowed, or low-lying districts or areas should be paid for by the property owners or by the municipal government. In case the expense is to be paid by the municipal government, can this expense be met out of current revenues, or will it be necessary to impose a special tax for that purpose?

This committee has now commenced to hold regular sessions, and although sufficient time has not yet elapsed to complete the main part of its work, yet its influence upon local sanitary conditions is already quite noticeable and many sanitary reforms are receiving the attention of the Municipal Board which have remained unnoticed in the past. Large tracts of ground have been set aside by private individuals, the Catholic Church and the Government, which are rented free for the first six months, and only a nominal rental to be charged thereafter. To these sites more than 700 houses, in which over 3,000 persons resided, have been removed from low, unsanitary sites. The new sections are traversed by wide streets and alleys, and have drainage and water systems. They are therefore accessible to the sanitary carts, so that garbage and rubbish can be readily removed and proper toilets installed. The houses on the sites which were abandoned were not built on street lines; in fact, they often consisted of nothing more than a closely built collection of houses which were only reached through a single narrow passageway. They were inaccessible to the fire department apparatus, often formed harboring places for criminals, and it was shown that the death rates in such sections were often much higher than in other places in the city. The ground was flooded at high tide, and the effective disposal of human excreta under such circumstances was practically impossible. The opportunities which such conditions gave flies, insects, and even the hands of the people to convey cholera organisms, especially where many human "cholera carriers" existed, can be readily understood. As a whole, the residents of these sections have removed their houses without much opposition. Some have refused to obey the orders issued and the cases have reached the court of first instance. The court, however, rendered its decision in favor of the Bureau of Health, that it has the right to declare premises unsanitary and to order the occupants to vacate. At the present rate great improvements may be expected in Manila during the next few years and a still lower death rate confidently hoped for.

Leper Segregation.—The work of collecting lepers still goes on. All islands except Mindanao and the provinces of Cagayan, Isabella, and Nueva Vizcaya have been gone over at least once. Of a total estimate of 3,500 lepers it is believed that there are yet about 600 lepers to segregate.

In making trips for the collection of lepers many cases of extensive ulcerations which result in atrophy of the feet and hands and often of the entire limbs are encountered. The contractions produced by the scar tissue often cause severe deformities. Heretofore, a tentative diagnosis of syphilis has been made in these cases on account of the fact that many of them respond to the therapeutic test and spirochæte are found in the lesions. Recently, however, it has been observed that many of these cases show the scars of yaws, from which it would appear possible that the above described individuals may be afflicted with a tertiary form of yaws. A study of this question is proposed in the near future.

Smallpox has made its appearance in a number of places throughout the islands, but it is very rarely that a person who shows evidence of vaccination contracts the disease and no death has come to the notice of the Bureau of Health in which a good vaccination scar could be found.

Some time must necessarily elapse before the complete elimination of smallpox from the islands can be expected, owing to the deleterious influence which the climate has on vaccine and the difficulty which is encountered in getting the vaccine to remote places in potent condition.

Filipina Nurses.—The training school for Filipina nurses which is being jointly conducted by the Bureau of Education and the Bureau of Health has now reached its third year, and from all appearances the Filipina women at the end of their four years' course will be as competent as their American sisters. It is now proposed to send a number of the Filipina nurses to the United States to be trained as instructors of nurses, in order that they may return here and conduct schools for their own people.

New Legislation.—The bill placing the Director of Health on the Municipal Board has already passed the Commission and is now before the Assembly.

Plague.—Plague has made its reappearance in Hongkong, about six cases being reported for the week ending April 3, which is a very much smaller number than usually occurs during this period of the year. Plague has also made its reappearance in Amoy, and the Public Health and Marine Hospital Service has imposed a quarantine against Amoy of seven days on all steerage passengers or persons who ordinarily travel as such. Lately the United States has stationed a medical officer at Amoy.

Negotiations are now under way for the construction of a steam disinfecting plant by the steamship companies that do business in Amoy, the same to be under the general supervision of the medical officer of the United States. This will make another outpost of sanitation which the United States is establishing throughout the world in order to protect it against the invasions of dangerous, communicable diseases.

Progress of Medical Science.

Boston Medical and Surgical Journal May 27, 1909.

Cancer of the Cervix Complicating Pregnancy.—After a comprehensive though brief reference to the literature of this subject, J. T. Williams reports seven cases. He gives some interesting figures as to the frequency of cervical cancer complicating pregnancy. Thus in 100,000 pregnancies cancer of the cervix occurred 57 times. He has found 605 cases reported, 446 of these being since 1886. The frequency of the reverse condition, viz. pregnancy complicating cervical cancer, he estimates as 64 pregnancies in 4,062 cancers. He adds an elaborate bibliography, and concludes as follows: (1) Cancer of the cervix does not prevent conception, and in a large percentage of cases antedates the pregnancy. (2) Cancer of the cervix, as a rule, grows with great rapidity during pregnancy and the puerperium. (3) While the prognosis of cancer of the cervix is more grave during pregnancy, it is not hopeless. (4) When an operable cancer of the cervix is discovered during pregnancy, no matter at what period, immediate operation is indicated. (5) Up to the present time statistics favor the Wertheim operation, preceded by cesarean section if the child is viable. (6) In inoperable cancer with a living child at term, conservative cesarean section is the method of choice. If the child is dead or premature a suprapubic delivery will give the best result.

The Classification of the Malarial Plasmodia.—C. F. Craig, of the U. S. Army Service, reviews the work previously done and gives a classification based on our current accepted knowledge. He believes that the estivo-autumnal fevers are due to two distinct parasites and as (to his knowledge) the quotidian plasmodium has never received a distinct name, he suggests for it *Plasmodium falciparum quotidianum* regarding it as a sub-species of *P. falciparum*. His classification in full is as follows: Division, *Protozoa;* class, *Sporozoa;* order *Hæmosporidia;* genus, *Plasmodium;* species, (1) *P. malariæ*, Marchia et Celli, quartan malarial plasmodium; (2) *P. vivax*, Grassi et Feletti, tertian malarial plasmodium; (3) *P. falciparum*, Blanchard, Estivo-autumnal plasmodium, tertian type; sub-species (4) *P. falciparum quotidianum*, Craig, 1909, quotidian estivo-autumnal plasmodium.

New York Medical Journal, May 29, 1909.

Indications for Operations on the Stomach.—J. J. Gilbride says that the most common condition of the stomach for which an operation is performed is stenosis of the pylorus, and the onset of symptoms of stenosis at this point with or without previous stomach disturbance in persons over 35 years of age should receive prompt surgical attention. Cancer of the stomach is strictly a surgical disease when it is recognized sufficiently to permit of an operation. As this disease appears most frequently at the pylorus the initial symptoms may be those of stenosis, at or after the thirty-fifth year. In certain cases of extreme cancerous involvement of the stomach a jejunostomy may be advised to prevent death from starvation. So also a gastrostomy may be advised in carcinoma of the cardia. The frequency of the occurrence of cancer on the basis of gastric ulcer calls for more aggressive treatment of chronic ulcer of the stomach. The treatment of acute gastric ulcer is medical unless some accident such as perforation should occur or some other complication should develop. Continued bleeding in ulcer, even if of small amounts, and repeated hemorrhages demand surgical treatment. A single large hemorrhage is best treated medically. In chronic ulcer when the patient fails to get well after a reasonable time under proper medical treatment, or when there are relapses of symptoms, the patient should be operated on. Duodenal ulcer which occurs most commonly in the first few inches of the bowel always calls for operation. It is often difficult to distinguish it from gastric ulcer. The great majority of cases of gastroptosis can be treated by mechanical dietetic and medicinal measures. An operation is necessary only in those instances in which there is an obstruction due to a kink or other cause. Gastroenterostomy has been done in a few refractory cases of hyperchloridia. A few cases of atonic dilatation of the stomach have been reported in which gastropletion was done with beneficial results. Adhesions which cripple the functions of the stomach call for operation. Benign tumors call for operation. So also operative intervention may be required in instances of acute dilatation of the stomach not relieved by lavage and in hernia through the linea alba interfering with gastric mobility.

Dacrocystitis.—A general description of this condition is given by A. T. Herzig. In the catarrhal form or blenorrhea of the lacrymal sac we should relieve any intranasal obstruction of the duct, have the patient express the secretion frequently and use astringents and at the office express all secretions from the duct and then with a small lacrymal syringe, clean the sac out first with some cleansing solution, such as sterile water, or a very much diluted Thiersch's solution, following this by an injection of a one per cent. silver nitrate solution. In the acute form, if we are unable to prevent the formation of an abscess we should bring the latter to a speedy termination by making an artificial opening. The author makes a large incision, curettes the abscess cavity, and then drains it with sterile iodoform gauze. He touches the inside of the sac with a ten per cent. solution of silver nitrate, this being done daily at first, later at less frequent intervals. Otherwise, the abscess is treated the same as any other phlegmon. It is bad to incise the abscess before fluctuation has taken place. Later on, the duct should be catheterized to relieve any stricture that may be present. In the chronic form, the medical treatment consists of gradually dilating any strictures that may be present and syringing the sac first with a cleansing solution and then with a one per cent. solution of silver nitrate daily, and later on at less frequent intervals. The home treatment for these cases consists in giving the patient an astringent eyewash and having the patient express the secretion from the duct as fast as it accumulates. If this does not result in an improvement within a reasonable time, that is to say twenty treatments, which extend over a period of two or three months, the author advises complete enucleation of the sac. It is wrong to advise enucleation at first, as there are a great many of these chronic cases that can be cured by this treatment.

The Otitic Significance of Tonsillectomy with Reference to Digital Enucleation.—H. B. Blackwell describes his method of digital tonsillectomy, nothing essentially new being presented. He regards the operation as curative and prophylactic in both acute and chronic suppurative and non-suppurative inflammation of the middle ear.

Journal of the American Medical Association, May 29, 1909.

Resistance to Cancer.—H. Gideon Wells notes the still unsatisfactory results in the surgery of cancer, and asks if we have any right to expect enough better results to preclude the desire to find some other means than surgery for its relief. He admits that there seem to be at present some facts in the biology of tumor growth that indicate a possibility of success in this search. To obtain a specific therapy for an infectious disease two methods are available. We may either stumble on a cure empirically or we may study the way the body defends itself and endeavor to assist or intensify this natural method. Perhaps we may consider Ehrlich's method of therapeutics, by more or less empiric methods obtaining something that has a favorable influence on an infection, and then enhancing this influence by adding various and sundry radicles to the original more or less hopeful appearing substance. The most logical method at present, Wells thinks, is to learn how the body cures itself when natural recovery takes place and then, if possible, to enhance this attempt. We may start with the assumption that no malignant growth ever succeeds in growing to the extent to which its natural proliferative power entitles it. One of the commonest occurrences in malignant tumors is necrosis or less extreme degenerative processes, and such tumors are influenced by the state of health or vigor of their host. Their progress is generally much less rapid in the old than in the young. The fact that the rate of growth of cancer is in direct proportion to the nourishment and vitality of the patient, quite the opposite from what occurs in infectious diseases, would seem to make for the non-parasitic nature of such growths. Of greater interest to us are the instances in which malignant tumors show healing changes, independent of such conditions, which may appear as retardation of growth or recurrence after removal, retrogressions of secondary growths after removal of the primary tumor, of disappearance of portions of tumor tissue after an incomplete palliative operation or even spontaneous healing of a primary tumor without operative intervention. Total healing without operation and without recurrence is practically unknown, but this does not necessarily mean that it may not occasionally occur. Two cases are referred to which suggest that when cancer follows chronic trauma the defensive mechanism of the body may be able, in the early stages, to overcome the cancerous proliferation if only the original irritant is removed. A number of other cases are reported, from various authorities, of spontaneous healing of cancer, but the evidence concerning the healing of portions of carcinomas left after operations is far better than of cases in which healing has occurred when no operation has been done. A large part of the paper is taken up with references to cases of these forms of healing, and he reproduces the notes of Dr. Alexander Harvey of a case which he has had a chance to study, in which the secondary growths disappeared after the removal of the primary one and the autopsy revealed the scars. The patient died, with symptoms resembling uremic coma, very probably from a cerebral lesion, after eighteen months of apparent health succeeding the operation. The examination of the head itself was not permitted. Other similar or somewhat similar cases of other surgeons are also referred to. Just how the removal of the primary growth thus influences the metastases is hard to say, but Wells suggests, as possible, a sort of autoimmunization from cancer substance forced into the circulation by the operative procedure. As supporting this view he adduces a suggestive case described by Mackey. The conditions under which metastases are formed is also another source of evidence of the resistance of the body to cancer. The least resistant organs are the ones that are affected. Just now our chief hope lies in experimental work with transplanted tumors in animals, in which, besides a natural congenital immunity to some extent, there is sometimes produced a varying degree of acquired immunity, both active and passive, the first more successfully than the last. There is, however, some evidence that the blood of animals spontaneously recovering from tumors may render animals more or less resistant and even cause healing of tumors in inoculated animals. All these accumulated observations during the few recent years of cancer research give much hope that eventually we may do something for the cancer patient besides radical operation.

Blood Transfusion.—R. T. Frank and G. Baehr publish the results of further experiments with the use of a vascular bridge or link composed of a fresh animal blood-vessel, first described by them some months ago. They mention the difficulties of other methods and enumerate as the advantages afforded by the use of the bridge: (1) A sufficient length of vessel is ob-

tained without extensive dissection of the artery of the donor or the vein of the recipient; (2) the link as now prepared by them has lost some of its elasticity and is well-stretched, so as to afford an unobstructed lumen within the cannulæ, and a technique familiar to every surgeon (from its similarity to that used in intravenous infusion). The links are prepared by cuffing dogs' carotids at both ends over Crile's tubes, stretching them on a wire frame and fixing them for twenty-four hours in a 2 per cent. solution of formalin. The formalin is removed by two changes of sterile salt solution (thirty to sixty minutes each), and the prepared pieces, or links, as they are called, are permanently preserved in paraffin oil. Full details of the method of preparing these links are given, also of the technique, which closely resembles that so familiar in intravenous saline infusion, the infusion cannula being represented by the cuffed link. Tests were also made of the sterility, some of them rather severe, but no growth, even when infected with *Bacillus anthracoides*, occurred after the tubes had been immersed in 2 per cent. formalin over ten hours. Out of twenty-six experimental transfusions performed by means of these prepared links, but one failed, and this was due to the kinking of the vessel during its preservation. These cases are tabulated. The authors say that, as far as can be predicted, the use of these links affords a simpler and easier method of transfusion than those hitherto described, and they hope that it may soon be tried on the human subject.

Angina Pectoris.—W. W. Kerr reports five cases of fatal painless angina which illustrate the frequency with which this condition may occur in connection with disease of the right side of the heart. He does not maintain that it is limited to cases in which the right ventricle alone is affected, since it may occur when both ventricles are diseased, but the presence of the symptom signifies that the right ventricle is seriously diseased as well as the left. In all the cases reported three features were noted especially: (1) There were changes in the wall of the right ventricle; (2) during the attack the pulse was small and feeble; (3) after the attack was over and in the intervals the radial pulse was of good quality. These he uses to explain this condition. The muscle being already deficient in power, any sudden or unusual call on it might produce the symptom. When the right ventricle only is affected we can easily understand why the radial pulse improves so rapidly when the seizure is over, but when the cardiac oppression and respiratory distress is simply intercurrent on the symptoms of general cardiac disturbance such improvement is not to be expected. According to Kerr, painless angina is more common than one would suppose from the infrequency with which it is reported, but probably it is not always recognized and the patient's symptoms are attributed to hysteria or some reflex disturbance. When they occur with a dilated right heart or distinctly atheromatous changes, the diagnosis is easy. But when physical signs are absent it is often difficult to give a positive opinion. If between the attacks the patient has a constant feeling of weight or destress over the precordia and has a tendency to take occasional deep inspirations, there is a strong probability that the right ventricle is affected and this is made certain if the symptoms are invariably produced or aggravated by exertion. This form of angina is altogether different from the painful type and in many cases requires entirely different treatment. In all probability it is due to some local obstruction in the coronary circulation, which may be organic, spasmodic, or a combination of both. The fact that the radial pulse varies in different cases, the tension being sometimes high, sometimes low, indicates that the attacks cannot be invariably attributed to increased resistance in the peripheral circulation and they cannot be explained, moreover, solely by the condition of the cardiac muscle itself. The causes of the obstruction are not the same in every case, and local vasomotor spasm is nothing new in medicine; spasmodic contraction may occur in the finger, in the body surface, or even in the vessels of the brain, and it is perfectly possible that there might be local obstruction from a minute embolus or sclerosis of a coronary branch. The changes in peripheral blood-vessels are, as Kerr believes, more coincidences than causes, and degeneration of the cardiac muscle may be the consequence of the impaired coronary supply, but not the cause of the seizures. The treatment of the two forms of angina will be entirely different during the seizures, but as a rule identical in the intervals. Since cardiac asthma is due to failure of the right ventricle, rapidly acting stimulants, such as caffeine, camphor, or strophanthus, will be indicated for the attack; while angina pectoris on account of the spasm will call for vasodilators such as amyl nitrite or nitroglycerine. It is not infrequent for the subject of coronary spasm to suffer also from a weak heart and then a combination of heart stimulant and antispasmodic is demanded. Between the attacks, the treatment is the same as that recommended in cases of chronic myocarditis and arteriosclerosis. A well-regulated diet is of the utmost importance; avoidance of mental and physical strain, and exercise, carefully adapted to the individual, are also advised. Arsenic and the prolonged use of iodides in small doses will often be found to have a beneficial effect on both cardiac muscle and the blood-vessels. Lastly, we should not neglect the elimination of toxic substances resulting from physiological activity or food metabolism.

The Lancet, May 22, 1909.

Normal Menstruation, with Absence of the Uterine Body.—A. Brown relates the history of a woman of fine physique whose menses had commenced at 13 and had continued regularly till she came under observation at the age of 28 for the treatment of sterility. The periods were normal as to amount and duration. The patient was an affectionate wife and fond of children, but sexually cold. She had been married three years. Under examination per vaginum and bimanually no uterine body could be made out. The cervix was of normal size and shape and the blood on the examining finger evidently came from the external os. Under general anesthesia another examination confirmed the previous findings. The author admits that a direct examination of the pelvic contents might have demonstrated the existence developmentally of a uterine body. No doubt the vaginal cervix supplied the monthly loss of blood.

Disappearance of a Tumor (Sarcoma?) Following Injections of Coley's Fluid.—The patient of W. C. Ashdowne was a woman of 45 years whose right arm had for seven weeks presented a swelling. Her only symptoms had been swelling and weakness on using the arm. Examination showed a hard, well-defined fusiform enlargement in connection with the lower part of the right humerus. The superficial veins were a little enlarged, elbow joint was normal in movement, arm was painful on use or on application of firm pressure, and there was an enlarged gland in the right axilla. There was no history of injury or syphilis. Antisyphilitic treatment was given for ten days, but the swelling steadily increased. She was advised to have an exploratory incision made, followed, if necessary, by amputation. This was declined and the use of Coley's fluid selected as an alternative. The author began with half-minim doses and increased them by quarter, half and one minim until a maximum of nine minims was given. The first injections were made in the arm outside the growth limits, but the later were made directly into it, twenty-three being given in all. They were followed by pain and swelling at the site of injection, with general malaise, headache, nausea and vomiting, with pains in the limbs and joints, followed by subcutaneous hemorrhages resembling bruises, but with only slight rise of temperature and increase of pulse rate. This treatment was continued for some time and finally the swelling had almost disappeared and the structure and outline of the bone had resumed the normal appearance.

The Cause of Death After Operation in Acute Appendicitis.—C. A. Morton notes that in many children who go through the operation well, unfavorable symptoms arise twelve hours or more later, such as pulse failure, vomiting, restlessness, drowsiness, delirium, coma and jaundice. There is little, if any, rise of temperature, no abdominal pain, rigidity or tenderness, yet the patient dies. What are these symptoms due to, asks the author, and what is their relation to the operation? They are probably a manifestation of toxemia. Perhaps sponging the peritoneum however gently may so damage it as to allow of absorption of inflammatory and poisonous material. In some cases the terminal symptoms suggest delayed chloroform poisoning. Lumbar puncture anesthesia might be employed in those cases. If we were convinced that the symptoms were due to absorption from the raw surface of the wound, we might take measures to destroy its absorbing surface by applying a solution of zinc or pure carbolic acid and packing between the drainage tube and the raw surface with iodoforin gauze. Even though absorption from the raw surface is quite a doubtful cause, it might be well, especially in children, to apply a little carbolic to the raw surface around the drainage tube, and to pack iodoform

gauze around the drainage tube, thus separating it from the raw surface. A suction drainage apparatus might be employed until the wound was granulating so as to drain the pus right away, or we might irrigate (if the peritoneal cavity is well shut off from the abscess sac) frequently or even continuously with salines so as to wash out in a very dilute form all toxins. Abstracted histories are given of twelve cases.

Therapeutic Effect of Radium Emanations in Some Diseases of the Skin.—H. Radcliffe Crocker relates his experience in a series of cases. In one a thin gelatine jelly had the solution of the emanations diffused through it and was applied to the fingers for eczema, and the results were very satisfactory. They were duplicated in a case of psoriasis of the knees. Again the radium emanation was dissolved in 2 c.c. of distilled water and injected subcutaneously in the interscapular region. Two cases of mycosis fungoides were thus treated with great benefit, though not with entire success. In a third case of a general chronic scaly eruption the results from injection were practically negative. The author says that the results are in their entirety distinctly encouraging and justify a further use of the emanation therapy. Radium is, he says, like a milch cow: able to give a daily supply for a considerable period, though, again like that useful animal, requiring intervals of rest also. We are not yet able to differentiate between the relative effects of the alpha, beta, and gamma rays. Ramsay estimates that in the gelatin method such as described, we lose 50 per cent. of the alpha rays, while all the beta and gamma rays remain available. On the other hand, by a simple solution in water of all the emanations, subcutaneously injected, we secure the entire ray strength. In the author's case the injections caused several times painful swellings, and this is one limitation of the method.

British Medical Journal, May 22, 1909.

Lactic Acid Bacilli in Melancholia.—Commenting on the fact that melancholia often arises from intestinal autointoxication, H. J. Norman reports one case of hypochondriacal melancholia, the patient being a male, jaundiced, with sallow complexion, and an obstinate constipation. He was placed on a diet of soured milk and lactic bacilli tablets, and the results were immediately apparent. The bowels moved easily and the author thinks that the ordinary aperient treatment would have produced the marked changes noted in the general condition. Mentally, the patient became much brighter and began to enjoy the ordinary occurrences of life.

Partial Thyroidectomy.—T. P. Dunhill considers this question with special reference to exophthalmic goitre and makes observations on 113 cases operated on under local anesthesia. Various phases of the question are: difference in type of the growth, response to operative treatment, when to operate, anesthesia, how much of the gland should be removed, and the crushing of the gland substance. Of his own operations, 2 were for malignant goitre, 88 for exophthalmic with 1 death, and 23 for parenchymatous or adenomatous with no death. Of the exophthalmic cases, 52 were typical cases with classical symptoms; 15 of these 52 had part of the second lobe subsequently removed. Of this class, in every case in which the removal of the larger lobe has not effected a cure, the removal of part of the second lobe has done so (always excepting the one case which died). In many of the latter cases one and a half lobes were removed at one operation. Eight cases had irregular heart beats and pronounced edema. Of these, 4 had part of the second lobe subsequently removed. The author had a third operation because the upper pole left after the second operation was unsightly. The original goiter had been of immense size. Every one of these stood the operation well. All are still alive but one. She had made a splendid recovery, and three months later went to her country home, engaged in a round of festivities for a week in a climate with the temperature of over 100° in the shade most of the time, and died very suddenly at the end of it. This case, before operation, had edema of the legs, body, and arms. There were striæ around the elbows like those on the abdomen of a multiparous woman, and the evening before operation fluid was drawn off from both pleural cavities. After the operation she passed immense quantities of urine each day. Every trace of edema disappeared until the week in which she died. All the others are very much improved. Two cases had irregular pulse, had intense tachycardia, but no glands enlarged and no exophthalmos. Of these, in one case the author subsequently removed a small piece of the lower pole of the left lobe. This represented the only failure of the series. Five cases of secondary exophthalmic goiter are reported. In this class cure is rapid and complete. Seven only of the cases of exophthalmic goiter among these students by the author occurred in males, which shows strikingly the great preponderance of females among the subjects of this disease.

The Surgery of Lingual Thyroids.—W. Stuart-Low comments on the anatomy of thyroid deposits in this situation and says that as excision of these lingual deposits has been followed by myxedema the surgeon should always consider carefully the question whether or not in these cases the normal thyroid in the neck is sufficiently developed to carry on itself the thyroid function in the body. In case of absence or small size of the cervical thyroid, one would hesitate to operate except when the size of the lingual deposit should prove dangerous to life. Enough of the lingual deposit should be left to carry on the thyroid function (in case of cervical absence) even at the risk of subsequent recurrence. Low advises the splitting of the tongue from tip to base, thus permitting thorough eradication. He prefers this method to that of subhyoid pharyngotomy, for while the latter is admirably adapted for the removal of growths at the entrance to the larynx, it has for the removal of growths at the base of the tongue the great disadvantage of opening a communication between the septic cavity and the large cervical wound. Moreover, if the transverse incision is carried any distance beyond the hyoid bone, the superior nerve may be cut, and the larynx is rendered insensitive, permitting food and discharge to enter the cavity and expose the patient to the danger of foreign body pneumonia. The procedure to be followed after exposure of the growth depends on its size. Incision with curetting and cauterization may suffice in some instances, but the author contends that it is a very much better plan to extend the operation to an excision of the capsule which, he says, consists of the dilated remains of the thyrolingual duct.

Deutsche medizinische Wochenschrift, May 6, 1909.

The Etiology of Puerperal Fever.—Ahlfeld devotes a long article to a review of the opinions held by the different schools of gynecologists in reference to the origin of puerperal infection. Menge and Krönig were the first to make a complete bacteriological study of puerperal fever and of the female genital passage, coming to the conclusion that the healthy vagina is free from pathogenic organisms, especially streptococci. In opposition to this claim Ahlfeld cites the numerous instances of septic endometritis following prolonged and ineffectual labor, in many of which no examination whatever has been made, and therefore no germs introduced from the outside. However, Krönig's views were accepted, the entrance of bacteria in cases of labor being explained by supposed impossibility of disinfecting perfectly the examining hand of the physician. Gradually, however, Ahlfeld's teachings concerning the constant presence of pathogenic bacteria in the female genital canal have become accepted. His claim that a complete disinfection of the hand is a possible and quite easily attained result has also been verified. The real light upon the origin of puerperal fever is thrown by the fact that every woman bears in her genital canal potential excitants of puerperal infection. The occurrence of the latter depends in great measure upon the existence of circumstances predisposing to autoinfection.

Lymphatism and Scrofula.—Moro says that lymphatic constitution and scrofula are clinically so similar as to be practically indistinguishable. As it has been abundantly proved that scrofula is a symptom complex accompanying a certain type of infection with tubercle bacilli, it was thought that lymphatic diathesis is also an expression of a similar infection. The application of the cutaneous test for tuberculosis shows that this view is not correct. Scrofulous children give a positive reaction; lymphatic children often fail to do so. Moro considers that lymphatic diathesis simply forms a very favorable ground for infection with the tubercle bacilli, without being due to such an infection. The history of most scrofulous children contains data showing that a lymphatic diathesis was present in them in the first years of life. The earmark of a lymphatic tendency is seen in the proneness of the tissues to suffer very prolonged and low-grade inflammations, during which the lymphatic tissues are primarily or secondarily affected. Moro has been able to corroborate his view of the relation of scrofula and lymphatism by observing the development of a positive cutaneous reaction in infants who did not give such reaction in the beginning of their illness. The author believes that the appearance of the reaction was due in such cases in all probability to the implantation of an infection with tubercle bacilli upon a previously simple lymphatic organism.

Book Reviews.

Operative Midwifery. By J. M. Munro Kerr, M.B., C.M. (Glas.), Fellow of the Faculty of Physicians and Surgeons, Glasgow; Obstetric Physician, Glasgow Maternity Hospital; Gynecologist, Western Infirmary; President of the Glasgow Obstetrical and Gynecological Society; Late Assistant to the Regius Professor of Midwifery, Glasgow University. With 294 illustrations in the text. New York: William Wood & Company, 1908.

This book is very much on the lines of Barnes' "Lectures on Obstetric Operations," which was published forty years ago, and the last edition of which is now twenty-three years old. As the author reminds us: "At that time antisepsis and asepsis in midwifery were only beginning to be discussed; abdominal palpation for the diagnosis of presentations and positions of the fetus was practised by only a few; the revival of symphyseotomy had newly begun; the modern operation of cesarean section had been described by Sänger only a year or two previously; while operations upon the pregnant or parturient woman for abdominal and pelvic tumors were had recourse to only in the most desperate circumstances." The present work contains more than is implied in its title; and besides Operative Midwifery as generally understood, chapters are included on abortion, uterine hemorrhages, and accidents that can happen to mother or child. The contents of the volume will fall neatly into five divisions: the first, dealing with dystocia the result of faults in the forces; the second, with dystocia the result of abnormalities affecting the fetus; the third, with dystocia the result of abnormalities affecting the parturient canal; the fourth, with obstetrical operations on mother and child; and the fifth, with uterine hemorrhages and the various accidents that can happen to mother and child. All the chief difficulties that are liable to be encountered in obstetrical practice are discussed in this volume, and the reader is shown what is believed to be the best way of overcoming these difficulties. The author generally gives the various views and opinions that have been held by different authorities, and at the same time makes clear his own preference; at times he is in the minority, but he can always give a reason for what he recommends. Among the best chapters in the book is the one on Rupture of the Uterus, in which, by the way, occurs one of the very few misprints which we have found, the author giving 67 per cent. as his mortality in hysterectomy for ruptured uterus, whereas the figures indicate a mortality of only 33 per cent. A few names are misspelled, and (in the preface) Professor Edgar is said to be "of Philadelphia." The book is well illustrated, and most of the illustrations are original. The literature of the subject is very fully given, the views of others are adequately presented, and the author's own opinions, based upon an extensive experience, are clearly stated. Altogether this is a work of sterling merit, and will prove invaluable as a companion to the ordinary textbooks on obstetrics.

Self Help for Nervous Women. Familiar Talks on Economy in Nervous Expenditure. By John K. Mitchell, M.D., Fellow of the College of Physicians of Philadelphia; Attending Physician to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases. Philadelphia: J. B. Lippincott Company, 1909.

This little book was written chiefly for nervous women, but male sufferers from functional nervous disorders, and the families and friends of the nervous, may all find in its pages much good advice. The author speaks of the terrible damage which may follow the use of such instruments as are employed in the Emmanuel method, in the hands of men moved only by enthusiasm without knowledge.

Instinct and Health. By Woods Hutchinson, A.M., M.D. New York: Dodd, Mead & Company, 1908.

This is a practical and thoroughly readable volume dealing with the general subjects of health, exercise, and diet, so much in the public eye during the past two or three years. The author takes in general a sane and wholesome view of these problems, and if he is not always convincing in his arguments he does succeed in making them entertaining by his originality and broad sense of humor. The book is written largely from the ethnological viewpoint, the author seeming to hold the opinion that in most respects we need to go "back to nature" and to the simple ways of our ancestors if we would enjoy life and health to the full. Dr. Hutchinson has little patience with faddists of whatever kind, and he succeeds remarkably well in showing up their foibles before the strong light of reason and scientific judgment. The titles of various chapters, such as The Ancestry of Health, Diet Delusions, Sleep and Its Significance, Baths and Bathers, and Clothes and the Woman, show how fully the general daily activities of the individual are touched upon and amplified. A chapter on The Sins of the Shoemaker will appeal to the orthopedists, who have been trying so hard of late to teach their patients the importance of correctly clothing the feet in order to prevent deformities and ungainly gait. People in middle life will find much in the final chapter on The Health of the Middle-Aged Man that will help them to a wholesome philosophy of living. In Dr. Hutchinson's words, "It is pure selfishness to wish to live longer than is best for the following generation. Our life is not for ourselves, but for the race, and if we have set that the tiniest notch higher upon its upward course, it is enough."

Die rationelle Behandlung der Zuckerkrankheit. Von Dr. A. Lorand, Brunnenarzt in Karlsbad. Second edition. Berlin, 1909: August Hirschwald.

The second edition of this monograph has been enlarged by the introduction of the results of recent work on the metabolism of diabetes, especially those researches leading to the theory of a relationship between the thyroid gland and diabetes. The writer discusses very fully the practical side of the dietetic treatment of diabetes and commends the use of natural mineral waters.

Lectures on the Pathology of Cancer. By Charles Powell White, M.A., M.D., F.R.C.S. Pilkington Cancer Research Fellow. Manchester: University Press, 1908.

Dr. White has presented in a very attractive form his lectures on cancer delivered in the University of Manchester in June and July, 1908. They present not the whole pathology of cancer, but rather a general outline of the subject dealt with in an original manner. Dr. White follows the practice of many other recent writers in classing all malignant tumors under the term "cancer;" he defines such a tumor as mass of organs, cells, or tissues, atypically arranged, growing at the expense of the organism, without subserving any useful function therein. He then gives a somewhat complex classification of tumors, which is designed rather to correspond to the appearances observed with the microscope than to fit into any theory of the origin of tumors from the different embryological layers. An interesting discussion of the differences between malignant and benign growths follows: Dr. White pictures very impressively the difficulties in differentiating the two varieties of tumor and insists upon the necessity of informing the pathologist of the clinical aspect of the case in addition to furnishing him with a good specimen, including, if possible, some of the surrounding tissue. The third part of the book is devoted to a discussion of the etiology of cancer, Dr. White showing himself a strong opponent of the parasitic theory. This part, of course, contains little original thought, but presents a fair outline of the subject. The last part of the book considers the treatment of cancer, the facts learned from the consideration of the pathology of malignant disease being utilized for many valuable hints in this important division of the subject. The book is illustrated by a number of plates, some of them giving the appearances obtained by the use of polarized light.

Clinical Diagnosis and Treatment of Disorders of the Bladder with Technique of Cystoscopy. By Follen Cabot, M.D., Professor of Genitourinary Diseases, Post-Graduate Medical School; Attending Genitourinary Surgeon, City and Post-Graduate Hospitals, New York. Illustrated. New York: E. B. Treat & Company, 1909.

In this little book of 224 pages the author often sacrifices literary elegance to presentation of much material. In the latter regard he more than complies with the promises made in the preface, wherein he frankly says he does not "attempt to cover the whole subject under discussion." The monograph will especially appeal to the author's pupils and to those who are at least somewhat advanced in genitourinary work. While the author's "chief object is to teach general practitioners the principal methods of diagnosing and treating disorders of the urinary bladder," he often goes afield therefrom and does so instructively. Thus in his chapter on Case Recording, he presents a most excellent scheme for the establishment of a bureau through which the public is to be instructed in the ravages produced by venereal diseases. He minutely works out the duties of such an educational bureau and reproduces in full the three leaflets he uses in his clinics and hospital services, namely, (1) Instructions to those having gonorrhea, (2) Instructions to those suffering from syphilis, and (3) Some Axioms of Health. In the same chapter the author emphasizes that "if the cost to the world in suffering and lives could be estimated, it would be found far greater than that caused by tuberculosis." The publishers have most excellently contributed to the book with superb illustrations, clear type, and very good paper.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Sixtieth Annual Meeting, Held at Atlantic City June 8, 9, 10, and 11, 1909.

(Special Report to the MEDICAL RECORD.)

HOUSE OF DELEGATES.

First Day, Monday, June 7.

THE FIRST VICE PRESIDENT, DR. T. J. MURRAY, OF BUTTE, MONT., IN THE CHAIR.

President's Address.—Dr. HERBERT L. BURRELL of Boston presented this address, which was read by the first vice-president, Dr. T. J. Murray, and which consisted of a few suggestions and recommendations. The growth of the American Medical Association, the extension of its work, and the importance of the questions constantly coming before the organization would make evident the wisdom of increasing the number of trustees. Dr. Burrell was of the opinion that making the president, ex-officio a member of the board of trustees would be instrumental in keeping this body as distinctly conservative as it should be. There were too many committees acting independently of the board of trustees. The policy of every committee should be approved by the board. Special committees should not be continued over a number of years. The expenses of travel of standing committees should be paid by the association. The growing tendency of some committees to use political methods should be curbed. Their motives were good, but when they came to politics they were but as babes in arms and if unrestrained would bring disgrace on the medical profession. While acknowledging the efficiency of the secretary, he thought it unfair to load too much responsibility upon one individual; the president was but a figurehead. Dr. Burrell regreted his inability to be present and hoped that the work of the House of Delegates would be conducted with that spirit of harmony that was conducive to effective work.

Report of the General Secretary.—Dr. GEORGE H. SIMMONS of Chicago submitted this report. The membership of the American Medical Association on May 1, 1908, was 31,343. During the past year 290 members had died, 1,439 resigned, 484 had been dropped for nonpayment of dues, 290 had been dropped as not eligible, and 55 members could not be found, making a total loss in membership of 2,558. Since May 1, 1908, 5,150 names had been added to the membership list, making the membership on May 1, 1909, 33,935, a net gain of 2,592 for the year. Attention was called to the necessity of appointing a reapportionment committee whose duty it should be to examine the membership lists of the constituent associations and to determine the number of delegates to the association to which each constituent association should be entitled for the ensuing three years. Attention was also called to the report of the committee on the regulation of membership, as it would be necessary to systematize and regulate this matter on a uniform basis throughout the entire organization.

As the present session brought to a close a period of ten years, during which the present incumbent had served the association as general secretary, a review of the past decade was made. The membership of the American Medical Association in 1899 was 7,907 and on May 1, 1909, it was, as shown, 33,935, an increase of 424 per cent. The increase in State society membership had been even more marked. While complete figures to show the membership of the various State societies in 1899 were lacking, as late as 1902 the membership, as nearly as it could be determined, was 34,000. At present the combined strength of the associations constituent to the American Medical Association was 67,362. In 1899 not a single State owned and published an official State journal. To-day there were eighteen. Among other benefits resulting from the reorganization of the association were those pertaining to medical education, instruction of the public, regulation of pharmaceutical and drug products, the publication of an official directory of the profession, and the compilation of uniform laws for the different States. While these problems were by no means solved, a practical beginning had been made in the permanent and equitable solution of each of them. There were permanent boards, committees, and councils striving for the careful solution of these problems throughout the entire year, instead of having to be content with a hasty and inadequate consideration of the general problems and the adoption of resolutions at the annual session. It was hoped that the near future would see many questions which had vexed the profession and the public for years past definitely and permanently settled, permitting the profession to advance to greater usefulness both to its members and to the public.

Report of the Board of Trustees.—Dr. WILLIAM H. WELCH of Baltimore read this report. The past year had been the most successful one in the history of the association from the financial as well as from the scientific, educational, legislative, and philanthropic viewpoints. Few members of the association realized the great amount of time, energy, and work which the gentlemen who were serving on committees gratuitously were constantly giving for the improvement and benefit of the profession as a whole and the community at large. The manner in which the committee of to-day acted and did things was in marked contrast to that of a few years ago, which only resolved but did nothing. In order to facilitate the work of the committees the board of trustees had appropriated many thousands of dollars, and the board felt that the excellent results of their labors fully justified the expenditure.

The Council on Pharmacy and Chemistry.—This council, which reported directly to the board of trustees, was constantly examining a large number of preparations with which the profession was being exploited and weeding out the frauds, so that the physician to-day need not be deceived by false representations into using or administering anything with which he was not entirely familiar. Many of these fraudulent preparations were put on the market by so-called chemical houses which existed as such only on paper, and which were organized for the sole purpose of "working" the profession and the people. This was, however, but a minor part of the council's work. There were many preparations placed on the market with honest intent and purpose by reputable houses, which, on thorough investigation by the council, were found to be below standard or to fall below the claims made for them. On presentation to the manufacturers of the results of the investigations, many of these preparations and products were modified or the claims made to conform more carefully to the facts, or the preparations were taken off the market, so that not only physicians but the people as a whole were being benefited to a degree not realized. In addition to the work done by the several members of the council in their respective laboratories, the association had a laboratory of its own in the Journal building under the supervision of Professor Puckner. The work here had grown so rapidly that the trustees had recently authorized the appointment of another chemist. The excellent work of this council had received general recognition not only

at home but abroad. It has aroused the attention of the medical profession of Germany, which did not realize existing conditions until this work was commenced. A vote of thanks was adopted by the trustees to the men who had given their assistance in the investigations of the council.

The Directory.—Attention was called to the revised Directory, which was at present nearly ready for publication. The association had endeavored to supply the medical profession and the public with an official register of the medical profession comparable to the Medical Register of Great Britain, combining, however, appropriate biographical and personal information so far as reliable data could be obtained. This book should consequently not be regarded as a source of revenue, but as an investment for the benefit of the profession and of the public.

A New Building.—When the building of the association was erected it was believed to be ample for all needs for a considerable length of time, but three years ago it became necessary to enlarge it and it was extended to the full depth of the lot, and an additional story added; the space under the sidewalk was also utilized, but working space was still needed. The trustees were unanimously of the opinion that a new building was the only solution of the problem and as the adjoining lot was owned by the association architect's plans and construction bids had been secured, believing that this course would meet with the approval of this body. The estimated cost of this proposed building was $200,000. The report would not be complete did it not recognize that this had been the most remarkable decade in the history of the association. Through its active committees a most comprehensive study of medical education in this country had been accomplished and most positive results attained in elevating and standardizing the same. The association had made itself felt in national legislation. It had laid bare innumerable frauds and made it impossible for them to be longer unknowingly perpetrated on the profession and the people. It was educating the masses in general matters pertaining to medicine through its bureau of public instruction; it was stimulating scientific investigation by means of rewards for orginal research and commendable scientific exhibits. It had organized the profession in the United States into an intelligent, coherent body, which had come to learn its rights, to know its power, and to feel its duties and obligations. All of this had been accomplished in the brief period of ten years. Appended to the report of the board of trustees was the report of the subscription department and that of the treasurer. The subscripion department showed that the total issue for twelve months was 2,806,900 copies of the Journal and the weekly average 53,978. This did not include copies sent to exchanges, to libraries, Government services, or abroad. The treasurer's report showed the excess of assets over liabilities to be $354,667.

Committee on Medical Legislation.—Dr. CHARLES S. BACON of Chicago read this report. This committee had under consideration during the past year the Navy Medical Reorganization Bill; bills relating to the public health and Marine Hospital Service; measures relating to the Federal and State regulation of the public health; relief measures for the surviving families of persons who had died in the service of the country; the uniform regulation of the practice of medicine by the different States; uniform regulation of vital statistics by the States; uniform State laws on foods and drugs; the attitude of the last administration in appointing a commission with the purpose of reviewing and thus overriding certain findings of the governmental agencies lawfully established for the interpretation and enforcement of the National Pure Food and Drug Act; and the general position of expert medical testimony. The history of the Public Health Bill was reviewed, and it became apparent at the hearing in January before the subcommittee of the House Committee on Interstate and Foreign Commerce (1) that there was some sentiment in Congress favorable to the creation of a Department of Public Health, with representation in the cabinet, and that looked on this measure as obstructive; (2) that the proposed amendment was looked upon as being so framed that the present organization of any and all departments could be changed at the discretion of the President, and that changes outside of the health services were believed to be the real object of this measure, which, in this particular, was looked upon as being disingenuous; (3) that there was a decided objection, expressed by the members of both branches of Congress, that the proposition contemplated the surrender by the Congress of a constitutional prerogative, and was an additional instance of the attempted encroachment of the executive on the legislative branch of the government; and (4) that the creation of a governmental bureau by executive order was without precedent, and that such a precedent ought not to be established. In view of these considerations the bill did not come up for passage, and this committee was authorized to state that its efforts to secure a more highly organized national public health service by practical and constitutional legislation would receive the cordial support of President Taft. The bill known as the "Personnel bill," relating to the Public Health and Marine Hospital Service, suffered the same fate as the bill just referred to. The present organization of the government made it impossible for any move to be made by the administration in public health matters until they should have been considered and passed on by the layman who happened to be at the head of the Treasury Department. This fact made it pertinent to enquire whether or not there would be a practical advantage in having, if not a physician, at least some man with a technical knowledge of public health matters as the particular assistant secretary of the treasury, to whom the Surgeon General of the Public Health and Marine Hospital Service reported, and who must be the adviser of our national health officer, otherwise known as the Secretary of the Treasury. The Naval Medical Reorganization Bill was now before both the House and the Senate, and should pass the regular session of this Congress on its merits. This bill provided for the reorganization of the Hospital Corps, together with the creation of the grade of chief pharmacist. Pharmacists represented the only warrant officers to whom the benefits of the advanced grade were not extended. The Naval Dental Bill, authorizing the appointment of dental surgeons in the Navy, had been introduced into both the Senate and the House at the present session of Congress, and, it was hoped, would duly come up for consideration at the regular session. Dental surgeons were needed in the Navy quite as much, if not more, than in the Army, which service enjoyed free treatment by dentists employed in accordance with law, and it seemed an unjust discrimination against men enlisted in the Navy not to provide for similar dental work. The Navy Department, during the last session of Congress, approved the insertion of a clause in the Navy Appropriation Act under "Pay of the Navy" providing for the establishment of a reserve corps for the medical department of the Navy, and recommended the insertion of this clause to Congress, but it failed of consideration. If this measure was enacted and the desired corps established: (1) The Medical Department of the Navy would be placed in close contact with the members of the medical profession throughout the country, and would be in a position to call them into consultation, and enjoy the advantage of their advice should occasion require. (2) It would secure for the medical department

adequate and efficient assistance, no matter what or how great the emergency demanded. (3) It would make the Army and Nay services equally attractive. This equality did not exist under the present policy of requiring all candidates for the Navy Medical Corps to pass through a probationary period as acting assistant surgeons under instruction at the Naval Medical School before being eligible for commissions in the regular service. The proposed amendment read as follows: "Provided that a medical reserve corps, to be a constituent part of the medical department of the Navy, is hereby established under the same provision in all respects (except as may be necessary to adapt the said provisions to the Navy), as those providing a medical reserve corps for the Army and as set forth in the act to increase the efficiency of the Medical Department of the United States Army." The value of hospital ships, from both economic and humane considerations, had been fully demonstrated by the experience with the hospital ship "Relief." This ship on many occasions saved to the service of the fleet a man of war which formerly would have to serve as carrier for the sick or wounded. The unseaworthiness of the "Relief" had required that she be retained in Philippine waters. The Department has authorized the refitting of the "Solace" as a hospital ship, but ships such as these were only makeshifts, and were not of a type suitable for the purpose; consequently the Bureau had urged the Department to make provision for two hospital ships based on plans already prepared under the Department's directions, the cost of each not to exceed $1,500,000.

Isthmian Sanitation.—The sanitation of the Canal Zone was being maintained at such a high standard and the status given the sanitary department under the present administration was so high and influential that no further legislation relating thereto had been required. The fact that the chief sanitary officer was now a member of the commission and that he had coordinate rather than subordinate powers was largely responsible for the fact that the work of constructing the canal with a minimum loss of human efficiency from disease and death was progressing with a rapidity never known before in the history of such an enterprise.

Work in the States.—The only measure actively taken up by the committee was the bill regulating the registration of vital statistics, which was endorsed by the House of Delegates at the Chicago session, and which after discussion of its provisions by the Section on Hygiene and Sanitary Science, as well as the American Public Health Association, was further amended and a final draft printed. This model bill was passed in Missouri. A modified form was passed in Arizona, and the Delaware vital statistics law was so modified as to admit that State to the registration area. The committee would continue its efforts along this line in selected States each year. The committee on legislation had endeavored to cooperate whenever possible with the various State associations for the furtherance of desirable legislation and for the defeat of vicious and undesirable bills. The committee had restricted its efforts in this direction, however, to those cases in which the State committee on legislation had asked assistance. Efforts in the direction of uniform food and drug legislation in the various States had also been inaugurated. At the annual conference on Medical Legislation held in Washington in January, 1909, a model bill had been drawn up by the Committee on Uniform State Legislation appointed by the Association of National and State Food and Dairy Departments. This bill contained an elaborate system of standards and definitions necessary for pure food legislation, and was endorsed by the conference, printed and widely distributed. A section on drugs would be drafted later, and they would then be in a position to advocate the adoption of uniform legislation on this important subject. The most difficult and intricate question now before the committee was that of the preparation of a uniform bill for the regulation of the practice of medicine. A large amount of material had been collected for the careful study of this question and the time seemed to be ripe for a general discussion of the entire subject. The committee recommended that it be authorized to call a general conference to take the place of its Annual Conference on Medical Legislature to be devoted to a discussion of the essentials of a uniform medical practice act for adoption by the various states. To such a conference should be invited all the members of the National Council, all members and especially presidents and secretaries of state examining boards, all members of state committees on medical legislation, representatives of various colleges, sectarian schools of medicine, prominent jurists, sociologists and economists.

Report of Council on Medical Education.—Dr. Arthur D. Bevan of Chicago presented this report. An abundance of information had been collected, tabulated and published regarding medical colleges, standards, students, graduates, facilities and equipment. Information had also been collected regarding elementary, secondary and collegiate education. This information had thrown much light on medical education and had revealed problems which otherwise could not have been seen. The report reviewed the work of the five annual conferences of the council on the subject of medical education. At the first conference the minimum standard was formulated requiring the student to have a preliminary education which would enable him to enter the freshman class of our recognized universities; the passing on the credentials of such an education by a state official; the graduation from an approved medical college requiring a four years' course of not less than 30 weeks each year with 30 hours each week of actual work; the passing of an examination for licensure before a state board. The council formulated an "ideal standard" which should be secured as rapidly as conditions warranted. The aim of the "ideal standard" was: A four years' high school education, a year's university training in physics, chemistry and biology, four years' course of medicine proper, and one year as interne in a hospital or dispensary. At the second conference the medical colleges were divided into three groups based on the failures of their graduates to pass the examinations of State boards. These reports, which had been published, had done much good in stimulating faculties to guard against the graduation of illy prepared students. At the third conference there was presented a detailed report of the personal inspection of the medical colleges of the United States by members of the Council. This inspection had been continued and a second inspection would soon be completed. At the fourth conference the secretary presented a graphic study of medical education in the various states and in the twenty most important countries of the world showing the comparative position of medical education in this country with that of the rest of the world. It revealed that while this country had a few medical colleges equal to any in the world, it was nevertheless far behind other countries in standards both of preliminary and medical education. The fifth annual conference, held in Chicago in April, 1909, consisted of one hundred prominent educators representing all the departments and specialties in medicine. The recommendations of this committee as to what constituted a proper medical course has attracted much attention, but it was agreed that a hard and fast medical curriculum for all colleges was not desirable and not for the best interests of the profession. The curriculum submitted by this committee was regarded as suggestive and educational only, and was not intended for adoption by colleges or state boards. Statements were made by examiners on state boards suggesting that in ad-

dition to the written examination the candidate be required to do some chemical work, to examine specimens under the microscope, to describe gross pathological and anatomical specimens, to make demonstrations on the obstetric mannikin and on the cadaver and to make application of bandages and surgical dressings. Several states had already introduced such practical examinations. The members of the Council were unanimous in endorsing this as a most important advance. Investigation revealed much confusion in standards not only among medical colleges but in high schools, colleges and all departments of education, but at no previous time were so many forces at work in the effort to standardize the different departments and to develop system and uniformity. Eleven medical colleges already required two or more years in a college of liberal arts for admission. Eighteen other colleges had announced an increase in their entrance requirements to two or more years in a college of liberal arts. Twenty-one other colleges required one year in a college of liberal arts. The State Examining Boards in six states had established higher requirements of preliminary education. There had been five important mergers of medical colleges, by which nine medical schools were replaced by four stronger ones. Five years ago there were 166 medical colleges in the United States; since that time 25 others had been organized, but 43 were closed, leaving 148 at the present time. If all the medical colleges of any large city could be merged into one great university, such as were found in Berlin, Paris or Vienna, it would be to the greatest possible advantage to the medical profession in this country. The teaching of medicine at night schools had been practically abandoned, although several schools still existed in St. Louis and Chicago. Among the defects and needs of medical colleges revealed by the investigation of the Council were that there were too many medical colleges. The methods of teaching medicine of fifteen or twenty years ago were still in use in some institutions. Medicine today demanded a more thorough preliminary training than was possible in the vast majority of our secondary schools. The teaching of medicine today demanded trained teachers, with salaries sufficient to enable them to devote their entire time to teaching and research work. In order to properly teach medicine, the medical college should own or control a hospital. Medical education should be brought into harmony with other departments of education. The medical school might obtain valuable suggestions from liberal arts colleges in the matters of supervision, standards of equipment, and methods of teaching. A medical school would be greatly benefited by becoming the organic medical department of a university which had a strong liberal arts department, *i. e.* the finance of the medical school would be controlled by the trustees of the university, and the educational standards would be fixed by the liberal arts department.

Report of Board of Public Instruction on Medical Subjects.—This board had inaugurated a plan of work which was passing through an experimental stage. Many of the avenues of publicity which it had been hoped could be used were found unavailable. Managers of newspapers and magazines were unwilling to accept matter without their editorial supervision which, in many instances, tended to impart a sensational character to the matter. Each periodical insisted on having the exclusive right of publication. For the present the Board had limited the work to a few subjects, such as typhoid fever, diphtheria, variola, dysentery, gastroenteritis in infants, cancer, ophthalmia neonatorum, malaria, meningitis, tetanus, rabies, Asiatic cholera and yellow fever. The appropriation would not admit of giving the work a wider scope. One newspaper syndicate had offered to distribute to 1,000 newspapers over the country one column weekly for $1,800. By resolution of the Board of Public Instruction one representative from each State in the Union had been invited to cooperate as an Auxiliary Board. Each member was expected to keep in touch with such matters as required publicity and to supervise the inauguration of publicity schemes in his own territory. Each article would be published in pamphlet form and kept in stock in the Bureau of Public Instruction at the American Medical Association buildings in Chicago. In the event of an epidemic of typhoid fever, or other infectious disease, these pamphlets might be at once dispatched to those places and distributed through physicians or other channels to the people. Cooperation of the state associations would be essential to the proper execution of the plans of the Board of Public Instruction, for the problems of each state had individual peculiarities which could only be met by the state and county societies. All articles compiled by the Board of Public Instruction would appear as unsigned documents emanating from the authorized body of the American Medical Association. It would be the policy of the board to avoid all controversial questions.

In Memory of Dr. Happel.—The board of trustees desiring to express their appreciation of the devoted and valuable services of Dr. T. J. Happel, a member of the Board of Trustees, who died on May 24, on motion adjourned the morning session in his honor.

Afternoon Session.

Committee on Organization.—Dr. J. N. McCormack of Kentucky reported a growing interest in the subject of organization everywhere, but more especially of the acceptance of the idea by educational institutions. The way in which teachers and students received the ideas connected with this organization made him believe that a generation of voters and educators could be trained so as to recognize the value of organized medical work and they could look to them for constructive legislative work. There should be cooperation between physician and teachers in every locality, and it was the duty of the physician to inaugurate this movement. Dr. McCormack referred to the antagonism that the organization had engendered on the part of quacks who, not satisfied with the failure to accomplish anything by attacks on the organization as a whole, had resorted to personal attacks which were absolutely without any foundation.

Report of Committee on Ophthalmia Neonatorum.—Dr. F. Park Lewis of New York reviewed the work of this committee since the year 1906. In March, 1909, a circular was sent to the various states asking the following questions: "1. What laws have been enacted or proposed governing the practice of midwifery or the reporting of cases of ophthalmia neonatorum? 2. Are physicians required to report this disease? 3. Are prophylactics provided by the Health Department for gratuituous distribution? 4. Do regulations provide for the early registration of birth certificates? 5. Is an inquiry made on the birth certificate whether a prophylactic has been employed, when omitted, the reason for its omission? 6. Have any special resolutions been proposed or action taken by the medical societies for the control of this disease? Have you suggestions to offer the committee that may be helpful in controlling this disease? Investigation showed that one-fifth of the blind in institutions in the various states and cared for by the State at a cost of $364 per capita per annum were thus afflicted as a result of ophthalmia neonatorum. Although many requests had been received requesting that a phophylactic be recommended, the committee had neither the authority nor the desire to recommend any special form of prophylactic, neither was it desirable to do so until the subject was more exactly determined. It had been shown by the late Dr. Snell at the Jessop Hospital at Sheffield that a careful sanitary toilet would prevent infection in a large proportion of cases, and if this

were supplemented by the judicious use of any of the silver salts, and by prompt treatment when infection occurred, the disasters of the disease would be practically reduced to the vanishing point. In each state there was a committee of experienced physicians ready to advise with the Department of Public Health and it had, therefore, been deemed wise to advise that in every State the subject be taken officially under consideration by them. Attention of the committee had been directed to the fact that in a disproportionately large number of cases, reinfection had occurred where prophylaxis had been employed. This differed widely from careful records from large numbers of cases and led to the belief that the solutions were often used in a perfunctory or careless way, or were not prepared in the proper manner. When any silver salt was used it should be in fresh solution unless it was prepared in hermetically sealed and light-proof receptacles, and used but once for prophylaxis. The Department of Health should make it very clear that when the nitrate of silver was employed some reaction followed, or the inexperienced might regard the transitory redness and gummy secretion as an infection and employ active treatment to the detriment of the cornea. If infection occurred its treatment should be immediate and under medical supervision. It should always be made clear that the treatment of a birth infection of the eyes must never be undertaken by a midwife or nurse. When a prophylactic was freely distributed it should be accompanied by a brief description of the disease and the necessity for prompt treatment. In order to achieve success two things were necessary, publicity and the placing of responsibility. In order to secure publicity, it should be the duty of this committee to secure by cooperation with the Department of Health in every community, or by such other means as might be desirable, by the issuance of impersonal descriptive leaflets, by public lectures, by practical exhibits, and otherwise a widespread knowledge concerning ophthalmia neonatorum, its method of infection, its prevention and the necessity of immediate and proper treatment. With such a knowledge the public would readily and heartly join in any rightly directed movement for its control. The placing of responsibility could only be secured by recording the notice of the birth with the properly constituted authorities when it occurred, and it was necessary that the registration be made soon after the child was born. The recent English law required "that it should be the duty of the father if he resided in the house at the time the birth occurred, and of any person in attendance upon the mother, at the time of or within six hours after the birth, to give notice in writing to the medical officer of health of the district in which the child is born." This was in addition and not as a substitution for the usual birth certificate. On such a report a statement was required as to whether or not a prophylactic had been employed against ophthalmia neonatorum. This served both as a warning and a record and enabled the department to keep in touch with the births in the poorer districts where often the eyes of the child were lost before the authorities knew that the child had been born. It was recommended that committees, which had assumed the responsibility of cooperating with the central committee, begin an organized movement for the control of ophthalmia neonatorum in the several states and territories. The movement for the control of ophthalmia neonatorum, which had for its object the control of ophthalmia neonatorum in the United States, had grown to one in which the whole civilized world had joined. At the Eleventh International Ophthalmological Congress held at Naples, April 3, resolutions were adopted recognizing the importance of ophthalmia neonatorum as a cause of blindness and the practi' ility of its control was admitted by the appointment of a committee charged with the duty of its consideration.

Report of Committee on Patents and Trade-Marks.—Dr. S. C. Bacon of Illinois reported that the committee had made a study of the work previously done in this line by the American Pharmaceutical Association. It had investigated the patent and trade mark laws of the United States and foreign countries and conferred with about fifty of the leading drug manufacturers of this country in reference to the proposed change in the laws. They concluded that such changes in the patent laws as were suggested in the resolution adopted at the session in Chicago in June, 1908, was impracticable. It was believed, however, that it would be possible to improve the situation by certain changes such as would be in a line with those recently adopted in England, restricting patents to articles manufactured solely or chiefly in the country. They had learned that changes in the patent laws in other directions were being considered by other organizations, and they recommended that the Association continue a committee to keep track of legislation on this subject and to cooperate with bodies interested in the improvement of medicine and drug patents. In regard to the evils arising from the registration of names as trade marks, they had come to the conclusion that these evils were to be remedied by the courts rather than by the enactment of new laws. Other questions were in a state of confusion. It was a question whether a manufacturer could be protected on trade mark principles in the use of a number of names, each used to indicate a particular product. Another question was as to whether a manufacturer had the right to give a chemical name to a medicine as the patent or descriptive name and use another more catchy name as a trade mark. In view of these and other questions it was recommended that the Committee on Patents and Trade Marks consider the advisability of trying to secure such judicial opinions, and in the event that such action seemed desirable it should be empowered to proceed by and with the advice and consent of the Trustees.

Report of Committee on Davis Memorial.—Dr. Henry O. Marcy said that this was not a report of progress. Owing to the San Francisco disaster and the financial depression it had been deemed best to defer active solicitation. It had been decided nevertheless that a sum of $25,000 should be raised and this was apportioned among different States. Massachusetts had exceeded her apportionment by nearly one-half. The State of Illinois and the city of Chicago had promised generous assistance. Upon the presentation of the last report it was regretfully stated that the Memorial Committee had refused further active assistance on the part of the States until the Association itself should give encouragement and support by contributing to the fund. The committee urged that this be done at the present meeting.

Report of Committee on Uniform Regulation of Membership.—Dr. T. S. McDavitt of Minnesota presented this report. After correspondence with the secretaries of the various State societies, it had become evident that if the by-laws of the Association were to be enforced, and if the membership of the American Medical Association was only to be held by members in good standing in county and State societies, a simple, easily operated and effective system for the transmission of such official information regarding membership must be established. The present lack of uniformity and system was expensive and also resulted in a large loss on account of members who were dropped, suspended or relinquished their membership owing to misunderstanding regarding the provisions for membership dues, etc. The committee recommended: (1) All State associations be requested to make their fiscal year conform to the calendar year and to request their component county societies to do the same. (2) This committee further recommended that this committee be continued, that it be increased by the addition of four State

secretaries and that it be instructed to draft uniform by-laws for the regulation of membership for state and county societies, as well as to devise a system of necessary blanks, forms, etc., which would be applicable for general use, and which could be recommended by the House of Delegates to State societies for adoption. It had been suggested that this committee take up the question of requirements for membership as it was evident that there was a lack of harmony on this subject. The constitutional provisions of the various States, as shown by the last copies of their constitutions and by-laws, had been tabulated. Questions had arisen in regard to procedure in matters of discipline upon which the constitution and by-laws were vague. This matter was referred to the Committee on Constitution and By-Laws.

A resolution was introduced requesting that the Association use its influence to prevent the use of the Geneva cross by other organizations or for other purposes than by the Army, Navy and Red Cross Societies. This resolution was referred to the Committee on Legislation.

Resolution to Create a New Section.—Whereas, it was held that not enough attention was paid by the profession in general to syphilis and venereal diseases; that syphilis belonged both to surgery and to cutaneous diseases and that in the minds of the laity syphilis and other venereal diseases were associated, it seemed advisable that a section on Venereal and Genitourinary Disease should be established by the Association. This resolution was referred to the Committee on Section Work.

Tuesday, June 8—Second Day.

Report of Committee on Scientific Research.—This committee reported that three grants of $200 each had been made during the past year for research work: One to Dr. Isabel Herb of Chicago for a contribution entitled "A Study of the Etiology of Mumps;" a second to Dr. H. T. Ricketts of Chicago for a study entitled "An Investigation of the Identity of Rocky Mountain Fever of Idaho With That Found in Montana," and a third to Dr. R. M. Pearce of New York for two papers entitled "A Study of the Elimination of the Inorganic Salts in a Case of Chronic Universal Edema of Unknown Etiology With Apparent Recovery," and "A Comparative Study of the Physical Changes in the Blood in Relation to Opsonic and Phagocytic Indices and Cell Content Under Normal Conditions." A grant of $200 was also made to Drs. D. J. McCarthy and M. K. Meyers of Philadelphia for an "Experimental Study of Cerebral Thrombosis." For the year 1909 five grants of $200 each had been allowed, two of $100 each, and one of $50. The committee had continued its policy of making grants to certain individuals and repeating these grants when the quality of the work had been such that continued support had been desirable. The committee was fully convinced that the amount expended by the Association for this purpose had been usefully employed and that an increase of the yearly appropriation to $1,000 would be judicious if this sum could be spared.

Report of Committee on Scientific Exhibit.—Dr. F. B. Wynn of Indianapolis presented this report. He said that ten years ago the scientific exhibits as a feature of the meetings of the Association were an experiment. They had now passed the experimental stage and become a permanent and important attraction of the meetings. He called attention to the pathological exhibit and the three research exhibits. The power of an appeal to the eye had long been recognized in commercial lines, as was fully demonstrated by modern methods of advertising. That they had been so long in applying this method to the education of the people seemed strange. The health boards had finally adopted this idea in the education of the people in regard to tuberculosis. The great need was in constantly keeping the subject before the eyes of the public. To this end popular lectures, health propaganda, etc., were an important feature, but the great need was for a permanent exhibit. An automatic lantern-slide cabinet had been invented suitable for railroad stations, theaters, stores, and all public places, which gave a graphic education on the subject of tuberculosis. This was one of the features of the scientific exhibit. The committee had offered a medal last year for the best tuberculosis exhibit, but none of the exhibits had been deemed worthy of the prize. The same prize had been offered again this year. The work of departments of public health in popularizing knowledge in regard to tuberculosis was a species of advertising and should be conducted along sane and judicious lines. Placards should be attractive but always dignified. They should bring out plain truths, and to this end they should contain sufficient science to drive the truth home, but not so much as to make them incapable of appealing to the lay mind.

Report of Council in Defense of Medical Research.—This Council reported that it had organized at a meeting in Philadelphia, in November, 1908, and that its work since had been classified under three heads, (1) investigating the conditions of animal experimentation and the opposition to it; (2) taking precautions against the abuse of animal experimentation and against misconceptions of the conditions and purposes of medical research; (3) diffusing information regarding laboratory procedures and the results of laboratory study of disease. In order to obtain information regarding the conditions of medical research in the United States, circulars were sent to 111 of the most prominent schools, and reports had been received from 80 of them. The information received was quite complete and would appear later in a series of papers. In order to understand the nature of the opposition to medical research, literature had been collected from all the societies in the United States, and the Council had subscribed to anti-vivisection journals, and had obtained from a clipping bureau the statements for and against vivisection which had appeared in the newspapers throughout the country. An analysis of this literature would be presented in a later publication of the Council. Hostile agitators had declared that irresponsible and untrained medical students operated on animals in private places outside of proper supervision. The evidence of such a condition of affairs had not been forthcoming, and the Council had sought to remove suspicion by advocating that teachers of medical science speak to students regarding the importance of the experimental method in medical research, the suspicion of laymen that animals were not treated humanely in laboratories, and the resulting agitation that might work injury to medical science from checking animal experimentation. There was no evidence that students did not realize the importance of the caution and that it was not obeyed. It was learned that in many instances such caution was accustomed to be given. In larger medical laboratories rules governing animal experimentation had been posted. The Council had been instrumental in having them adopted in a number of new places, and hoped that they would be made the regulations for research in all medical laboratories in the United States. Although such a measure would not change in any respect existing good conditions, it would indicate to newcomers and to those interested the good intentions of the investigators. The information which the Council had secured had been utilized in enlightening the editors of certain lay publications regarding the conditions of medical research, and also in regard to the character of the opposition to it. In order to forestall the possibility of hostile legislation the Council sent out during the sessions of the legislatures in the various States a circular letter to the deans of medical schools, and to members

of the National Auxiliary Committee on Medical Legislation, stating the objections to such legislation, which revealed an alert body of men scattered through the country prepared to do their part in securing the benefits of medical research. The Council had planned a series of papers by experts on the importance of animals in the development of various phases of medical science and practice in the hope of thus securing a body of evidence to which physicians could refer in case agitation on the subject of vivisection arose in their communities.

Wednesday, June 9—Third Day.

Endorsement of George Washington Memorial Association.—Dr. William H. Welsh of Baltimore said that the George Washington Memorial Association had been formed for the purpose of raising funds for the erection of a building that should be a fit meeting place for national and international societies. The inconvenience and discomfort undergone at the recent International Tuberculosis Cogress was sufficient proof of the need of such a building in this country, and it had been generally agreed that no more fitting tribute or more useful and appropriate memorial could be erected to the memory of George Washington. Other national organizations had endorsed the undertaking, and as such endorsement would involve no expenditure on the part of the American Medical Association Dr. Welsh presented this matter in the form of a resolution which the House of Delegates adopted.

Resolution on Davis Memorial.—A resolution recommending that the American Medical Association appropriate $5,000 toward the Davis Memorial, on condition that the State and county societies raise the sum of $20,000 within three years, the $5,000 not to be available until the $20,000 was raised, was adopted by the House of Delegates.

Section and Section Work.—The Reference Committee on Sections and Section Work stated that, as there existed a very active body for the study of anatomy in the Society of American Anatomists, and, since teachers of anatomy were no longer accustomed to doing practical surgical work, it was advisable to omit the words "and surgery" from the section known as the "Section on Surgery and Anatomy," and to call it hereafter "The Section on Surgery." A resolution to this effect was adopted.

This committee also recommended that the section known as "The Section on Cutaneous Medicine and Surgery" be changed to "Section on Dermatology." A resolution to this effect was adopted. A resolution was also adopted forming a new section, to be known as "The Section on Urology and Venereal Diseases." The committee also recommended that the president appoint a committee to consider the advisability of forming a Section on Anesthesia, the committee to be appointed from the several sections, and the board of trustees to be instructed to appropriate the funds required for this investigation. A resolution to this effect was adopted.

Report of Reference Committee on Legislation.—This committee recommended: (1) That the House of Delegates again endorse the establishment of a National Public Health Department, and presented a resolution to the effect that the American Medical Association reaffirm their stand and that they recommend legislation to that end. (2) That this association respectfully recommend a resolution to Congress amending the National Food and Drug Law and urging the necessity for this amendment. This resolution recommended (1) that they prohibit absolutely the use of benzoate of soda and such preservatives in the preparation and preservation of foods designed for interstate commerce. (2) That effective Federal inspection of food manufactories be enforced in order to prevent the employment in such factories of persons affected with contagious or infectious diseases, and, furthermore, that they prohibit the use of benzoate of soda and such preservatives in the disposal of waste products handled as food stuffs and foisted upon the public.

Dr. Welsh of Baltimore thought the resolution should not be adopted because it was an open question as to whether benzoate of soda was injurious; some claimed that in the quantities in which it was ordinarily used as a preservative it was absolutely harmless.

Dr. C. A. L. Reed of Cincinnati said that the attention of the legislative committee had been directed to that question, and that in framing the resolution they had been very careful not to say whether benzoate of soda was harmless or not. There were some undisputed facts that made it imperative to speak in no uncertain manner. Laying aside the question of salubrity, upon which there was such a difference of opinion, the fact remained: (1) That benzoate of soda was the last stand taken and held by those who used deleterious preservatives in food stuffs. (2) Laws had been passed which had driven out all other substances of this class. (3) This remaining one was used for the purpose of preserving waste products of canneries which were absolutely unfit for food. Near Baltimore there were many canneries with a large number of colored employees, who went about in the factories barefooted and barehanded. There were no regulations regarding expectoration. Fruits were peeled and cored and this waste often fell on the floor. It was collected with a rubber sweeper and used again. Without benzoate of soda this refuse could not be utilized. They wanted Federal inspection for purposes of cleanliness. Testimony was ample that subjects of tuberculosis and syphilis, even those with syphilitic lesions on their fingers, were employed without let or hindrance. It was time for the American Medical Association to speak in no uncertain terms. If they ignored the question it was equivalent to an approval of the present state of affairs.

The House of Delegates voted to present this resolution to Congress.

The Reference Committee on Legislation, in the matter of the "Navy Department Bill," approved and urged as follows: (1) A bill to reorganize and increase the efficiency of the Hospital Corps of the United States Navy and regulate its pay. (2) A bill authorizing the appointment of dental surgeons in the Navy. (3) A measure to provide for a medical reserve corps in the Navy. (4) A bill authorizing the construction of two hospital ships, not to exceed in cost $3,000,000.

The House of Delegates adopted the resolution to support these bills.

Uniform Medical Practice Law.—The Reference Committee on Legislation reported that it approved the resolution calling for a general conference on medical legislation for the purpose of considering the essentials of a uniform medical practice act suitable for adoption by the various States. Such a conference should consist of members of the National Council on Legislation, the Council on Legislation of the American Medical Association, members, secretaries and presidents of State Examining Boards, State committees on medical legislation, and deans of medical colleges.

The House of Delegates adopted the resolution calling for this conference, and the Reference Committee on Legislation endorsed the resolution, proposing that a committee be appointed to consider the advisability of establishing a relief fund for those who had devoted themselves to the cause of medicine, the resolution urging the passage of uniform State laws on vital statistics, and the resolution commending the work done for the relief of Dr Carroll's widow. The House endorsed and adopted these resolutions.

Drug and Patent Laws.—The Reference Committee on Drug and Patent Laws recommended that as further investigation along these lines was needed, the present committee be continued. The House acted on this recommendation.

Amendments to Constitution and By-Laws.—Two amendments were passed whereby during the interval between the meetings of the House of Delegates the Board of Trustees should supervise the action of committees, and any committee acting between sessions should be subject to the Board of Trustees.

Report of the Reference Committee on Scientific Nomenclature.—This committee recommended that the report of the standing committee on Scientific Nomenclature be adopted, and expressed great appreciation of the work done. The result of two conferences, one held in Philadelphia and one in Washington, of special section committees and associated committees of the American Medical Association, the Committee of the Vital Statistics Section of the American Public Health Association and Cooperating Federal Services, was a recommendation for the revision of the International Classification of the Causes of Death. Among the changes suggested were: Change "Epidemic Diseases" to "Infective Diseases"; disuse the word "croup"; divide title dysentery into amebic dysentery, bacillary dysentery and dysentery (undefined); make title Plague and add pestis minor, pneumonic plague, and septicemic plague; separate actinomycosis and trichinosis; the word "tuberculous" should be restricted to the specific disease tuberculosis, and the word tubercular should be discarded in this connection. The proposed rearrangement of tuberculosis was under the following titles: Total Tuberculosis, Tuberculosis of the Lungs, Acute Miliary Tuberculosis, Tuberculous Meningitis, Abdominal Tuberculosis, Tuberculosis of Joints, Glands, Spine, etc. In reporting cancer give point of origin, or primary site; specify, if possible, the variety of neoplasm. As a result of the conferences a prepared list of undesirable terms was agreed upon and the reasons for considering such terms undesirable. Among these terms were abscess, accident, injury, violence, undesirable because unqualified; other undesirable terms were atrophy, congestion, convulsions, dropsy, heart disease, heart failure, hemorrhage, hemoptysis, hydrocephalus, marasmus, operation, surgical shock, paralysis, peritonitis, pneumonia, pyemia, tuberculosis, tumor, typhoid pneumonia. These terms were either unqualified or vague. A rearrangement of the causes of violent death was also proposed. In regard to nomenclature proper the committee considered the Nomenclature of Diseases, drawn up by the joint committee appointed by the Royal College of Physicians of London, as, in the main, admirable, but they thought it had some defects requiring correction and that certain additions should be made. This committee recommended that in all diseases involving anatomical terms the nomenclature adopted by the German Anatomical Society, generally known as the *Basle Nomina Anatomica*, be adhered to. This nomenclature was superior to anything of the sort that had been proposed. It involved the retention of all diphthongs in Latin words. In such words as anæmia and diarrhœa they proposed to enclose the first letter of the diphthong in parenthesis, as an (a)emia, diarrh(o)ea. This method required the substitution of chorioid for choroid, Falloppian for Fallopian, etc., and they recommended this change in the interest of uniformity. They recommended that lukemia and septicemia be spelled luchæmin and septichæmia. They thought no other spelling defensible. Many other changes were recommended based on a careful study of all the suggestions received from the cooperating bodies and they were approved of at a meeting held in New York on April 1, 1909, at which meeting were present Dr. Wilbur, Dr. Batt, Dr. Cattrell, Dr. Meyer, Dr. Coleman, Dr. Guilfoy, and Dr. Frank P. Foster. At this meeting it was resolved to recommend the following additional titles: Paratyphoid, African tick fever, tropical bubo, hill diarrhea, epidemic gangrenous proctitis, Japanese river fever, basha fever, acute febrile jaundice (Weils' disease), glandular fever, mountain fever, Rocky Mountain tick fever, coccidioidal granuloma psittacosis, milk sickness, polyeythemia, cardiac arrythmia, heart block, achilia gastrica, asthenic bulbar paralysis. This committee was charged with making provision for a delegation to the Paris conference for revising the International Classification of Causes of Death. It was found that this matter was in the hands of the United States Government; this committee was not aware that any steps had as yet been taken by Congress to provide for a delegation.

Awarding of Prizes.—It was announced that the Gold Medal for the best exhibit of research work had been awarded to the New York Lying-in Hospital and the gold medal for the best tuberculosis exhibit had been awarded to the Indiana Society for the Prevention of Tuberculosis.

(To be continued.)

GENERAL SESSIONS.

Tuesday, June 8—First Day.

THE FIRST VICE-PRESIDENT, DR. T. J. MURRAY OF BUTTE, MONTANA, IN THE CHAIR.

Invocation.—The Rev. NEWTON CALDWELL of Atlantic City opened the meeting with prayer.

Address of Welcome.—HON. FRANKLIN STOY, Mayor of Atlantic City, said that it gave him pleasure to again welcome the American Medical Association to the city. He questioned whether there was a conference anywhere that had representatives from so many States and Territories. He was grateful that they had again chosen this city as the place of meeting.

Address of Welcome.—Dr. E. H. HARVEY of Atlantic City also welcomed the members of the Association on behalf of the Medical Profession of Atlantic City.

Address of Welcome.—Dr. DAVID ST. JOHN of Hackensack, President of the New Jersey State Medical Society, said that their welcome was intensified with each return to this city. He reviewed some of the advances made in research work which were enabling the practice of medicine to approach to an exact science. The opposition that they had encountered from those opposed to vivisection should act only as a stimulus to their efforts.

Introduction and Installation of the President-Elect.—Dr. MURRAY introduced Col. WILLIAM C. GORGAS, U. S. A., Chief Sanitary Officer of the Isthmian Canal Commission, the President-elect of the Association.

Address by the President.—Col. WILLIAM C. GORGAS then delivered his address (to be published).

SECTION ON DISEASES OF CHILDREN.

Tuesday, June 8—First Day.

DR. THOMAS S. SOUTHWORTH OF NEW YORK IN THE CHAIR.

Chairman's Address: The Field for Prophylaxis Among Children.—Dr. THOMAS S. SOUTHWORTH of New York read this paper. He said that the period between infancy and puberty was the most important, because it was the time of greatest development, and that the foundation of a good physique was laid in childhood. He stated that the beneficial effects of environment, education, and proper food were recognized by the profession at large. The high mortality among infants was due to overcrowding in our large cities and to the steady decrease in maternal nursing. He claimed that ignorant physicians and midwives were responsible for this latter condition. The education of the mothers as to the dangers of un-

necessary weaning was urged. He told of the serious results which sometimes occurred from the presence of adenoids and enlarged tonsils, and advised their early removal. He called attention to the fact that the premature loss of the first teeth had a serious effect on the development of the jaw, which resulted in disfigurement of the face. It was important to note that an examination of the ears and eyes was necessary in every patient. Prophylaxis was the highest ideal of our profession, and we were responsible for the safeguarding of the child.

Transitory Urinary Findings Associated with Some Diseases of Childhood.—Dr. Walter Lester Carr of New York presented this communication. He said that the common forms of kidney lesion found after or associated with acute diseases were generally appreciated. He believed many cases of influenza, tonsillitis, and enteritis gave symptoms of kidney changes that were evidently transitory, and were not always of a serious character. Sugar was found in the urine of babies that were fed on patented foods. Hyaline casts and albumin were discovered in the urine of children who had a lithemic family history, and also in the urine of children who had a record of intestinal indigestion. He advised an examination of the urine in every case of gastritis in children. Pyelitis was one of the obscure causes of fever in a child that had enteritis.

Dr. John Lovett Morse of Boston said that an infection of the kidney secondary to other diseases never showed edema. Albuminuria was regarded as a degree of toxemia, and on this account was of prognostic import. Pneumonia and meningitis in children usually were accompanied by an albuminuria.

Dr. F. S. Churchill of Chicago believed in making a careful uranalysis in every case. He stated that when the chemical test showed no albumin he examined the sediment for casts. Pyelitis was often found in a patient that had tonsillitis and otitis media, and it prolonged convalescence.

Food Intoxications in Childhood.—Dr. John Ruhräh of Baltimore read this paper. He cited several typical cases, and concluded as follows: (1) Improper feeding was the most frequent cause of the affection. (2) There was no separate symptom-complex for each form of food poisoning. (3) Poisoning was produced by the child's inability to utilize normal amounts of fats, proteins, or carbohydrates. (4) Treatment consisted of outdoor life in the country, restricted diet, and a mild laxative administered once weekly for several weeks.

Infantile Eczema; Recent Views Concerning Its Pathology and Etiology.—Dr. Isaac A. Abt of Chicago presented this paper. He said the older authors thought infantile eczema was due to overfeeding and constipation. He believed that eczema in children was dependent on constitutional disturbance. There was a relationship between infantile eczema and bronchial asthma. Many cases showed a lithemic family history. The complications of infantile eczema were albuminuria and heart disease. Treatment consisted in the use of oils or vaseline to soften the crusts, which were removed slowly to prevent fever. The area was covered with zinc oxide ointment and dusted with talcum powder. Fowler's solution was given internally. Diet was regulated and good results were obtained from the use of skimmed milk and buttermilk.

Hair-Ball or Hair-Cast of the Stomach and Its Occurrence in Children.—Dr. W. W. Butterworth of New Orleans read this paper. He stated that there were less than fifty cases of hair-ball reported as occurring in man. Thirteen cases were reported occurring in children. He reported the case of a girl, age eight years, who had complained of gastric disturbances, and a tumor in the epigastric region. Diagnosis was not made antemortem. The postmortem revealed a cast resembling the shape of the stomach, which was composed of human hair, the color of the patient's. The habit of swallowing small strands of hair was quite common in early life, especially among young girls.

Adenoid Hypertrophy During the First Year of Life and Its Treatment.—Dr. Rowland Godfrey Freeman of New York read this paper. He said that physicians paid too little attention to the presence of adenoids in early infancy. He removed adenoids in the first year. It was important to advise early operation. Operation was rapidly performed without an anesthetic. Slight pyrexia was no contraindication. When performed under an anesthetic, nitrous oxide was used. There was no shock to the infant in either case. The instrument used was the curette Hemorrhage was checked by adrenalin solution—1-5,000.

Dr. John Lovett Morse of Boston said that he believed in the removal of adenoids when they produced symptoms, without regard to age.

Dr. F. S. Churchill of Chicago said he preferred not to operate on adenoids when there was any fever present.

Dr. S. W. Kelley of Cleveland stated that he was opposed to using anesthetics in very young infants. An anesthetic was seldom necessary.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Tuesday, June 8—First Day.

Dr. Walter P. Manton of Detroit in the Chair.

The Chairman's Address on Mental Alienation in Women and Abdominopelvic Disease was read by Dr. Walter P. Manton of Detroit. He said that for twenty years he had been studying this condition, that sympathetic insanities had been described by Hippocrates, that somatic insanities had long been appreciated and mental diseases were known to be due to bodily disease and yet these had been largely ignored in treatment by the alienists. The relation of diseases of women to mental disturbances at the time of puberty, menstruation and menopause had been made prominent by gynecologists. The State had undertaken to care for the insane but should also attend to the bodily sufferings leading to the morbid states of mind in the insane. Eighty-one per cent. of insane women were shown to suffer from pelvic disorder. Post-operative insanities were rare, occurring less than once in one thousand cases as recorded in institutions, but many were temporary and were not included in these statistics. A mental breakdown was more liable to follow operation on the pelvic organs than that on any other organ except the eye. Following the puerperal period, except in cases of sepsis and toxemia, insanity was rare. Of the somatic conditions associated with insanities abdominal lesions due to adhesions, etc., led to imaginations suggesting that the intestines were being eaten up and the like. In addition to the definite local lesion an unstable mental organization was always present as a substructure. The local pelvic disease rarely led to mental debility except when some constitutional condition, such as sepsis or toxemia, was also present. The pelvic condition was only one factor in the mental condition. In the cases of puerperal insanity there was an additional mental instability present. In a certain number of cases relief of the mental condition followed the cure of the somatic condition, and in every case the somatic condition should be primarily treated.

The Operation of Choice in Retrodisplacements of the Uterus.—Dr. A. E. Benjamin of Minneapolis said that retrodisplacement associated with disease of the pelvic organs always needed operation, otherwise the retrodisplacement alone might not need treatment. No one type of operation would answer in all cases. The ventral suspension of Kelly once popular had given much relief, but had also caused much harm. Alexander's operation was

not popular on account of technical difficulties. Most operations had their objections. He had gotten best results from a modified Gilliam operation, making a medium incision, opening the abdomen and correcting other pelvic conditions, then dissecting back the skin, pushing the forceps through the internal ring, getting the round ligaments, and pulling the uterus forward. The anterior ends of the round ligaments were then spread out in fan shape and fastened to the fascia. In this operation only normal tissues were used, the weak parts of the ligaments were avoided and there was no interference with function of bowel, bladder, or uterus.

Dr. Barrett of Chicago said that the choice of operation should provide safety and simplicity, allow intraabdominal inspection, use normal ligaments, preserve their best parts, and leave them in normal position. If all these were present the success was almost sure. The operation of Dr. Benjamin in its intraabdominal finding of the round ligament and utilization of its best part in its normal canal should give the ideal results.

Dr. Bovée of Washington, D. C., said that no one operation was suited to all cases. In many cases shortening of the round ligaments was sufficient, but it was often necessary to cut the short uterovesical, and shorten the long uterosacral, as well as the round ligaments. He cited one case in which he had done a ventral fixation and eight months later the patient had been operated on again for prolapse. The cervix was found at the vulval outlet with the fundus still adherent to the abdominal wall eight inches away.

Dr. Boldt of New York said that while no one operation was suited to all cases, Alexander's operation gave excellent results in the cases for which it was originally intended in the freely movable uterus without adnexal disease. But many of these cases could get along without operation, or by the use of a pessary. In the conditions where the pelvic floor was relaxed he had found nothing equal to suspension.

Dr. Hall of Cincinnati said that he considered it very rare that suspension should be allowed on account of the possible intestinal obstruction. He thought the operation should be abandoned.

Dr. Marcy of Boston said that in inguinal hernia the main factor of cure depended upon reconstruction of the canal. In Alexander's operation for retroversion, if the canal was split up hernia would frequently be found and a curative operation on the hernia in addition to the Alexander operation was a great benefit.

Dr. Peterson of Ann Arbor said that he always opened the inguinal canal and shortened the round ligaments, thus curing the hernia at the same time, as did Dr. Marcy. He never used ventral suspension and he had too many relapses after the Webster-Baldy operation.

Dr. I. S. Stone of Washington, D. C., said that there were some displacements that were never curable. The condition behind the retroversion and its true cause could be understood only by a better study of the pathology. There was usually a visceroptosis and no round ligament operation could be expected to cure such a condition. A relaxation of all the abdominal and pelvic ligaments preceding the retroversion caused a descent of the viscera, and treatment should be aimed at the support of all the viscera, or better, at a prevention of the visceroptosis. Another reason for failure in many of the round ligament operations was paralysis of the nerves and obliteration of the blood-vessels caught in the suture of the ligament.

Dr. Fry of Washington said that the discussion of the question as to which was the best operation for retroversion was like asking which was the best remedy for whooping-cough. He used suspension but occasionally got fixation. The Alexander operation was unsatisfactory on account of the difficulty in finding the ligaments and did not cure the prolapse of the ovary. He had given up suspension principally on account of the objections raised from the experience of other operators. The Gilliam operation gave a great deal of pain after operation. He preferred to do a Webster-Baldy operation, often with a Pfannenstiel incision, which relieved the prolapse of the ovary. There would be no atrophy of the ligament if only one-half of its diameter was included in the suture.

Dr. Cole of Buffalo said that he believed in the treatment of visceroptosis, but thought it necessary to give previous medical care before all operations and thorough examination to provide a full diagnosis before a round ligament operation was undertaken, which could only cure one feature.

Dr. Potter of Rochester, N. Y., said that the reason we did not cure more patients was because we did not get them early enough. She believed in the careful examination in all cases of dysmenorrhea in virgins and treatment to prevent the later complications.

Dr. Shoemaker of Philadelphia said that a careful study of his patients had shown that many cases of retroversion did not need any operative treatment. Treatment of other pathological conditions when present frequently relieved the symptoms. He laid emphasis on the seriousness of infection of the inguinal canal.

Dr. Benjamin, in closing, said that pronounced retroversion gave symptoms which could frequently be improved by attention to the patient's general condition and muscular development. The suspension he objected to on account of the intestinal obstruction possibilities, and in the Baldy operation the ligaments hugged the uterus and the blood supply was constricted.

A Study of the Anatomy and Clinical Importance of the Sacroiliac Joint.—Dr. Fred H. Albee of New York City said that the presence of a synovial cavity with the possibility of movement of the sacroiliac joint was questioned by anatomists and described most varyingly in text-books. His own dissections of fifty specimens showed a constant presence of a synovial membrane and capsule of a fairly uniform size and definite location. This capsule was thin anteriorly and very liable to rupture in that direction. The lumbosacral cord lay close to it, and in a constant relation to it, giving rise to possible sciatica in case of disease of this joint. The sacrum and the ilia separated easily when the symphysis pubis was cut and the anterior layer of the capsule ruptured. The interosseous ligament regularly separated from the ilium. The joint tended to tip downward and forward and sprains occurred easily. In Walcher's position an increase of eight millimeters in the conjugate diameter was gained, due to movement of this joint. In symphyseotomy even greater motion was obtained. He laid special stress on the fact that the sacroiliac was a true joint and open to metastatic infection and especially liable to rupture into the pelvis. He cited four cases of disease of this joint, two of them sprains cured by strapping, one of dislocation reduced under ether, and one postpartum also cured by strapping.

Dr. Frederick of Buffalo said that this paper brought up the important point of differential diagnosis between conditions in the female pelvis referable to the female organs and those simulating these affections but not due to peculiar gynecological conditions. The symptoms in common were the backache, pelvic tenderness, and neurasthenia. Some cases of diseases of the sacroiliac joint showed hyperesthesia of all the pelvic organs and could be cured by supporting the hips and the lumbar spine.

Dr. Peterson of Ann Arbor said that while the diagnosis was not easy, certain cases of marked pain in the back occurring after operation he had prevented empirically by using a mattress pad two to three inches thick on the operating table. The Trendelenburg and lithotomy positions put distinct strain on the sacroiliac joint.

Dr. Barrett of Chicago said that certain cases of pelvic infection were due to a rupture of an abscess of this sacro-iliac joint into the pelvic tissue and gave rise to suspicion of gynecological conditions.

Dr. Morris Solis-Cohen of Philadelphia called attention to the fact that sacroiliac disease was due to malposition in standing, or sitting, with an abnormal lordosis of the spine.

Dr. Wynekurg of Scranton said that this joint was the most abused joint, especially by obstetricians in high forceps deliveries, where the strain was divided between compressing the child's head and rupturing the weak anterior capsule of this joint. He thought that cesarean section should always be preferred to high forceps delivery.

The Endometrium and Some of Its Variations.—Drs. William S. Gardner and Emil Novak of Baltimore presented this communication. They said that they had undertaken a study of the normal histology of the endometrium in relation to the menstrual function, in the light of the work recently done by Hitchman and Adler, who had shown a constant cycle of changes in the condition of the endometrium leading up to the menstrual discharge. To a large extent the writers had confirmed this work. The material obtained, however, had shown the condition considered characteristic of the premenstrual stage at periods from nine to fourteen days after the menses; therefore, they had considered that these endometrial changes were probably due to changes in the blood-vessels and blood pressure in the pelvis. The blood pressure was highest at the premenstrual epoch, and any pathological hyperemia might give the same appearance. The glands with papillomatous outgrowths considered by Opiz characteristic of pregnancy evidently were not such. The stroma cells seemed like the decidual. They did not believe that the date of the menses could be told by the histology of the endometrium.

Dr. Marcy of Boston said that many years ago there had been shown to be a necrosis of the endometrium in animals simulating menstruation.

Dr. Clark of Philadelphia said that three years ago the American Medical Association had asked for a simplification of the nomenclature of endometritis, that this work might now well be revised in the light of the present paper. It was easy to understand how the diagnosis of "adenoma suspicious of malignancy" could be made from curettings procured at a time approaching menstruation or in conditions of pelvic high blood pressure. He thought that when uterine curettings were sent to a pathologist they ought to be accompanied with the patient's menstrual history, to give him a chance to study the condition of the endometrium in its normal phases, and learn not to confuse the pathological and normal physiological changes

---

SECTION ON SURGERY AND ANATOMY.

Tuesday, June 8—First Day.

"Pulmonary Complications in One Thousand Consecutive Laparotomy Cases."—The chairman, Dr. John C. Munro, of Boston, read this paper. Of the total, 30 per cent. were appendicular; 21 per cent. were hernias; 10 per cent. liver and pancreas; 6 per cent. were gastric. Of the thousand cases, eleven or 4-10 per cent developed pulmonic conditions. Four were cases of simple bronchitis; five were lobar pneumonia; three were fatal. This was a much lower percentage than had been reported from European clinics, and the author had been unable to find any single explanation of this fact. In Europe from 4 to 5 per cent. was the common figure. Age, sex, climate were in general of little significance. The anesthetic had been ethyl chloride, followed by ether, carefully given by the drop method. Morphine and atropine were always used; the patients were almost always out of bed in 48 hours, and always sat up as early as possible after operation. Water and a free diet were given as soon as possible, and the patient was encouraged to move freely as early as possible. This divergence from the usual post-operative course, combined with the very perfect asepsis and nursing, made possible by coordinate hospital work, was probably the collective cause of the low thoracic post-operative involvement reported.

Localized Subphrenic Tuberculosis.—Dr. C. A. Powers of Denver reported a case of caseous infiltration between the liver and diaphragm which had produced very typical symptoms of gall-bladder disease. The mass was removed and the region curetted. The pathological report showed tuberculosis. Later the appendix was removed for tuberculous involvement. The mode of passage of germs through the diaphragm was not yet clear, but lymphatic currents traveled in both directions. Some authorities held, however, that transmission was always by active growth.

Treatment of Tuberculous Pleuritis and Empyema.—Dr. Emil G. Beck of Chicago read this paper. He advocated the use of a 33 per cent. bismuth-vaselin paste. It worked more successfully in empyema even than in ordinary sinuses. He presented two series of cases treated by this method, and stated that if signs of poisoning developed the paste could be removed with the help of hot oil. It was not necessary to distend the cavity on introducing the bismuth.

Address on Thoracic Surgery.—Prof. P. L. Friedrich of Marburg, Germany, made this address. He said that while pneumothorax lessened the motion of the chest and thus aided the operator, it added a real danger to the patient by collapsing the lymphatic channels and thus favoring sepsis. Infection was by far the greatest danger to be feared in any chest work. The differential pressure had proved to be of the greatest aid in controlling hemorrhage and no serious operations on the chest should be undertaken without it. He spoke of the technique of closing wounds of the lung, advising the use of silk, and stated that while minor work could be done without extensive rib resection, any active treatment of abscess or gangrene of the lung required wide resection. The closure of the bronchi above the cartilages was very difficult and demanded special technique—this was not yet satisfactorily evolved. He had used an elastic ligature in some cases. The two-stage operation was being studied in Germany, but its indications were still problematical. On the whole, the results of operations in empyema and certain forms of pulmonic tuberculosis had been, during the past eighteen months, very encouraging. Lesions should be unilateral for successful surgical intervention. He described the technique of a transverse sternal thoracotomy which, after ligation of the mammaries, gave an excellent field for thoracic exploration. Longitudinal section was much more difficult and slower. As to the future of intrathoracic surgery he thought it would be possible with the aid of perfect technique actually to invade the heart itself and effect repair of diseased valves. Meanwhile, the great prospect of the future was in the field of exploratory thoracotomy.

Pneumonectomy with the Aid of Differential Pressure; an Experimental Study.—Dr. Willy Meyer of New York read this paper. He said that there no longer existed any question as to the importance of differential pressure in the surgery of the chest. It greatly facilitated any procedure. He alluded to the use of the angiotribe as an aid in severing and inturning the larger bronchi. Air was retained in the cavity after lung resection for many weeks. He said that the balloon was a new addition to thoracic surgery, as was also the combination of negative and positive pressure

Intrathoracic Physiological and Technical Studies.—Drs. NATHAN W. GREEN and H. H. JANEWAY of New York read this paper. One of the most important elements for successful intrathoracic work was the introduction of a physiological apnea. The authors had made use of two methods of over pressure at the Surgical Research Laboratory of Columbia, in one of which the air was delivered directly through intubation, the supply and exhaust being controlled by a circular valve, while in the other the air had been delivered after the manner of the ordinary Brauer Chamber. This, as usually employed, had not the advantage of over-oxygenating the blood. To the ordinary box a valve had been added which was actuated by automatic electric attachments, and which was capable of emptying the box suddenly of all over pressure about eighteen times a minute. This simulated the ordinary respiratory act except that it was in greater volume. Thus the patient could be hyper-oxygenated very soon after entering the chamber and all the advantages of the intubation method were thus given an ordinary Brauer box. Professor Joseph A. Blake was now using this apparatus in New York. Two types of operation had been done in sixty-eight days. The one was a side-tracking of the cardia, the other embraced resection of the cardia. The first was done with little or no mortality, the second was followed by a very high mortality. This might be due to a disturbance of normal physiological action, for death sometimes occurred without gross evidence of sepsis. Any invasion of the esophagus, even by means of specially designed buttons, was a grave matter, for sepsis was much more common than after any form of operation on the lungs.

Dr. C. A. POWERS of Denver, in opening the discussion, said that the thoracic organs, unlike those of the abdomen, were immediately concerned with life. Hence this region, now opening to the surgeon, had until to-day been closed.

Dr. MELTZER of New York said that it was physiologically incorrect to suppose that no difference existed between the positive and negative pressures. There was much interference with carbon dioxide exchange in overpressure.

Dr. ROBINSON of Boston said that clinically the results of positive and negative pressures were identical—that the essential point was for surgeons to use a form of differential pressure rather than to depend on the fixation of the mediastinal partition. Most cases of empyema would in future be shown to be due to the failure of the surgeon at the time of primary operation to utilize differential pressure, and make the lung fast to the chest wall.

Dr. N. W. GREEN of New York spoke of the method of removal of lobes or of entire lungs, noting that the technique evolved in the Surgical Research Laboratory of Columbia, two years ago, had proved relatively free from danger when used on healthy dogs. Not so, however, in intervention on the esophagus where, despite unusual precautions the mortality was exceedingly high. It probably was not alone a matter of sepsis, but was concerned with a physiological disturbance as yet uninterpreted. There were many chances for exploratory work in the chest, and with properly applied differential overpressure, combined, probably, with rectal anesthesia, thoracotomy would be as safe as an ordinary laparotomy. Atropine had been used at the laboratory as routine preparation for thoracotomy for several years. Furthermore, Schäfer of Edinburgh had spoken of its similar use at the 1908 meeting in Chicago. Its employment was therefore not new. Inasmuch as sixty mm. of mercury could be recorded by expiratory effort, an overpressure of ten mm. must be absolutely harmless.

Dr. MURPHY of Chicago said that the treatment of empyema cavities lay in the successful sterilization of their walls followed by the introduction of an enzyme to create soluble albumoses, which were absorbable. A 2 per cent. formalin-glycerin solution was useful. Effusions, if sterile, should be left alone. Nature put them there to compress the lung in order to promote repair.

Dr. OCHSNER of Chicago considered the use of bismuth paste a very great advance.

Dr. FRIEDRICH, in closing, said that exploratory thoracotomy would be the triumph of the future.

Dr. JANEWAY, in closing, said that while operations might be done on the chest without differential pressure, there could not possibly be any progress made in the surgery of the esophagus without the employment of this technique. He made a strong plea for systematic and continued experiments on animals, and urged that as epithelioma of the esophagus had long been known to occur in early stages as a removable growth, a systematic examination with proper instruments should be made of all suspicious cases.

SECTION ON MEDICINE.

Tuesday, June 8—First Day.

DR. JOSEPH L. MILLER OF CHICAGO IN THE CHAIR.

Medical Supervision of Boarding Schools and of Athletic Contests Among Schoolboys.—Dr. NATHANIEL BOWDITCH POTTER of New York reported his observations of thirty-eight boys from six schools; the ages were between fourteen and three-quarters and twenty-one years; observations were made before and after one-mile runs, which lasted from five and one-third to ten minutes. He noted that the pulse became irregular in 11, or 29 per cent.; before the run 25, or 60 per cent., had a pulse of 80 or more; after the run 14, or 37 per cent., had a pulse of 150 or more, and 8, of 33, or 24 per cent., had a pulse of 110 or more. With regard to heart dulness, it was increased to the right in 11, or 29 per cent.; to the left in 15, or 39 per cent., and above in 2, or 5 per cent. The pulmonic second sound was increased in 21 boys, or 55 per cent.; the aortic second sound was increased in 7, or 18 per cent. In 4, or 10 per cent., there was a thrill. There was an apical murmur in 17, or 44 per cent., and a basal murmur in 21, or 55 per cent. In all acetone in the urine was absent. Before the run albumen was present in the urine in 9, or 23 per cent., and casts in 6, or 16 per cent. After the run albumin appeared in the urine in 31, or 81 per cent., and casts in 16, or 43 per cent. On the morning following the run albumen was present in none of 6 cases, and casts appeared in but 1 of 6 cases, or 16 per cent. The result of his observations pointed to the fact that in each school where from six to eight boys were selected to engage in athletic contests, there was at least one boy whose condition required a very careful supervision before entering these contests. His paper was written merely to stimulate interest in this subject and in the collection of statistics to show that more care should be given in the selection of those who were in boarding schools and who were about to engage in athletics.

Dr. DE LANCEY ROCHESTER of Buffalo knew of three serious cases of cardiac trouble which developed in boys under observation in school athletics. In athletics one of the most serious things they had to contend with was the fact that they were to engage in a contest; competition was what made these boys overexert themselves. There was danger in the masters in the schools encouraging the boys, urging them on in the athletic contests, thus making physical injury possible.

Dr. RICHARD C. CABOT of Boston spoke of what was found by a Cambridge man in the urine of men who had engaged in a boat race—large amounts of albumin, blood, and casts; and yet the urine was free of these within forty-eight hours after the contest.

Dr. Black of California believed that these contests developed endocarditis; they were developing heart troubles in children by encouraging athletic contests. When children were but eight years of age they were encouraged to make one-mile runs, and he knew instances in which they fell from exhaustion and unconscious on the track; and these were the little boys in the primary grades. This he considered an outrage.

Cardiac and Vascular Complications in Pneumonia, with Special Reference to Treatment.—Dr. Frederick Forchheimer of Cincinnati read this paper. He discussed the subject under three headings, viz. (1) the normal heart which became diseased in pneumonia; (2) the heart which was already diseased in pneumonia; (3) the effects of vasomotor paresis and paralysis. Because of the peculiar action of caffeine in stimulating the vasomotor centers and its action upon the heart he had administered this drug in a routine way during the past twelve years; this agent always increased the blood pressure, unless there was some organic lesion, which increased it. The only contraindications for its use would be abnormally high blood pressure, when there was danger of doing harm by the possibility of increasing it, a condition which might present itself in cases of cerebral arteriosclerosis, or in recent endocarditis. He had never seen any other effect upon the heart than that of diminution in the rate in pneumonia when the drug was given in proper doses. He employed the double salts, as they were more stable when dissolved in water and less irritating when administered hypodermically than any of the other salts of caffeine. Besides dilatation of the right heart as a menace in pneumonic patients, other cardiac conditions which might develop were pericarditis, acute myocarditis, and endocarditis. Endocarditis was the most frequent complication. It seemed that acute myocarditis occurring in pneumonia was a post-febrile form, and as such led to sudden death from acute myocardial insufficiency. As pneumonia was a bacteriemia it was not remarkable that the septic form developed, relatively, quite frequently. The treatment of these conditions was the same as that applied to them under other conditions. The treatment of pneumonia with coexisting cardiac lesions had been variously described; some authors gave digitalis in every case, while others gave it only for specific indications. Dr. Forschheimer now restricted the use of digitalis to those cases in which there was a probability of decompensation because of the additional work put upon the heart. In diseases of the myocardium were found upon the whole the most dangerous complications of pneumonia. Whenever any manifestation of myocardial insufficiency developed, it should be treated as an acute myocardial insufficiency, and the results would vary with the form of myocardial disease and with the individual condition. In the fatty heart, little could be expected from the use of digitalis or strophanthus, when the myocardium was already weak or when there existed arteriosclerosis. In the heart of Bright's disease when, notwithstanding the existence of renal disease, the blood pressure went down, caffeine should be given in large doses and digitalis as well. In arteriosclerosis the blood pressure was an infallible guide to therapy. Pericarditis did harm in various ways, either by producing myocardial insufficiency by extension to the myocardium, by the production of adhesive processes, or by the presence of fluid in the pericardium. When the latter existed, the fluid should be removed, otherwise the myocardial insufficiency should be treated.

Dr. De Lancey Rochester of Buffalo said that dilatation of the right heart occurring in pneumonia was not very uncommon, and was one of the conditions in which venesection was of particular value. He recalled twelve cases of pneumonia with dilatation of the right heart, and in each case he believed life was saved by the prompt removal of from 200 to 400 c. c. of blood, and as an illustration of its value he reported one case in detail.

Dr. Frank Billings of Chicago agreed with Dr. Forschheimer that active measures were necessary when the cardiovascular syndrome developed; until that time not all were agreed as to what should be done. It was very necessary that one should know not only when to give drugs but when not to give drugs. He said that the longer he lived and attempted to care for pneumonia patients the less was he inclined to give drugs until they were necessarily called for. The moment, however, that cardiovascular symptoms appeared, when the cardiovascular syndrome became manifest with the lowered blood pressure, with failing left heart, etc., the time had then arrived for active work. First of all he believed in the proper use of digitalis, but not as ordinarily given, by the mouth. He used a preparation of the leaves of the digitalis. Camphor was an agent which would rapidly raise the blood pressure in a failing heart; he gave one or two grains in the ordinary camphorated oil. Musk also was an agent which would raise the blood pressure. Strychnine was absolutely useless in these conditions except through its action on the nerve centers. In those cases of failing right heart, with dilatation, etc., he believed that venesection was the one thing which was productive of good results, if done immediately, no matter if the patient was plethoric; one should bleed, and bleed freely, and at the same time carry out other indications for treatment. After all the watchful and vigilant care of the pneumonia patient, without the use of drugs, was the ideal treatment; an attempt should be made to preserve the functions of the individual's body.

Dr. John H. Musser of Philadelphia called attention to the importance of remembering that in cases of early cardiac failure the cause was pericardial effusion; one often saw patients treated for heart failure or acute dilatation of the heart during a course of pneumonia when the removal of a few ounces of fluid from the pericardial sac would entirely relieve the symptoms. Of course, Dr. Forschheimer would agree that the best treatment of the heart was to begin the management from the first period of the disease, as soon as the pneumococcus infection was recognized. Therefore, the results that would follow would depend upon such early form of management. In the large majority of cases he preferred to rely upon fresh air, upon the judicious local treatment, hydrotherapy, regulating the amount of food taken, with particular care that the patient be not overfed.

Dr. Alexander Lambert of New York said that eight years ago he became disgusted with the results of the treatments employed in cases of pneumonia and the very unsatisfactory results obtained. Therefore in his division in Bellevue Hospital he determined to try to compare the results of the simultaneous treatment of patients with alcohol and nitroglycerin and drugs which raised the blood pressure. In one division there were 125 patients, while in the other there were 137 patients. He learned that among the patients who were treated with alcohol and nitroglycerin the death rate was 10 per cent higher than in those who were treated with drugs which raised the blood pressure.

An Experimental Study of Gastric Tetany.—Dr. W. G. MacCallum of Baltimore said that the severe cases of gastric tetany that he had seen all ended in the death of the patients. The etiology of the condition had not been understood, and several theories had been advanced to explain it, and the best known probably was that it was due to dessication of the tissues. The French tried to explain it as the result of an autointoxication from the absorption of poisons from the stomach. It was very desirable that the nature of the disease should be determined in order that some form of therapy might be carried out. The work done last year led them to the conclusion that

a sort of tetany could be stopped by the administration of the salts of calcium. Tetany of gastric origin they tried to approach experimentally, first producing tetany by causing an obstruction at the pylorus, in that way keeping the stomach empty. Feeding was carried on through an esophageal fistula. Animals so treated developed tetany, but not so severe as after parathyroidectomy, after the lapse of five or six days. Tetany developed even after large amounts of water were given. The first theory was disproved because gastric tetany did not depend upon the deprivation of water which caused a dessication of the tissues. As the stomach was washed clean, and contained no food whatever, it did not seem possible that it could be the result of an autointoxication from absorption of poisons from the stomach, for no fermentation could occur. In the mornings there was found a considerable quantity of gastric juice, sometimes as much as 500 or 600 c. c. It was possible for them to cure these animals temporarily by the administration intravenously or subcutaneously or by way of the intestine of sodium chloride. This would cure them of their tetanic contractures, but only temporarily, however. They were not able to keep the animals alive for any length of time by the administration of this salt.

Dr. ALLEN A. JONES of Buffalo reported the case of a middle-aged woman who was unconscious for a considerable length of time, and in other respects presented the typical picture of tetany. The woman recovered, but was again seized with tetany, unconsciousness, etc., and again recovered. She probably had gastric tetany; she had a very high hydrochloric acidity and some obstruction with food stagnation.

Dr. NATHANIEL BOWDITCH POTTER of New York said he had had under observation one year ago a case of gastric tetany, and Dr. Herter had examined the stools and urine, but found no evidence of any deficiency in calcium, and no evidences of intestinal putrefaction. They gave the patient calcium in reasonably large doses and she recovered, but they did not believe, however, that the calcium salts did much good.

Chronic Infectious Endocarditis.—Dr. FRANK BILLINGS of Chicago gave a description of the disease with its clinical course, including the positive demonstration of the microorganism by blood cultures. The disease was probably much more prevalent than the literature indicated. Among 14 cases, 11 were pneumococcic and three streptococcic; the pneumococci found in these patients were primarily found in streptococcic form. The source of invasion was an interesting question; in two patients an attack of tonsillitis had preceded the infection; in one case there had been influenza which led to an involvement of the heart and the pneumococci had been found; in two cases there had been a pyorrhea alveolaris, and in the pus from the abscess the pneumococci with other organisms were demonstrated. Drug treatment was absolutely useless. Two patients were given antistreptococcic serum; one received two doses, the other repeated doses. Experience had shown that if they were to use an antistreptococcic serum they must have it from the strain of bacteria that infected the individual to be treated; consequently the antistreptococcic serum now in the market was practically useless. As to vaccination with the pneumococci or gonococci their results had been absolutely negative.

(To be continued.)

Opposition to a State Tuberculosis Sanitarium.—The Governor of Texas has vetoed a bill for a tuberculosis sanatorium on the ground that such an institution would attract indigent invalids to the State. The physicians of the State hope that in two years' time they can ask another Governor to sign a similar bill.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending June 5, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	400	193
Diphtheria	371	30
Measles	1,458	30
Scarlet Fever	274	19
Smallpox	..	..
Varicella	142	.
Typhoid Fever	44	7
Whooping Cough	66	10
Cerebrospinal Meningitis	7	12
Malarial Fever	..	..
Totals	2,762	301

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service for the week ending June 4, 1909:

THE CONQUEST OF THE TROPICS FOR THE WHITE RACE.*

By W. C. GORGAS, M.D.,

ANCON, CANAL ZONE

ASSISTANT SURGEON-GENERAL, U. S. A.

After looking over the ground very carefully, I can find no particular field of work that should be called to the attention of the Association. We have progressed markedly in the last ten years along the line of raising the standards of medical education. This was the great aim the Association had in its formation. We should continue to push this work during the coming year as in the past.

During the past few years the Association has also done excellent work along the line of examining into various medicinal preparations put on the market and expressing an opinion as to their genuineness. This is a very useful work and should be continued.

We have recently begun to try to influence legislation in a direction favorable to medical and sanitary matters. Our field for usefulness in this direction is very great. These activities have been well covered by the Association during the past year, and I have no doubt they will be equally well sustained during the coming year.

It has been customary for the incoming President to urge on the Association some line of action which he thinks particularly useful. It seems to me best that the Association follow, during the coming year, along the lines mentioned above, just as it has done during the past year.

Dr. S. Weir Mitchell of Philadelphia has suggested that our Association should erect in the national capital some suitable monument in memory of the medical officers on both sides who lost their lives in the performance of their duties during the war between the States. Our Association now represents the medical profession of the whole United States. No period in the history of our profession can be selected in which greater devotion to duty was shown than was evidenced by the medical officers who served in this war, nor can any war be pointed out in which a greater number of medical officers gave up their lives in the performance of their duties. I, therefore, recommend that the Association take steps looking to the erection in the national capital of a suitable monument in memory of the medical officers on both sides who gave up their lives in the performance of duty during the war between the States.

I have consulted with my friends, and have given careful thought, as to what lines my address should follow. And I have concluded that, as I believe no special recommendations from me as to action on the part of the Association are needed, it would be best to outline some phase of our sanitary work at Panama, the description of which would be generally useful, and, possibly, generally interesting. With your permission, then, I will make this address on our sanitary work at Panama, as it bears on malaria, and as to how these measures could be applied in other localities.

I hold that it has been proved that malaria is carried from person to person by the bite of the female of a particular species of mosquito—the anopheles—and that it is conveyed practically in no other way. Our measures are principally directed to the destruction of this species of mosquito. The anopheles propagates itself by laying its eggs, about a hundred at a laying, on the surface of fresh water. These eggs float around until they are hatched by the heat of the sun. The young live a larval and pupal stage of about eight days in the water, at the end of which time they have developed into full-grown mosquitos.

This mosquito seeks clean, fresh water in which grass and algæ are abundant. As soon as the eggs hatch the larvæ flee to the grass and algæ for protection from small fish and their other natural enemies. The adult anopheles is weak in flight, and does not habitually move about much. We place a hundred yards as practically its ordinary flight. The adult is much afraid of wind and seeks undergrowth, grass, and plants near the ground for its protection.

The anopheles, then, requires clean, fresh water in which there is plenty of grass and algæ for the development of its larvæ, and, when grown, does not fly farther than a hundred yards. It also needs brush and grass for its protection against the wind. Our measures for destruction are based on these two peculiarities. We destroy all the breeding-places within a hundred yards of the locality we desire to protect, so that the mosquito can find no water in which to lay her eggs, or where her larvæ can develop. At the same time we clear off the brush within the same area, so that the adult cannot find protection against the wind.

Measures for the destruction of breeding-places have to vary with the locality. Wherever we can drain at a reasonable cost, we do so. This drainage is generally done with superficial ditches or subsoil tiling. Subsoil tiling is the ideal antimalarial drainage system. It does away entirely with mosquito-breeding, and after it is once laid in there is no further expense for keeping the ditch open. In the tropics vegetation grows so rapidly that a ditch has to be cleaned out every two weeks so as to keep the channel free from breeding-places. This is so heavy an expense that we find it much more economical to concrete all superficial ditches. A con-

*President's address at the sixtieth annual session of the American Medical Association, at Atlantic City, June 9, 1909. From advance sheets through the courtesy of the editor of the *Journal of the American Medical Association*

crete ditch should be swept out frequently, else obstructions will form many small pools. Drainage is *par excellence* the great means for anopheles destruction. But in many instances on account of the too great expense drainage cannot be resorted to; if, for instance, the town is situated near a large swamp or lake. In such cases the mosquito larvæ can live only around the edges, where they are protected from the small fish by grass and algæ, or in holes made by the feet of animals in the soft soil at the margins of the water. In such cases we keep the brush and grass cut along the edge of the water near the town and see that animals are not allowed access here. Or the town may be situated near the bank of a small stream. In this case we would keep the stream and banks free from grass and algæ in the neighborhood of the town. When we can do so safely, we use sulphate of copper for killing algæ. When we cannot use the above methods we kill the larvæ with either crude petroleum or phinotas oil. Petroleum destroys the larvæ by spreading over the surface and smothering them. Phinotas oil acts by directly poisoning them. The above are the principal methods for destroying larvæ, and I look on the destruction of larvæ as the principal means for controlling malaria.

We keep the brush and grass cut within a hundred yards of the point to be protected. Both grow very rapidly at Panama, and this is a large item of expense. It is a great economy to get the ground in such condition that horse mowers and scythes can be used. Using the subsoil tile greatly facilitates getting the ground into this condition. Along the line of the canal most of the localities at which we have been at work for a year or longer are already in this condition. Brush-cutting I consider as only second in importance to drainage as an antimalarial measure. If brush and grass are thick about a dwelling, mosquitos seek them as shelter from the wind. If brush and grass are continuous, the female anopheles will wander from a breeding-place by short flights for a mile or more. A cleared space of a hundred yards or more will, in general, stop her flight.

In adapting these measures to special conditions as they arise, practice and experience are of great advantage. And the greater knowledge a man has of the habits of the mosquito with which he is dealing, the more likely he is to succeed. My surprise has not been so much at the difficulties of getting rid of mosquitos as at the great results of apparently inadequate measures.

Colon, a town of 15,000 inhabitants, is built on an island just above sea level. The houses, where the ground has not been filled in, have to be built on piles from two to four feet high, and approached by wooden footways raised above the water. The heavy rains in the wet season make this part of the town a freshwater swamp. Mosquitos of all varieties were very numerous in Colon. The brush was cut away for half a mile back of the town. This area was then intersected by several small canals twenty feet wide by six feet deep, and all the swamp connected with these canals by surface ditches. This allowed the fresh water to run off, and all ditches to be filled daily with sea-water. We also looked carefully after all water-containers, cisterns and barrels in the town. The result has been that Colon is almost free from mosquitos of all kinds. Such results were not expected. It was hoped by these measures to get rid of the hurtful mosquitos, the stegomyia and anopheles, which do not fly far. But it was not expected to affect to any great extent the culex, which is strong on the wing and still breeds for many miles in the swamps beyond.

Besides measures directed at mosquito destruction, we screen with wire gauze the houses of all employés. Most of our houses are built with galleries, on to which the doors and windows open. These galleries are screened rather than the doors and windows. This leaves only one or two openings to a house which have to be looked after with regard to being kept closed. The screening should always be supervised by some one of experience in mosquito work, as there are many points that are overlooked by the ordinary carpenter. We also urge on the people the use of mosquito-bars. Most of us, however, have become careless about this, as in the well-drained districts, where the houses are well screened, mosquitos are rare. All employés are urged to take three grains of quinine daily as a preventive against malaria. On the average about 20,000 doses of quinine are taken daily by our 45,000 employés.

To carry these measures into effect we have the forty-five miles of country along the line of the canal divided into seventeen districts, each district in charge of an inspector, and the whole under the charge of one chief inspector.

The chief inspector has in his office a man familiar with the life history of mosquitos; another, expert in tiling and ditching, and a general inspector. These men keep in constant touch with the district inspectors and act as their teachers and instructors.

The district inspector is held responsible for his district. He has twenty-five or thirty men for ditching and brush-cutting, a force of carpenters for keeping screens in repair, and one or two quinine dispensers. The men are not required to take quinine, but the dispensers visit all the camps and barracks daily offering quinine to such men as care to take it. Each district inspector is notified monthly that he must keep his expenditures within a certain sum. The chief inspector keeps in such touch with the various districts that this sum can be increased or decreased as necessity arises.

The medical officer in each district reports weekly the number and locality of the employés in his district suffering from malaria. This report is consolidated every week in the central office, giving for each district the number of employés in that district, the number of cases of malaria which occurred during the week among these employés, and what percentage the number of cases of malaria is of the whole number of employés. A copy of this report is sent weekly to each district inspector. The work of the district inspector is judged by this report. If the malarial rate rises in a district the special inspectors from the central office go out to the district and they, with the district inspector, are expected to find the cause of the rise and correct it.

The results as to malaria have so far been very satisfactory at Panama. Table 1 shows the malarial rate:

TABLE 1—MALARIAL RATE AT PANAMA.

Year	Force	Cases	Rate per 1,000	Deaths	Rate per 1,000
1904	6,747	422	125	9	2.66
1905	10,511	8,496	514	92	5.57
1906	26,705	21,938	831	199	7.45
1907	39,344	16,709	424	138	3.51
1908	43,890	12,372	282	59	1.34

You will see from this table that there has been a steady decrease in the malarial rate and that at pres-

ent it is less than one-fourth of what it was in 1905. I see no reason why if the proper methods are kept up the rate should not continue to decrease indefinitely.

The general health of our force is excellent. Considering the whole population under our sanitary jurisdiction, including the cities of Panama and Colon, the death rate is shown in Table 2.

TABLE 2—DEATH RATE IN THE POPULATION UNDER AMERICAN SANITARY JURISDICTION.

Year	Population	Number of Deaths	Rate per 1
1904.	35,000	1,224	52 45
1905.	42,699	2,793	65.41
1906.	66,011	3,544	49.10
1907.	102,133	3,435	33 63
1908.	120,097	2,983	24 83

The Canal Zone, where the health work is under the chief sanitary inspector, the rates are as shown in Table 3.

TABLE 3—DEATH RATE IN CANAL ZONE.

Year	Population	Number of Deaths	Rate per 1
1907	54,366	1,768	31
1908.	67,146	1,273	18

While this is not small as compared with most parts of the United States, it is small for tropical regions and small as compared with many parts of Europe.

The death rate among the employees of the United States government from all causes (including violence), considering the whole force, has been as shown in Table 4.

TABLE 4—DEATH RATE AMONG GOVERNMENT EMPLOYEES

Year	Force	Number of Deaths	Rate per 1
1904	6,213	82	13
1905	16,511	427	25
1906	26,765	1,105	41
1907	39,443	1,152	28
1908.	48,890	571	1

The rate for 1908 is probably not any higher than that of a similar body of men doing the same work in New York State.

The rate for Americans from all causes, including violence, has been as shown in Table 5.

TABLE 5—DEATH RATE FOR AMERICANS IN PANAMA

Year	Number of Men	Deaths	Rate	No. of Women and Children	Death	Rate
1904	865					
1905.	3,029					
1906	5,000	35	7 00	800		
1907	4,300	42	9 76	1,337	4	3
1908	5,459	42	7 69	2,174	2	9

This is certainly no higher than for a similar population in any healthy part of the United States.

I believe that the debility from which the white man has suffered in the past at Panama and in other tropical countries is due to malaria principally, and that if he protects himself from this infection he will remain vigorous and strong in the same degree as he will in a temperate climate; and as a reason for this belief I advance the condition of the Americans at Panama. We have about eight thousand of them living under about the same conditions as they would live at home if doing the same work. They are exposed to the weather as much as they are at home, a large proportion of them being exposed for eight hours daily to the tropical sun and rains. Yet the figures I have quoted above show that their general health remains fully as good as it was at home.

The only difference between ourselves and the whites formerly in Panama is that we have protected ourselves from yellow fever altogether and malaria to a great extent. Yellow fever has a great effect on the death rate of a non-immune population, but very little effect in causing debility, whereas malaria is a disease which may last for years in the individual, and in a locality like Panama causes a widespread debility in the whole population.

For the white man going to the tropics it is neither difficult nor expensive to protect himself from malaria. All that is necessary is to screen his house well and drain and clear off the brush within a hundred yards of his residence. This is much less expensive than the measures a man has to take in the temperate zones to protect himself from cold.

The advances in tropical sanitation in the last fifteen years have shown that the white man can live in the tropics with as good health as he can in the temperate zones. This has been demonstrated by both of our military occupations of Cuba, and also by our occupation of Panama. The white man can protect himself against disease in the tropics at no greater expense than he would have to undergo in order to protect himself against cold in the temperate zones. The returns for his labor are many-fold greater in the tropics than in the temperate zones. I think, therefore, that the tendency in the next few centuries will be for the white man to drift to the tropics, and I dare predict that, by the time the year 1909 is as old as is at the present day the Norman conquest of England, localities in the tropics will be the centers of as powerful and as cultured a white civilization as any that will exist in temperate zones.

I believe that our work in Cuba and Panama will then be looked on as the earliest demonstration that the white man could flourish in the tropics and as the starting-point of the effective settlement of these regions by the Caucasian. I am inclined to think that at this time the construction of the Panama canal will be known less as a great commercial accomplishment or engineering feat than as the first demonstration of the fact that the white man can flourish in the tropics in spite of those most trying conditions which have in the past rendered it impossible for him to thrive.

CAISSON DISEASE.*

By M. ALLEN STARR, M.D., LL.D.,
NEW YORK.
PROFESSOR OF NEUROLOGY, COLUMBIA UNIVERSITY.

In the last few years, when work in caissons has been carried on constantly in this city, the phenomena of caisson disease have become familiar to all hospital physicians. These cases are of special interest to the neurologist, because the majority of the symptoms presenting themselves are due to disturbance of function in the nervous system. It is well known that these symptoms are produced by the development of air bubbles in the blood vessels consequent upon the sudden relief of air pressure after it has been exerted for some time in the caisson. These air bubbles act as emboli in the

*Read before the Practitioners' Society April 5, 1909.

blood-vessels and produce a stasis in those vessels, and consequent disturbance of function and nutrition in the nervous tissues supplied by those vessels. In some cases this disturbance of nutrition is temporary, and in the course of a week all the symptoms, even when severe, pass off. In other cases the symptoms remain a much longer time and appear to be very serious, yet in the end the patients recover. In a third set of cases the symptoms remain permanent with only a slight degree of recovery, and the patients are confirmed invalids. In a fourth set of cases the result is fatal within a few hours or days of the onset. It is quite remarkable, however, to find in a study of several hundred cases of caisson disease presenting nervous symptoms, that the large majority of these cases recover, even though they had at the outset presented symptoms of a cerebral or spinal nature which, if not due to this cause, would have presented a very unfavorable prognosis, and inasmuch as in fatal cases well marked degenerations in the nervous system have been found, this recovery appears to be quite extraordinary.

An analysis of about three hundred cases which have occurred in recent years shows the following list of symptoms occurring in the order of frequency:

(1) Myalgia, or severe pain in the muscles, and especially in the muscles of the back, but also in the muscles of the extremities, seems to be a uniform accompaniment of the disease. It occurred in 105 of the 310 cases here analyzed. It is the symptom which has given rise to the common term used by the workmen for this affection, viz., "the bends," the patient being practically doubled up with pain and unable to move the muscles or to straighten himself out, as in a case of intense lumbago.

(2) The second most frequent symptom is an affection of the ears, either a rupture of the drum or such an intense congestion of the inner ear as to produce symptoms comparable to Ménière's disease; vertigo, vomiting, intense prostration, tinnitus aurium, and deafness. These symptoms occurred in 68 cases.

(3) Pain in the joints, classed together as arthralgias, occurred in 60 cases, in many of them being attended also by myalgia. It seems probable that in these cases there has been a sudden effusion of fluid into the joints, stretching the capsules of the joints without any acute inflammatory condition, and in proof of this the frequency of swelling without heat or redness can be cited.

(4) In 26 cases acute paraplegia developed and as these cases are of particular interest, both in their progress and in their recovery, the following case is cited in full:

A young engineer of the Pennsylvania Railroad, who had been in perfect health and had been accustomed to work in caissons, and who had a knowledge of the dangers attendant upon too rapid a transit from the compressed air to the ordinary atmosphere, neglected the ordinary precautions and on one occasion passed out of the caisson without delaying a sufficient time in the two intermediate chambers. He was seized immediately with vertigo and intense headache, with great pain between his shoulders, and within fifteen minutes found himself completely paralyzed below the neck. He was taken to the hospital in a state of prostration. During the first twenty-four hours he was delirious, restless, but incapable of moving any muscle below his neck, had retention of urine, and had considerable difficulty in breathing. The cerebral symptoms then began to subside, but when I saw him, on the fourth day after the onset, his paralysis had not in any way improved. There was no cranial nerve palsy, and the motion of his head upon his neck was free. He could abduct his arms, there being no paralysis of the deltoid, upper pectoral or trapezius muscles, but he had absolutely no power of flexing or extending the elbows, of moving the hands, of moving the trunk, or of moving the limbs. There was priapism, with retention of urine and a paralysis of the rectum, which had to be emptied mechanically. He had some sensation of touch, temperature, and pain in the arms and hands, though this was less acute than on the face. Below the line of the eighth rib he was totally anesthetic. His respiration was diaphragmatic, and he was unable to distend the chest by any inspiratory effort.

He thus presented the picture of a transverse myelitis at the level of the fifth and sixth cervical segments of the spinal cord, such as is seen in injuries, or occasionally in an infective myelitis. Such a case ordinarily would have the most unfavorable prognosis both as to life and as to recovery, especially as in this case a tendency to bedsores at any portion of the body subjected to pressure was evident. In spite of this condition, however, this young man went on to a rather rapid recovery. He was confined to his bed for two months, but within two weeks of the onset it was evident that power was returning little by little in all of the muscles, and at the end of two months he was able to sit up and to stand when held. The tendency to bedsores subsided in six weeks from the onset, at the time when the power to voluntarily turn himself in bed had been regained. Sensation returned slowly, that to pain and temperature returning before that to touch. The control of the bladder was not regained until two months after the onset. His recovery was steady and at the end of four months from the time of the beginning of the disease, he was sufficiently well to go back to work.

It is well known that the prognosis in myelitis is, as a rule, most unfavorable, for even after the dangers attendant upon the onset of total paralysis are avoided, viz., bedsores and cystitis, there is usually left a state of spastic paralysis which persists through life. In the cases that have been recorded of spinal cord symptoms occurring in caisson disease, it has been possible to classify the cases; some which resembled those of spastic paraplegia due to an affection of the lateral columns, others which resembled locomotor ataxia due to a lesion of the posterior columns, and cases of atrophic paralysis with a disturbance of temperature and pain sensations due to lesions of the gray matter, and, finally, cases which presented symptoms common to all these affections and which are classed together as chronic myelitis. But in all of these various types of spinal lesion occurring as a result of exposure to the dangers of caisson disease, recoveries have been recorded. The explanation for such recoveries is to be found in the fact that the collateral circulation in the spinal cord and the anastomoses of the spinal blood vessels are very complete, and we must believe, therefore, that the circulation is resumed in the vessels which have originally been obstructed by the presence of air within them.

(5) Monoplegia has been observed in 17 cases, cerebral in type rather than spinal, and undoubtedly due to localized areas of softening, or to malnutrition in the cortex produced by bubbles of air in the

veins of the brain. That this condition is possible is proven by a specimen here presented, which I owe to the kindness of Dr. Larkin, of the Laboratory of the College of Physicians and Surgeons. It shows the existence of air bubbles in the veins of the cortex of the brain in a patient who died of caisson disease. It is evident that such bubbles can act exactly as emboli, and hence, if in the cortex, are more liable to produce monoplegia than hemiplegia.

(6) Symptoms of intense vertigo of cerebral nature, undoubtedly due to emboli in the cerebellum, were noted in 14 cases. These resembled in many respects the symptoms of Ménière's disease, already mentioned, but were followed by paraylsis of some of the cranial nerves, indicating that the origin of the symptoms was not in the ear.

(7) The seventh most frequent set of symptoms were classed together as asphyxia, the patients showing all the signs of faintness with irregular heart action, but these are, of course, temporary in their nature. Thirteen patients suffered from this symptom.

(8) Aphasia has been observed in a number of the cases.

Recoveries have also been recorded in many of the cases where the symptoms were largely cerebral. Thus in cases presenting the phenomena of acute transitory mania, in other cases presenting symptoms of hemiplegia, in other cases presenting the symptoms of various types of aphasia, and temporary deafness and temporary blindness, as well as in those very numerous cases in which peripheral disturbances of the auditory nerve has been produced by lesions of the inner or middle ear, recoveries have been recorded. It is evident, therefore, that in the cases of apoplexy or of paraplegia occurring in connection with caisson disease, the prognosis is very different from that in cases occurring under other circumstances.

It is well known that the important element in the treatment, is to replace the individual as soon as possible after the onset of the symptoms, in a chamber containing compressed air and to keep him under two or three atmospheric pressures for several hours, reducing this pressure very gradually. Fortunately, in our hospitals at the present time, such air chambers have been instituted. If this cannot be done, the most successful treatment appears to be to stimulate the circulation by strychnine, and to increase the arterial tension by ergot.

THE VALUE OF CYSTOSCOPY IN GYNECOLOGY.*

By ARTHUR STEIN, M.D.,
NEW YORK.

In surgical conditions, more especially in affections of the genitourinary organs, the value of cystoscopy is well recognized by everyone. This can hardly be said in connection with diseases of the *female* genital organs, and yet in the latter the field of usefulness of the cystoscope is a large one. Numerous investigations in recent years have demonstrated the occurrence of certain affections of the female genitourinary system, partly primary, partly secondary, which present themselves but seldom or not at all in the male. For this reason, gentlemen, I shall give you a general outline of what we as gynecologists can hope to accomplish in diagnosis and therapy by the liberal use of the cystoscope.

I shall not describe the picture presented by the normal bladder, as only practical experience and not didactic teaching can acquaint one with the illuminated bladder. I shall, however, refer briefly to the peculiarities of the normal *female* bladder. Due to its close approximity to the genital organs, the appearance of the female bladder shows several differences in comparison to the male bladder. These differences appear especially in the form of protuberances into the bladder, as well as in the form of pocket-like recesses and diverticula. Accordingly, the inspection of the female organ, especially in its lateral sacculations, is more difficult than that of the distended ovoid male organ. The peculiarities of the female bladder are attributable to numerous causes. Normally, and especially that holds true in cases of sharp anteflexion, the fundus of the uterus lies upon the posterior bladder wall making a more or less marked impression. The cystoscopic picture here shows a protuberance which may resemble a tumor by throwing a shadow on the lateral wall of the bladder. The gravid uterus or the foetal head toward the end of pregnancy compress the bladder so that it resembles a mere fissure. A retroflexed gravid uterus has the same effect, at the same time pushing the neck of the bladder upwards. The posteriorly and laterally displaced uterus will displace the bladder. Myomata of the uterus, especially if multiple and of the subserous variety, tumors of the uterine appendages, all distort the bladder wall in various ways. In other words, a thorough inspection of such bladders amounts to a tedious winding through valleys with the cystoscope, while the endoscope examination may reveal absolutely normal findings.

After these general remarks, I shall now take up the female affections in which the cystoscope is of great value to us and shows striking pictures. Beginning with *inflammatory* conditions of the bladder, about which the general practitioner is most frequently consulted, the pictures are exceptionally varied. There are, however, a few characteristic forms which are especially prevalent in the female. I refer to the inflammation of the neck of the bladder—cystitis colli vesicae—and of the trigonum. In these two forms the inflammation frequently confines itself to the localities mentioned, though it may extend over the entire bladder, in which case the appearances at the neck and trigonum are less prominent. The frequency of cystitis of the trigonum is striking. Recently published statistics show that it occurs in 20 per cent. of all the forms of cystitis in females. Judging from my own experiences these figures are, if anything, too low. This fact that in so many cases only a certain part of the bladder—neck or trigonum—is involved, makes it evident that bladder irrigations, which are unfortunately still used as routine treatment in these conditions, will not be followed by satisfactory results. In these cases, as well as in all other affections in which even the slightest involvement of the bladder is suspected, it is necessary to bring the diseased area directly before the examining eye, that is, to use the cystoscope. Two, I might say typical, cases out of my practice will prove this to you. The first concerns a woman who was referred to me after having been treated for one and one-half years for a cystitis following labor. The treatment had consisted in bladder irrigations at regular intervals. When she first came to me the catheterized specimen was ammoniacal, contained pus and bacteria. A careful examination excluded any involvement of the kidneys. The endoscopic examination revealed at a glance that we were deal-

*Paper read at a meeting of the Eastern Medical Society, March 12, 1909.

ing with a pronounced cystitis coli et trigoni together with a slight involvement of the remainder of the bladder. Here only local treatment, that is, cauterization of the neck and trigonum could have been of any avail. The outcome of the treatment verified this view. After five weeks the patient, who had been getting bladder irrigations for such a long time without improvement, was without a subjective symptom, while her urine was absolutely clear. This case, to which I could easily add numerous others, shows definitely the value of cystoscopy as the only certain method of diagnosis, and as there can be no correct therapy without a correct diagnosis it also proves the therapeutic value of the cystoscope. The second case is equally instructive: An elderly woman came under my care after she had been treated for cystitis over a period of several years. A minute examination of the urine and an endoscopic examination showed that there was no inflammatory condition of the bladder or kidney present. The vesical symptoms had been caused by a weakness of the bladder. In this case the success of the treatment again substantiated the diagnosis. After a few electrical massage treatments of the neck of the bladder by way of the vagina, the vesical symptoms which had lasted for years had entirely disappeared and had not returned many months later. Such text-book cases demonstrate without doubt the value and importance of a cystoscopic examination. The latter enables us to recognize the presence or absence of pathological changes, and thus to draw conclusions as to what line of therapy is to be pursued. With the introduction of the cystoscope, the diagnosis "irritable bladder," as shown by Bierhoff and Knorr, has almost become extinct; only very rarely are we justified in making this diagnosis. The cystoscope is indispensable for making the diagnosis "cystitis trigoni" as in this condition the urine may contain but little pus and at certain times of the day may even be free from it. Frequently the trigonum is the only seat of disease in the entire genitourinary tract, and often it is combined with chronic inflammatory conditions of the vagina, cervix, uterine appendages or parametria. One of its most frequent cause is the gonococcus; the latter, however, is only found with great difficulty in the urine, or more often it is impossible to demonstrate it at all.

Foreign bodies of the most varied type are only too frequently the primary cause of a cystitis. Cystoscopy is incontestably better than any other method for determining their presence in the bladder except the use of the *x*-rays. In addition it informs us as to the localization and extent of the cystitis and as to its origin, that is, whether it is primary or secondary. Calculi, foreign bodies and tumors of the bladder are often complicated by a secondary infection which manifests itself in a more or less severe cystitis. The clinical symptoms of the latter are so prominent that only the cystoscope can enlighten us as to the true state of affairs. Among the diffuse cystitis cases, cystitis cystica is quite common among women. In this form flat reddish-gray vesicles are found especially in the region of the trigonum, though they can also be present in other parts of the bladder and may even extend over the entire organ. They are usually surrounded by a red ring. They are more irregularly distributed as compared with the tubercles in a tuberculous cystitis and usually not along the course of the vessels. Tubercles are circumscribed, larger, have a different color, and are distinctly raised.

Among the foreign bodies in the bladder the calculi, if we have a right to consider them such, hold a prominent place. In many cases the symptoms are almost sufficient to establish a diagnosis. In others the diagnosis must rest upon the result of physical examination. While I do not wish to underestimate the value of the metallic sound in the hands of an experienced surgeon in these cases, and not speaking of the value of the *x*-rays, I feel certain that an examination with the cystoscope is far superior to that with the sound since it gives absolutely accurate information. Then, too, stones lying in pockets may entirely escape detection with the sound. All those who have seen them have become convinced for all times of the value of endoscopic examination. This is especially true when, as it has happened to me several times, one detects a calculus with the cystoscope after no other method of examination was able to reveal the cause of the symptoms. The sound does not throw any light upon the composition of the calculi, nor does it give us, as a rule, any exact knowledge as to their size. Endoscopic examination, on the other hand, quickly demonstrates the presence or absence of calculi and if present, their size, shape, number, and to a certain degree their composition. One can also see the calculus and ascertain whether it is movable or imbedded in the vesical wall. Furthermore, the cystoscope gives us accurate knowledge in regard to any accompanying complications and thus paves the way for the proper treatment. An inspection of the stones reveals the character and color of their surface, and thus we can form some idea as to their chemical composition. We know that the urates, the most common variety of vesical calculus, are yellow or brown, that the phosphates have a white or whitish-gray appearance and that the oxalates, which form the so-called mulberry stones, are greenish-gray or greenish-black. We furthermore know that the oxalates are very hard, the urates usually very soft, and can thus draw important conclusions as to the therapy to be pursued. Because the cystoscopic examination is a better guide to the necessary therapy than any other clinical method, and because it makes possible endovesical treatment—a mode of treatment which I am certain is destined to outflank the cystotomy in many cases—for these reasons every case suspicious of calculi should be cystoscoped both in the interest of patient and physician and thus disagreeable surprises avoided. In regard to the endovesical treatment of calculi, and this applies to benign bladder tumors as well, it is more easily carried out and accompanied by less danger in the female than in the male. This is so for the reason that an operating cystoscope usually can be more freely moved about in the female bladder, and because the female parts readily permit of two simple procedures: Dilatation of the urethra and colpocystotomy.

Turning now to foreign bodies in general, you well know, gentlemen, that the female bladder in particular can be the seat of the most varied and most curious foreign bodies. Such bodies usually find their way into the bladder through the urethra into which they are introduced for sexual excitement, or in hysterical patients, or by mistake in attempts at criminal abortion. Often they enter the body without any fault of the patient, for instance, when ectopics or dermoid cysts, undergoing suppuration, break into the bladder. We may then find hair, teeth, bones, etc., in the bladder. After abdominal operations, sponges, gauze drains, or

even forceps may suppurate into the bladder. Such cases have been reported in literature and they point to the great value of cystoscopy, because the latter alone enables us to make the correct diagnosis and therefore to carry out the proper treatment. It is not rare that ligatures, which were employed outside of the bladder during gynecological operations, find their way into the bladder, especially after a supravaginal hysterectomy, at which the cervical stump is left extraperitoneally. It is therefore always well to keep in mind the possibility of the presence of ligatures in the bladder in all cases in which suture material with long resistance, that is, with a long absorption limit, has been used in the neighborhood of the bladder wall. The cystoscope alone is able to enlighten us as to whether the wandering of a ligature is in progress, has, or has not taken place.

In cases of tumor of the bladder we meet with similar conditions. The symptoms are frequently none other than those of a cystitis. Hematuria, the most characteristic symptom of tumor, is frequently intermittent and does not necessarily indicate the presence of a bladder tumor. Therefore, all patients who give a history of having had blood in the urine should certainly be cystoscoped, even if the urine is absolutely clear at the time the patient presents herself for examination. Among the benign tumors, the fibrous polyps and villous papillomata both present striking endovesical pictures. A true fibrous polyp juts into the lumen of the bladder and floats to and fro. The villous variety may either be sessile or pedunculated; these consist of a connective-tissue center which is studded with innumerable small villi like the branches of a tree coming off from its trunk. Whether these tumors should be treated by colpocystotomy or by the intravesical method by means of the operative cystoscope, the individual case can only decide.

In primary carcinoma or sarcoma of the bladder the cystoscope is not of so great importance. The endoscopic picture in these cases frequently differs but little from that of a severe cystitis in which the entire bladder wall is thickened and made rigid by edema and inflammatory infiltration, the mucosa being considerably puffed out. When the tumor is raised above the level of the surrounding mucosa, small irregular, easily bleeding areas can be seen jutting into the bladder lumen. Only under the latter conditions can we hope to make the diagnosis of malignancy with the cystoscope. On the other hand, cystoscopy is of value when we wish to ascertain whether the bladder has become involved in cases of carcinoma of the portio or cervical canal.

This brings us up to the question of *changes in the bladder which are secondary to diseases of the genital tract.* Great differences of opinion are found in literature as to the value of the cystoscope in determining a secondary involvement of the bladder in cases of carcinoma of the cervix. I believe that it is possible by means of the cystoscope to make a positive statement as to the non-involvement of the bladder, and in some cases to state with certainty that the carcinoma has extended to the bladder. Sometimes, of course, it will be impossible to reach any positive conclusion as to whether the bladder has become involved or not. And yet, gentlemen, I advise you to always use the cystoscope before operating for carcinoma of the uterus, in order to get some idea of the condition of the bladder and thus guard against disagreeable surprises during operation. When the carcinoma first begins to encroach upon the bladder we only notice a mechanical displacement and a congestion of the floor of the bladder. This frequently means that the separation of the bladder from the uterus will be attended by difficulties. In more advanced cases we see a bullous edema caused by circulatory disturbances of the bladder mucosa. This consists of translucent vesicles which at first are flat and then become larger. Such an edema is a bad prognostic sign. In the markedly advanced cases we see carcinomatous growths in the bladder in the form of hard, irregular, papilloma-like masses which bleed easily on being touched.

Among the benign uterine tumors the myomata often have a detrimental influence upon the bladder. About two-thirds of all women with uterine myomata have bladder symptoms. Large myomata undoubtedly influence the bladder by the constant compression of the latter. This, however, cannot be said of the smaller tumors which do not even come in contact with the organ; in these cases a dilatation of the perivesical vessels as well as an alteration of the surrounding connective-tissue must be considered as possible causes of the bladder symptoms.

There is no doubt of the practical importance of cystoscopy in women with uterine myomata, for a knowledge of the character of the anatomical changes causing the bladder symptoms is of no little consequence in deciding upon the kind of treatment to be applied for the tumors.

Finally there remains to be mentioned the fistulae which develop as a result of trauma to the ureter or bladder. They are of great interest not only to the specialist, but also to the general practitioner. It is obvious that here too the cystoscope has a field of usefulness both as an aid to locating the fistula and as an aid to its treatment. In vesicovaginal fistulæ it enables one to recognize the size and situation of the defect. Then, too, it is of practical importance to know just where the ureteral orifice is situated in relation to the fistula, in order to avoid including the ureter in a suture when repairing the bladder defect. The bladder can usually be filled in cases of vesicovaginal fistula, by placing a tampon saturated with oil into the vagina. In ureteral work the subcutaneous injection of 20 c.c of a four-tenths per cent solution of indigo-carmine (according to the method of Voelcker-Joseph) is often invaluable. The injection is made in the gluteal region and after ten minutes the urine is colored blue. It is a great aid in locating the ureteral orifices in cases in which displacements, sacculations, or prominences make this more difficult than usual. Furthermore, in the diagnosis of ureteral fistulæ or ureters which have been accidentally included in a ligature during an operation, indigo-carmine is indispensable. From one ureteral orifice the blue-colored urine will be seen spurting at intervals, the other one will either discharge very little urine or none at all. Thus one can find very quickly the injured side and operate accordingly. The good or bad result of an implantation of the ureter can be ascertained in no better way than by the cystoscope.

Only a few words more about cystocele and prolapse. In advanced cases of prolapse we find the whole bladder distended, as usually the urination is difficult owing to a dislocation of the urethra. The sequelæ are: A chronic cystitis, as there is a stagnation of urine in the descended parts of the bladder and a pronounced hypertrophy of the muscular wall. In very pronounced cases of cystocele and prolapse

the whole trigonum disappears and is only to be found in that part of the bladder which lies outside of the vulva. For a correct diagnosis it is advisable to reduce the whole prolapse and then to make a cystoscopic examination, as it is clear, that the whole technique of the cystoscopic examination is not very easy in an unreduced prolapse.

Much more could be said about these interesting pathological conditions, as well as about retroflexion and pelvic cellulitis in their relation to the bladder, as well as about ureteral catherization, but lack of time prevents me from doing so. Pathological changes, technique, and therapy must also be left for some future time. My purpose this evening was to draw your attention to the close relationship between the female bladder and female genitals, and to convince you that the cystoscope is indispensable in gynecology. If I have succeeded in doing this I have accomplished what I set out to do in preparing this paper.

1 West Eighty-fifth Street.

ON THE AMOUNT OF PEPSIN IN VARIOUS DISORDERS OF THE STOMACH.

By MAX EINHORN, M.D.,
AND
GEORGE L. LAPORTE, M.D.,
NEW YORK.

Of the specific elements of the gastric juice hydrochloric acid has been subjected to the most thorough investigation, physiologically as well as pathologically. A number of clinicians have endeavored to ascertain the presence and quantity of pepsin in different ailments of the stomach. The old method of determining the presence of pepsin consisted in using a small piece of the white of a hard-boiled egg (Leube). This permitted only a rough estimate of the amount of pepsin.

An improvement of this method is Mett's procedure. This consists in placing small, calibrated glass tubes filled with coagulated albumin into the gastric juice and estimating the amount of pepsin from the quantity of albumin digested in the glass tube.

Bettmann and Schroeder[1] have devised a novel method of estimating the pepsin. They call it the "foam method;" it consists in mixing an albuminous solution with the stomach contents and shaking thoroughly until a great deal of foam develops The time it takes for this albumin foam to disappear indicates the relative amount of pepsin.

Illoway[2] coagulates 10 cg. of albumin and places this in 10 c.c. of the gastric juice. The time taken to digest this indicates the relative amount of pepsin. Among the newer tests for pepsin the Jacoby-Solms[3] ricin method can be considered the most practical. The method consists in the following: 1 g. of ricin and 5 g. of sodium chloride are dissolved in 100 c.c. of water and filtered. To 2 c.c. of this solution 1 c.c. of diluted stomach contents and ½ c.c. of decinormal HCl solution are added. The quantity of pepsin is determined from the amount of dilution in which the stomach contents will cause a disappearance of the ricin deposit. Solms recommends that the mixture be left in a thermostat for three hours and designates that amount of gastric juice which is just sufficient to clear up entirely the 2 c.c. of 1 per cent. ricin solution when kept at blood temperature as one pepsin unit. Normally stomach contents contain about 100 pepsin units to the cubic centimeter.

Goodman[4] has tested the Jacoby-Solms method and is satisfied with its results. He comes to the following conclusions: The normal amount of pepsin may be placed at 100-200 units. In hyperacidity there is usually no increase of pepsin; in subacidity, however, a diminution in the quantity of pepsin takes place constantly.

One of us (Einhorn) has simplified the method by using especially graduated pepsin tubes and also a vacuum tube as a warm water container and further by shortening the time to half an hour.[5]

This modification makes it easy to apply the ricin test. Although quite a number of writers have already tried to ascertain the amounts of the pepsin ferment in gastric diseases, it appeared to us of value to gather our experience in this respect in order to have our own opinion.

We have examined the amount of pepsin in a number of patients according to the Jacoby-Solms method and the rest according to Einhorn's modification. We submit the results in the following two tables:

* Achylia gastrica. † Carcinoma ventriculi

21 cases of absence of free HCl, and 37 cases of normal acidity.

In looking over the results of these tables we find that there is no strict relation between the amount of pepsin and the acidity in the group of hyperchlorhydria and normal acidity.

In fifteen cases of achylia the ricin deposit was cleared up entirely only once, and in five cases of cancer of the stomach without free HCl it also occurred only once. In one case of achylia the amount of pepsin was fairly considerable, as the precipitate disappeared in seven minutes (case 99).

Among the cases of hyperacidity we find in Table I, among 16 only two, Nos. 2 and 16, that show a correspondingly increased amount of pepsin; in Table II, among 32 cases, only five (46, 55, 58, 74, 75). In all other cases of hyperacidity the amount of pepsin did not exceed the normal limits.

The result of these conclusions harmonizes with those reached by Solms and by Witte. Solms says: "In spite of an increase of HCl the pepsin units do not seem to rise. If we consider our table from the clinical standpoint and ask ourselves whether with the aid of this new method the diagnosis of diseases of the stomach would be materially facilitated, we must answer that at present no definite judgment can be formed on the diagnostic or therapeutic value of the method. In diseases with diminished secretion of hydrochloric acid pepsin production was less, whereas conversely in hyperchlorhydria an increase of pepsin production could rarely be demonstrated."

Johannes Witte[6] comes to the following conclusions: "In normally acid stomach contents there is no strict parallelism between acidity and pepsin values. Functional diseases of the stomach usually remain under the average.

"In hyperacidity: (1) The increase of acidity is accompanied by a marked increase of pepsin action. Neuroses remain below the average. (2) Within this group there is no parallelism between acidity and pepsin action.

"In subacidity and anacidity: Compared with the normally acid cases they show uniformly low pepsin values. Within this group there exists generally a more marked parallelism between acidity and pepsin values; it is, however, not regular. In all cases of absence of free HCl pepsin is present even if only in traces (only one case shows no pepsin action). Neuroses yield relatively low pepsin values. In carcinoma distinct traces of pepsin action are recognizable."

Pepsin and rennet usually occur together; in fact the physiologists are not yet in accord whether rennet and pepsin are two different ferments or whether the action of dissolving albumin and coagulating milk is not due to one and the same substance (Pavloff and his school). It appeared to us of value to make a comparative study between the amounts of pepsin and those of rennet in some of the cases. The test for rennet was done in the following way:

To 2 c.c. of milk in a test tube, one, two, or five drops of stomach contents, diluted three times, were added, and after one-half hour, observations were made as to coagulation. In the table the actual amount of dilution with water and milk together has been given for each sample of gastric contents.

It is therefore evident that when pepsin is present rennet is also present. When pepsin is absent, rennet is also often absent, except in cases 67, 78, 97, and 110, where rennet was present when pepsin was not found, at least not in the dilutions em-

ployed. Of 16 cases examined, *no* correspondence was found between the amounts of rennet and pepsin in 8 cases (49, 50, 51, 67, 78, 80, 97, 110).

The following is the result:

CALCULUS IN THE LOWER SEGMENT OF THE URETER IN THE FEMALE,

WITH SPECIAL REFERENCE TO THE OPERATIVE METHOD.*

By A. E. ISAACS, M.D.,

NEW YORK.

SURGEON, BETH ISRAEL HOSPITAL.

Cystoscopy with ureteral catheterization, and especially radiography in its present standard of development have added two most valuable and efficient measures to our armamentarium for the investigation and diagnosis of diseases of the urinary organs. Especially in the determination of the presence of stone in the kidney or ureter are these procedures of service, and eminently so in the localization of the calculus. Diagnosis in the absence of these measures must be more or less problematical because the symptom-complex of other conditions may so stimulate calculus that the differentiation cannot be made definitely. There may be calculi of composition so pervious to the *x*-ray that with it they cast no appreciable shadow. While these are the exception, the possibility is always to be borne in mind when the radiographic result is negative. On the other hand when a shadow is obtained on a radiograph taken under proper conditions and its interpretation made by an experienced radiographer the diagnosis is almost beyond question and entirely so in conjunction with other available data.

It is well to confirm the diagnosis by ureteral catheterization as such conditions as foreign bodies in the intestines, or calcareous glands in the mesentery, or phleboliths in the veins may, when present, simulate the shadow of a stone. These conditions or other possible ones outside of the ureter would interpose no obstruction to the passage of the catheter. Better still a radiograph with shadowgraph ureteral bougies in situ would indicate on the plate the relation of the suspected shadow to that of the bougie which occupies the tract of the ureter.

The indication of the position of the stone is of the utmost importance from the operative standpoint. Before the advantages of localization by the *x*-ray were available the procedure was first to explore the kidney through a nephrotomy incision through which the ureter could also be sounded and the calculus localized. An additional operation, either at the same sitting or subsequently, was then required to remove it. This is the procedure that I followed in one of the cases reported herewith when the radiograph was not positive, and therefore this experience all the more impressed me that this method is unnecessarily complicated, and, though it may be useful for exploratory work under certain conditions, as I thought it would be in my case, it may usually be dispensed with when not especially indicated by evidence of trouble in the kidney.

This applies more particularly when the lower segment of the ureter is the portion involved, and especially so when this condition occurs in the female. Within the past year four almost similar cases came under my care, the results of observation and treatment of which, besides demonstrating the value of the cystoscope and radiograph, cleared up to my satisfaction the mooted question of the preferable mode of operative approach to the lower segment of the ureter in the female, which is the main point I want to bring out in this paper, and to which I will revert later.

The symptoms presented by these cases are also instructive. They go to show the incorrectness of the ideas, prevailing to a great extent even in the profession, that pain due to calculus in the ureter is differently located or may be differentiated from the pain caused by stone in the kidney, and that the paroxysmal pain of renal colic begins with the engagement of the calculus in the upper ureter, continues during its passage, and stops with the dropping of the stone into the bladder, and that repeated attacks are due to passage of additional stones. While this sequence may be true in some cases, the histories of these demonstrate that engagement from the kidney pelvis is not necessary to start a paroxysm nor delivery to the bladder to end one, but that paroxysms may begin and end and recur indefinitely with the calculus holding its situation in the ureter. In these cases the character and location of the pain was similar to that usually complained of when the source of the irritation is in the kidney. The attacks were paroxysmal and very severe in

*Read at the meeting of the Section on Surgery, N. Y. Academy of Medicine, March 5, 1909.

all four cases. Subjective pain was referred mostly to the lumbar region, radiating to the thigh and groin, and objectively the kidney region anteriorly and posteriorly was tender during attacks. Urinary frequency and bladder irritation were not marked symptoms and were only brought out by close questioning as moderately existent during the paroxysms. In the interval of attacks there was perfect freedom of all symptoms, no pain or discomfort, subjective or objective.

Case I.—Bessie S., schoolgirl, age 15. Came under my observation March 3, 1908, and entered the Beth Isreal Hospital. For four years she had attacks of severe pain in the left side, increasing in severity and frequency, accompanied with vomiting, each attack lasting one or two days, though the last had kept on for a whole week. Examination of her urine showed a specific gravity of 1020, acid, a trace of albumin, many white cells and uric-acid crystals. A radiograph showed no stone in the kidney but a suspicious shadow in the pelvis. Cystoscopic examination with catheterization of the ureters showed the bladder negative, good secretion from either kidney, both urines alike, but, while the right urctheral catheter slip up to the pelvis without any hindrance, the left would enter only a short distance. This taken together with the suspicious radiographic pelvic shadow suggested another radiograph which was made directed specially to the pelvic region, and which gave a distinct shadow confirming the presence of a pelvic ureteral calculus. As the symptoms pointed so directly to the kidney, I did a nephrotomy so as to cover the possibility of an infected kidney. The kidney and its pelvis were found normal in size and appearance. A bougie introduced through the cortical incision passed without hindrance down the ureter for a distance of some twelve inches from the outside of the kidney cortex where it met an obstruction, thus confirming the presence of the calculus in the lower ureter very near the bladder. The ureteral operation was postponed for a subsequent occasion. Recovery from nephrotomy was uneventful except for repeated severe paroxysms of pain similar to those previously complained of, and easily accounted for by obstruction caused by the engagement of blood clots passing down from the operative field to the site of the stone in the ureter.

Two weeks later she went on the table again for the ureterolithotomy. Preliminary to the operation her ureters were catheterized again for assurance that her attacks of colic since the first operation had not resulted in or been caused by the advance of the calculus into or towards the bladder. Conditions were found the same as before, the left ureter admitting the catheter for only one and a quarter inches. With this localization the retroperitoneal operation was done, regarding which I will speak later as there are certain features in the operation common to all the cases on which I wish to lay stress. A crescent-shaped phosphatic calculus three-quarters of an inch long by one-quarter of an inch in diameter was found. Its surface was very rough and so firmly imbeded in the lining of the ureter that it took considerable manipulation to dislodge it. A curious feature of the calculus, though one that has been observed before, is a longitudinal groove about one-sixteenth of an inch in diameter, extending its whole length, which allowed the urine to trickle through most of the time, yet at other times must have become obstructed, possibly by swelling of the mucous membrane, and so caused the severe attacks of pain. The ureter above the calculus was dilated to three or four times its normal caliber. Convalescence was prompt and smooth.

Case II.—Lena D., age 23, married four years, had two children, the last 17 months old, was admitted to the Beth Israel Hospital March 13, 1908. For three years she had had attacks of pain in the right lumbar region, at intervals of about two weeks and lasting about two days. Pain during paroxysms was constant, limited to the lumbar region and not radiating, very severe and usually accompanied by vomiting and sometimes by syncope. There was no urinary frequency or irritation even during attacks, and between attacks she felt perfectly well. Physical examination was negative except for a slightly tender local point at about the brim of the pelvis on the right side. Vaginal examination was negative. The urine was of 1014 sp.gr. and contained pus cells in moderate number; otherwise it was negative. On catheterization of the ureters the left permitted the passage of the catheter to the kidney while in the right ureter it could not be introduced for more than two inches. The radiograph gave a shadow corresponding to the location of the calculus as indicated by the ureteral examination. Inguinal retroperitoneal ureterolithotomy was done on March 23, and an ovoid calculus a good half inch long by a quarter inch in diameter, probably composed of calcium oxalate and covered with rough projections, was removed. Recovery was prompt and without any untoward symptoms.

Case III.—This was in the same patient as case II, but on the opposite side. She was readmitted to the Beth Isreal Hospital December 3, 1908, with the history that since her operation, eight months previously, she had had no pain till two days ago, when she was taken suddenly with very severe colic on the left side, persisting up to the time of her admission. Radiograph showed a stone low down in the pelvic ureter, and catheterization showed an obstruction in the left ureter about three inches from the bladder. After allowing a reasonable time for the stone to pass of its own accord, which it did not do, she was operated on December 12, and a very rough triangular-shaped calculus, about one-half inch long by one-quarter broad, was removed. She made a smooth recovery and left the hospital in two weeks.

Case IV.—Beckie C., age 21, not married, was admitted to the Beth Isreal Hospital February 1, 1909, with an acute attack of pain in the right iliac region, this being the fifth attack within six months. She was sick for three days and the symptoms were suggestive of acute appendicitis as well as of ureteral calculus. The urine contained many pus cells and phosphate and oxalate crystals. A radiograph showed a shadow indicative of calculus in the right pelvic ureter. Confirmatory catheterization of the ureters was not done because the patient began to object to an operation and I did not want to allow her time to change her mind. Through the iliolinguinal incision the appendix, distended and acutely inflamed, was removed, then the peritoneum closed and the usual retroperitoneal ureterotomy proceeded with. A small stone was located very low down, seemingly within two inches of the bladder.

Although calculi may become impacted in any portion of the ureter there seem to be points of election in the course of the canal that are the favorite sites. Morris gives three points: First, one or two centimeters below the commencement of the ureter; second, where the ureter crosses the brim of the

bony pelvis, and third, at the intermural portion of the ureter where it passes between the coats of the bladder wall before entering.

On the location depends to a great extent the method of operation. The procedure for removal is fairly well established in either male or female when the calculus is situated anywhere from the renal end to a point an inch or two below the pelvic brim, or even if it be lower than this in the male. In cases of impaction above the brim lumbar incision, extended as far downwards and forwards as necessary, with retroperitoneal exposure of the ureter, is the accepted procedure. In impaction below the brim the ilioinguinal incision is the usual procedure in the male, but in the female its use has been restricted to those cases in which the impaction is above the point where the ureter enters the region of the broad ligament. The more complex anatomical relations of the lower three or four inches of the ureter in the female make its approach by this method much more difficult, and, according to some authorities, almost impossible. Whether the objections to this mode of approach in the female were the result of trial by those who present them, or whether they were only the result of anticipation of difficulty on account of the complicated anatomy of the region, is not stated. How great the difficulties are considered may be judged from the variety and ingenuity of the methods proposed and carried out to reach the pelvic ureter in the female. Morris says: "When in the female the stone is impacted below where the ureter leaves the pelvic wall, but still at a distance of from two and a half to three inches from the bladder, . . . the best way to extract it is by the sacral route," and further on he describes the "sacral" operation devised by himself which he used in two cases to reach the ureter, concededly a more difficult and complicated operation than the ilioinguinal. He mentions also the vaginal, transsacral and other methods employed by various surgeons to reach that portion of the female ureter in question. The ilioinguinal he says is out of the question in these cases, and quotes other writers to the same effect. So far as I have been able to look over the subsequent literature I have not found any writer to question this view.

The four operations here reported were in females and the calculus in each case was very near the bladder, in one, one and a quarter inches, in two, two inches, and in one, three inches from the bladder outlet. According to all accepted authority I should have made my method of approach from below, either vaginal or sacral. But it seemed to me that I could work down from above more easily in spite of the anticipated difficulties which did not impress me as being greater than those encountered in other difficult intraabdominal or pelvic work.

The usual incision parallel to and about an inch from Poupart's ligament, beginning about the level of the anterior superior spine and extending almost to the spine of the pubes, was used, with division of all the structures down to the peritoneum. The latter was raised from the pelvic wall until the iliac vessels were exposed, when the ureter was located adhering to the raised peritoneum. The ureter, in its exposed portion, was separated from the peritoneum and a traction strip passed around it to draw it up out of the pelvis for separation. This was comparatively easy as far as the base of the broad ligament. Here it was very adherent, yet separable with the blunt end of a scalpel handle, while under traction from above. During this separation probably one inch or somewhat more of the ureter distal to the point of separation, together with its surrounding and yet adherent structures, could be picked up between the thumb and finger of one hand and palpated sufficiently well to determine whether it contained the stone or not. The traction from above was of material assistance in permitting this to be done. Following along in this manner the stone in each case was located. After location very little more separation was necessary, just sufficient to allow the finger tips to engage the distal aspect of the stone through the ureter and its coverings so as to enable its being milked backwards towards the exposed portion of the tube. In all four instances the stone lay beyond the uterine artery which could be located by its pulsation, but the expedient of milking the stone backwards and proximal to the artery eliminated the necessity of its division and ligature. In one of the cases, CASE II, the separation of the plexus of veins at the base of the broad ligament from the ureter caused some hemorrhage which was inconvenient to handle on account of the depth of the cavity at the bottom of which it took place. Yet with a little care and persistence it was fairly easily controlled. In the other three cases there was no troublesome hemorrhage though the calculus was lower in the ureter than in Case II. In three of the cases the stone was milked up to a convenient situation for incision of the ureter, the ureter incised on it, the stone removed, and the ureter closed with catgut sutures passed through the outer layers only. A narrow strip of gutta percha tissue was inserted as a drain from the site of the ureteral incision to the lower angle of the wound which was entirely closed with layer sutures. In the first three cases there was no sign of urine through the wound and the drains were removed within a week. All had perfect primary union. The fourth case did not go as smoothly as the others though the result was fortunately just as good. Inability to milk the stone backwards into the exposed portion of the ureter was a disappointment. It seemed to be too firmly embedded in the mucous membrane and I had to desist after using as much force as I thought within the limits of safety for the ureter. The ureter was then incised and a sound passed with the object of pushing the stone into the bladder, which I thought I had succeeded in doing, as I failed to locate it again either with the sound or by palpation. The ureter was sutured and the wound closed with a small gutta-percha drain as usual. On the fourth day, urine began to discharge along the drain. A few days after operation a radiograph showed the calculus in the ureter, but somewhat lower than its previous location. Two weeks after operation cystoscopy showed three small fragments in the bladder and no obstruction on catheterization of the ureter. A radiograph taken after this did not show the calculus. The urinary leak through the fistula decreased gradually and stopped entirely three and a half weeks after operation. The course subsequent to operation indicates that the calculus was broken by the attempts to dislodge it. That the fragments remained in the ureter and, with the swelling of the mucous membrane due to the traumatism, caused obstruction with backing up of urine and its discharge through the incision. With subsidence of the swelling the fragments passed on into the bladder and allowed the incision in the ureter to heal.

That the inguinal retroperitoneal operation in the

female is not only practicable but fairly easy of accomplishment when the calculus to be removed is as low down as one and a half inches from the vesical orifice of the ureter, is fairly proven by these cases, and I have no reason to doubt from experience with them that even were the calculus lower it could be similarly attacked and either forced backwards along the ureter or forwards into the bladder, though when in the intramural portion of the ureter it might be more easily removed transvesically.

A point in the technique that counts for a great deal is the traction strip, a strip of gauze or a heavy ligature passed around the ureter, not tied, by which the latter is raised from the pelvis as much as its surrounding connections will permit, bringing these adherent structures up into view for separation. This raising of the ureter with its adherent surroundings also permits of palpation, between the thumb and finger, of the yet unseparated portion, which is recognized by its being held under tension. Through the surrounding tissues the stone can be felt in the ureter and may be dislodged by milking it backwards into the exposed portion of the tube.

For the radiographic and cystoscopic work in connection with these cases I am indebted to Doctors I. S. Hirsch and W. S. Schapira, radiographist and cystoscopist, respectively, to the Beth Isreal Hospital.

THE ETIOLOGY OF CARCINOMA.

By ABDULLAH K. SALLOM, M.D.,

KOUSBA, MT. LEBANON, SYRIA.

For many years the cause of carcinoma has been the fascinating subject around which has arisen much speculation. The gross appearance was described by such ancient authors as Celsus, Galen, Antius, and Soranus, but the etiology of the disease remained for a much later period to be taken up and systematically investigated. The work that has been done had been exceedingly great; the literature has become massive, but it has been so baffling that to-day we witness here and abroad an army of tireless investigators at work and the establishment of organized laboratory research. The theories which have been advanced at one time or another to explain the cause have been many and varied. They have been the source of great influence in directing research along particular lines. Of these, two require a brief consideration.

The embryonic theory as first advanced by Cohnhein assumed that during the development of the body in its embryonic stages certain cells were not utilized, and that these rests, as they have been called, still retaining their potential power of growth, later in life, either without provocation or because of some irritation, were supposed to assume active growth, and hence, develop into a tumor. This theory, though advanced without any concrete evidence, found quick favor, and later inquiry demonstrated the fact that there were in existence tissue islands which, in some instances, might be regarded as sources from which tumors might grow. In the case of benign tumors this theory is both applicable and interesting. It is extremely easy to imagine certain cells to remain dormant and to proliferate later in life and become the same structure they would have been had they developed during the embryonic stages.

When, however, the attempt was made to apply this theory to malignant tumors, it signally failed. It failed to determine why one tumor should develop into a malignant one and another into a benign one. It failed to explain why malignant tumors recur, infiltrate, give metastasis, and have such marked destructive effects upon the human body. Indeed, it would be impossible to cite at the present time the many things which it does not explain and the many facts with which it does not come in accord. Moreover, many experiments have been carried out which prove that the embryonic theory cannot be applied to malignant tumors. One of these, performed by Cohnheim and Maas, may be cited. Into the jugular vein of animals small pieces of periosteum were introduced. After a few weeks or months the animals were killed and the lungs examined. It was found that the pieces of periosteum grew in the vessels in which they had become impacted. The size of the new growth, however, was limited to the lumen of the vessel. When this size was reached in every case further growth was arrested, and the bone was in time removed by absorption. From this experiment alone the question suggests itself, why was the further growth of the bone arrested? Why did not the periosteal emboli grow, infiltrate, and become malignant tumors? The attempt has been made to answer these questions by stating that the

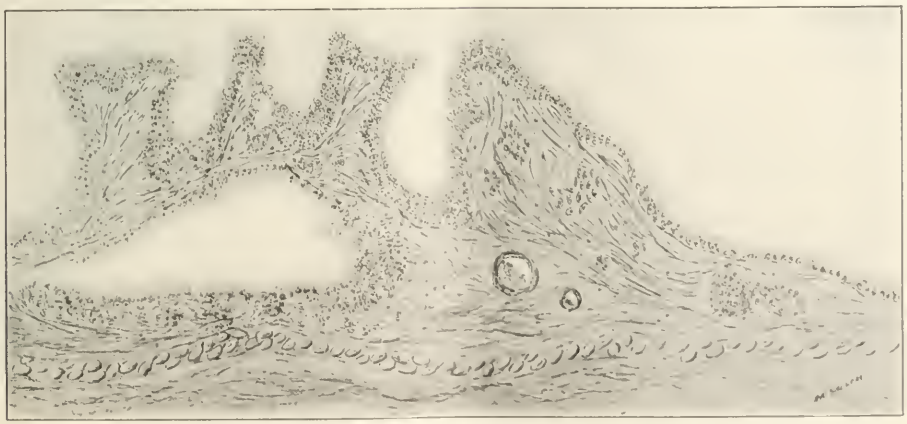

FIG. 1.—Section of the left ear of a rabbit in which nonsterilized Sudan III in olive oil was injected

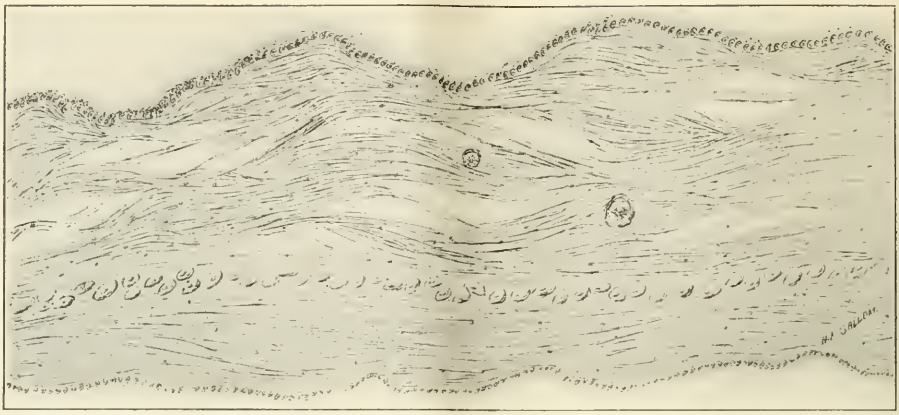

Fig. 2.—Section of the right ear of a rabbit in which sterilized Sudan III in olive oil was injected.

normal resistance of the tissue stopped the growth. But why did not that same resistance prohibit the growth of the piece of periosteum from the beginning? It has been admitted even by those who upheld the embryonic theory that there are other determining factors in the production of the tumors; but it has also been insisted upon that these isolated cells or rests are a necessary factor. Whether they are or are not it becomes evident that we must seek these so-called "determining factors," for it is only by the discovery of these that we can hope to find the true cause of carcinoma, and to combat it successfully by rational therapeutics based upon such discovery.

Sufficient stress has not been laid upon the marked difference between benign and malignant tumors. They resemble each other only in a superficial way and differ in many important ways. Therefore, any theory which attempts to explain the cause of both benign and malignant tumors in the same way must fail. The embryonic theory belongs properly to benign tumors. To determine the cause of malignant tumors other theories are necessary.

The second theory belongs properly to malignant tumors. It is the infectious theory. It suggested itself because of the marked resemblance of carcinoma to many of the recognized infectious diseases. Though bacteriological research has failed to reveal any microorganism as the possible cause of carcinoma, the belief among those who are thoroughly familiar with the clinical aspects of the disease is rapidly growing that in some future time the disease will be defined as a chronic infectious disease due to a specific microorganism, against which epithelial cells are best able to combat.

Many formidable objections have been raised against the infectious theory. It has been urged that even in extensive cases of cancer of the tongue, jaws, or pharynx, quantities of cancerous particles find their way into the stomach, and yet the mucous membrane of the gastrointestinal tract escapes. This, I believe, cannot be urged as a fair objection. The answer is the same as that for cases of pulmonary tuberculosis. It is a well-known fact that thousands of tubercle bacilli are always to be found in the mouths of tuberculous patients, and yet these patients rarely get tuberculosis of the mouth. Another objection urged against the infectious theory is that in typical infectious diseases the microorganisms are transplanted to the new situation, while in carcinoma the cells are transplanted and the secondary growth is always like the primary. In looking over the literature concerning this point little authority was found for the statement that the cells are transplanted. Evidently since no microorganism was found, it was assumed as a matter of fact that the cells were transplanted. Moreover, even if this were true it does not necessarily argue against the infectious theory. There are several possibilities. It might be assumed that the microorganisms are intracellular, and that when the microorganisms are carried to a new situation the cells are taken, also. There is another possibility. The microorganisms may have been carried to a new site and the epithelial cells may have been attracted to this secondary focus by a special positive chemotactic force. It is not forced when it is added that these epithelial cells, which are at the primary focus, combating the invading foe, should feel this chemotactic force most strongly and be attracted to the secondary focus. If this occurs we must get a new growth, alike in all respects to the primary. Such have been the objections urged against the infectious theory. It will be clearly seen that these objections can be readily set aside. Furthermore, we should not expect, on account of our ignorance, to be able to explain everything. If we could there would be no need for any theory.

In marked contrast to the objections against the infectious theory, there are numerous important facts which support it. The fact that carcinoma is almost always primary, being first a local and then a general infection, the cachexia and profound destructive changes which it brings about, the metastasis which it gives all strongly indicate that it is really an infectious process. Benign tumors have no such marked effects upon the body, and it is a common phenomenon to see either a primary or multiple growths. In these respects benign tumors essentially differ from malignant growths. Another important phenomenon often observed is that malignant tumors recur and grow very much more rapidly, and, hence, are more malignant after an unsuccessful attempt at removal. There can be but one possible explanation. That the tumor does recur has been explained on the basis that all of the growth has not been removed. This, however, is not always the case. In many instances recurrence

is not due to failure of the surgeon to remove all of the growth, but to the soiling of the healthy tissue.

It must be admitted that soiling also occurs in the removal of benign tumors. In this case, however, the cells which have been left behind are acting as foreign bodies, and are removed before growth and proliferation takes place. In case of malignant tumors, the cells which have been left behind are not acting as foreign bodies, but are protecting the body against the invading foe—hence their active growth and proliferation. That tumors grow more rapidly and show greater malignancy after an unsuccessful attempt at removal is easily explained if a few well-known facts are borne in mind. The center of the growth is not the active part. It may even be sterile. In carcinoma, as in a number of infectious diseases, the progressive growth is due to the establishment of independent growths in the periphery of the tumor. It is there that the battle is waging. The center is only the battlefield where the battle has been fought and lost. With this in mind the explanation is extremely simple. When the surgeon attempts the removal of the tumor he necessarily opens up new channels, any barrier which may have been set up against the disease is broken down, and the disease progresses the more rapidly. Unintentionally, soiling of healthy tissue takes place, and in this way it happens that the surgeon indirectly advances the disease. Of this I have already written.

Besides these facts there are many predisposing factors which support the infectious theory. Heredity, traumatism, prolonged irritation and inflammation have been considered as more or less important predisposing factors. Great importance was formerly attached to heredity, but it is now regarded of but little importance. The same condition of affairs has occurred in the history of other infectious diseases, notably tuberculosis. The tendency of the present time is to regard the offspring as inheriting a constitutional predisposition to the formation of new growths, and, being surrounded by those who have the disease, he is the more likely to acquire it.

Traumatism, prolonged irritation, and inflammation have been regarded and are important predisposing factors. An attempt has been made to advance the theory that prolonged irritation is the cause of tumor formation. In regard to benign tumors, this factor may be the exciting cause of the active growth of the isolated cells or rests. In regard to malignant tumors, the traumatism, prolonged irritation, and inflammation are important only inasmuch as they reduce the vitality of the tissue and make it a favorable media wherein the microorganism may grow. The importance of these factors can be readily estimated by a brief consideration of carcinoma of the alimentary tract. It has been found that cancer of the alimentary canal is very frequent; that the stomach is by far the most usual situation, especially at the pylorus; and that the duodenum, jejunum, and ileum are very rarely attacked, while the colon and rectum are very frequently the seat of the disease. In the small intestines the food is in a liquid or semi-liquid form and causes no irritation or traumatism, while in the stomach and larger intestines some degree of traumatism or irritation is usually present. When a slight abrasion occurs an opportunity is afforded the microorganisms to gain access to the tissues and set up the new growth. It, therefore, becomes evident that careful cooking and chewing of the food are of very great importance in the prophylaxis of malignant disease.

From the above discussion it becomes evident that carcinoma is really an infectious process, and that we must bend our efforts toward the staining and isolation of the microorganisms concerned. We should, however, bear in mind the fact that the microorganism is one of low virulence, as is shown by the chronic course of the disease, and that it possesses high resisting power toward stains. This at once suggests a possible means of identification if the microorganisms can be made to take the stain.

At the very beginning of the work Dr. Allen J. Smith suggested that I should try the effect of oils as a possible cause of carcinoma. But I could not bring myself to believe that the oils had anything to do with the disease. It was a few days later, while meditating upon the subject, that I thought even if the oil should produce a carcinoma it might not be due to the oil, but to the microorganism which contaminated it. If this were true I could then prove that the oil had nothing to do with carcinoma, and that the latter was really an infectious disease. I therefore decided to try the following experiment at the Pathological Laboratory of the University of Pennsylvania, which proved that my thought was correct.

One gram of Sudan III was taken and placed in 10 cubic centimeters of olive oil. The red oil was then divided into two equal parts, one of which was sterilized on five successive days by placing it in boiling water for fifteen minutes. The sterilized red oil was then taken and injected into the right ear of the rabbit. Then an equal amount of non-sterilized oil was injected into the left ear. This order of injection was quite important, inasmuch as the same syringe was employed, and it was necessary that the sterilized oil should not become contaminated with the non-sterilized oil. After ten days the rabbit was killed and pieces of each ear removed for microscopic examination.

The first drawing is taken from a section of the left ear, in which the non-sterilized oil had been injected. It will be seen that there is marked thickening of the epithelium, dipping down deep into the subcutaneous tissue in many places. Here and there are to be seen isolated collections of epithelium. They vary greatly in shape and size. The tissue is edematous, this being due without doubt to the red oil.

Figure 2 represents a section taken from the right ear in which the sterilized oil had been injected. The tissue does not show much change. It is edematous. The epithelium is not thickened, and is even thinner than is shown in the drawing. It does not dip down into the subcutaneous tissue. There are no such isolated collections of epithelium as are seen in the first drawing.

From this experiment alone it can be seen that the Sudan III and olive oil are not the cause of the marked change which has been produced. There must be something which has been killed by the sterilization. If it were not so we should get the same change in the one as in the other. Most likely it is the microorganisms. If this is so we have the explanation of why some investigators failed to get any result while others did. Those who did get results used the oil which had been contaminated, while those who did not get results used oil which was not contaminated or which had been sterilized.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, June 19, 1909.

AN EXTREME OF LEPROPHOBIA.

WHEN we read of cholera panics among the ignorant peasantry of Italy or Russia, we smile a superior sort of smile, and wonder to what extremities the senseless fear of disease will drive the unlearned. But when we read of the Medical Examining Board of Oklahoma witholding a license to practise from any physician suffering from pulmonary tuberculosis; of health officers in several States becoming hysterical when a leper escaped from his place of unjust confinement a few years ago; of the officials of another State making prisoners of a retired army officer and his wife because one of them was alleged to have leprosy; and now of a man, whom competent authorities have declared not to be a leper, imprisoned in the Capital of the country because he inquired of his physician if possibly he had leprosy, we wonder whether there is a science of public health. This last mentioned case, in which public interest has been aroused by the recent examination of the victim by a well known dermatologist of this city, seems to call for some comment, for it presents a peculiarly flagrant instance of official cruelty inspired by unreasoning fear.

The case, briefly stated, is as follows: A man, aged thirty-six years, born in North Carolina, and living there most of his life, served nine years in the army, about two years in the Philippines and a short time in Cuba; in neither of these countries did he see a case of leprosy nor ever hear it mentioned. In June, 1908, he went to work in a pulp mill where he came in contact with a certain liquid made from "black ash," which is very poisonous and irritating. The hands became inflamed, then the face, and later the feet. There were a dozen or so in the mill who were more or less similarly affected. On August 18 he went to Washington, D. C., to get relief from the distressing inflammation of the skin. According to his statements the hands and forearms were greatly swollen and also the face, so that the eyes were almost closed; the feet and lower legs were also acutely inflamed. As the physician to whom he had applied was examining him, the patient innocently and foolishly remarked, "I wonder if I have leprosy." The hint was taken and the case referred to the health authorities. The inspector is said never to have seen a case of leprosy, but accepted the patient's interrogative diagnosis, after a hasty examination, and called in another physician, who had seen some leprosy many years ago; the latter regarded the case as "strongly suspicious." He excised a portion of the inflamed skin from the forehead and reported the finding of bacilli, "corresponding morphologically with those of leprosy." On this evidence the man was quarantined and has been kept a prisoner since August 21, 1908. So far as can be learned, no further attempt was made to establish the diagnosis, and until the arrival of Dr. Bulkley of New York, on May 9, of this year, no one well acquainted with diseases of the skin had ever examined the patient, although there are numbers of men in Washington perfectly competent to determine the nature of the trouble. At the first visit of the New York dermatologist the patient was stripped and the case was studied for an hour and a half. On May 30 another similar study of the case was made for three-quarters of an hour. At both of these examinations pieces of skin were punched out and were placed at once in absolute alcohol, most carefully stained, and examined by many pathologists, among them Drs. William H. Welch of Baltimore and William H. Park of New York. Absolutely no sign of leprosy was discovered, certainly no leprous bacilli. A third visit was made June 6. There were then absolutely no signs of leprosy on the face; the nose was aquiline, the lips and ears normal, and there were no lesions within the nose or mouth.

Analyzing this case we cannot see the slightest ground for even guessing that the man had leprosy. He went to Washington with an acute inflammatory dermatitis, caused by a vegetable poison and of only five or six weeks' duration. Leprosy would have taken as many years to have involved an equal area so severely. During his imprisonment all this has slowly disappeared, without treatment, the cause being removed.

The whole case seems to be one of official overzealousness, but the excess of zeal is in danger of becoming something worse by the action of the health officer in placing every possible obstacle in the way of the man's freedom. The officials of the New York Health Department have said in writing that he would be admitted here, as, "for some years past the Board of Health of this city has considered that leprosy in this climate is not of so infectious or contagious a nature as to require segregation." The New York Skin and Cancer Hospital has written that the patient "will be admitted to the wards of this hospital whenever he may come," adding "We have had many cases of true leprosy in the Hospital, often for considerable periods of time, dating back twenty years, and have never seen reason to fear the disease;" and yet the Washington officials, according to the newspaper reports of June 14, will not only not discharge him from custody but have even doubled the guard around his place of confinement. Even assuming that Dr. Bulkley is mistaken and that the man is really a leper, which, in view of the gradual disappearance of the dermatitis, is scarcely possible, there is absolutely no excuse for depriving him of his liberty.

Every well informed physician, the professional leprophobiacs perhaps excepted, knows that leprosy is far less communicable than tuberculosis, yet no health officer would think of imprisoning the tuberculous—nor yet the syphilitic, though the latter are a very real menace to their fellows and are almost certain to infect others, innocently or criminally. This case might well be made a text for instruction of the public regarding the nature of leprosy, so that others may escape the consequences of an excess of zeal on the part of sanitary authorities.

PHYSICAL TRAINING.

Judicious physical training in combination with rational living goes further than any other mode of life in developing the muscles, stimulating vitality, and strengthening the constitution. In these times, when the tendency of individuals to concentrate in large centers is becoming more and more marked, and when the strain upon the mental faculties is growing more and more intense, owing to the calls upon them entailed by modern systems of education, it is incumbent upon those responsible for the upbringing of the young that every effort should be made to build up a healthy body. Modern conditions of life have greatly intensified the difficulties in the way of successfully bringing about this object. Social wastrels in all civilized countries are increasing at an alarming rate, and the physique of the mass of the population has very much deteriorated.

Physical training to do the most good should not be undertaken with the view of simply developing the muscles, therefore gymnastics alone is contraindicated, or rather gymnastics should not be utilized merely with the idea of turning out specialized athletes but to produce what is known as the good all-round man. The systems of physical training in vogue in Germany and in Great Britain differ widely. In Germany the object seems to be to develop a man's muscles, whereas in Great Britain the aim appears to be to increase strength, agility, and power of endurance, so that while the finished product in Germany looks and probably is the physically stronger man, yet so far as endurance and agility are concerned he would not be able to compete on equal terms with the best type of British athlete. The reason why the Germans as a people are in physique generally superior to the British, and it may be said also to the American, is that physical training in Germany is universal and far more thorough.

Surgeon Kenelm Digby Bell, R. N., read a paper, on April 14, before the British United Service Medical Society in which he spoke very highly, judging from his experience as a naval medical physical instructor, of the Swedish system of gymnastics, and described its three fundamental characteristics: (1) The nature and intention of the exercises; (2) the progression of the exercises, and (3) the definite arrangement of the exercises in the daily lesson. He explained that the system is in reality educational gymnastics, that every exercise has a special physical effect embodied in it which is chiefly dependent on the changes produced in accordance with the laws of physiology, in the organs of locomotion taking part in the movement, and in those parts of the nervous system which are called into play by it; and each exercise is practised solely to produce that effect. One feature of the Swedish system particularly deserving of notice is that great attention is paid to the development of an expansible and resilient chest in the young and its maintenance throughout life, in order that breathing may be free at all times, and the fixed condition of the chest, the frequent objection to most of the older forms of gymnastics, may be prevented. In fact, the Swedish method of physical training is said carefully to avoid those exercises calculated to develop big and fixed muscles, exercises which in the nature of things must in the majority of instances produce overstrain. The results aimed at are suppleness, coordination, smart reaction, and agility. The Swedish system is by no means perfect, many defects in it could be easily pointed out; but, on the other hand, it is perhaps the best system known, and is incomparably superior to ordinary gymnastics.

Urban life, which is after all the life of the mass of civilized people, has an injurious effect on physical development, and steps must be taken to counterbalance the physical evils entailed on modern city dwellers. Material prosperity is of little use if the inhabitants of a country are deteriorating in physique and stamina while piling up wealth. The battle is to the strongest, which means the most physically and mentally fit, and the nation which does not use every possible means to preserve the health of its citizens is certain to go down. Medical men can do much by example and precept in the direction of spreading the gospel of health. They should be both pioneers and preachers, and it is an auspicious sign that they are everywhere becoming alive to their responsibilities.

The Cause of Goiter.

Since the discovery of the action of the secretion of the thyroid gland on general metabolism, much more interest has been taken in goiter than previously, and the appreciation that the factor of greatest importance in this disease is not the size of the gland but its secretory power has led to many theories as to the underlying cause of hypo- and hyperthyroidism. A recent ingenious contribution to these theories is one brought out by McCarty in the June number of *The American Journal of the Medical Sciences*. He suggests that the cause of goiter may be a reversion to type. He calls attention to the fact that probably in an earlier period in the development of man the thyroid was a gland opening freely into the alimentary tract through the thyroglossal duct. In modern man for some reason the demand for the thyroid secretion in the alimentary tract has been lost, the thyroglossal duct has closed, and the gland has been converted from a freely secreting one to one of sluggish activity. The writer calls attention to various examples of human reversion, as secreting male breasts, supernumerary breasts, and bicornate uteri, and suggests that possibly the reversion in the thyroid gland may take the form of an increased secretion.

The effect of such an increased secretion in a gland with an obliterated duct may be compared to the sudden obstruction of the duct of a normally secreting organ. The results of such obstructions may be of two kinds. If the gallduct is obstructed the secretion, in the form of bile, is forced back into the circulating blood and produces a systemic effect—jaundice; while if the ureter is blocked the result is more apt to be cystic formation with gradual loss of secretory activity of the kidney. McCarty thinks these two processes are comparable to the effect on the thyroid, the jaundice suggesting hyperthyroidism and the cystic kidney the so-called benign goiter. In either case of course the gland would enlarge. What the cause of this reversion is and the nature of the substance which acts to stimulate the thyroid secretion the author makes no effort to explain, but leaves the investigation to the physiological chemists. McCarty's theory is interesting, but its weak point would appear to be that the hypersecretion should affect the same organ so differently. It is easy to understand the same influence affecting various organs differently, but that is not the case in point. If all forms of goiter are due to hypersecretion of the gland, it is to be hoped that the cause of this may lie in the mode of life or character of food rather than in a reversion to the type of primitive man. With the insuperable obstacles to all efforts of scientific breeding of the human race the necessity of overcoming a reversion to type for the prophylaxis of goiter would not give an encouraging outlook for the stamping out of the disease.

Sanitary Conditions in Cuba.

It is most gratifying to learn from the letter of Dr. M. Duque, Secretary of Health and Charities of the Republic of Cuba, printed in another column, that the health conditions in that island are in so satisfactory a state, and that our correspondents, whose reports were the occasion of recent editorial comment, were mistaken in their belief that yellow fever existed there. Some very suspicious cases have undoubtedly occurred, but in each instance examination by competent diagnosticians has shown that the trouble was not yellow fever, and the President of the Havana Board of Infectious Diseases, Dr. Agramonte, writes that there has not been a case of the disease in Cuba since 1908. Even had the cases been found to be yellow fever there would have been no danger, for until the diagnosis was established the patients were isolated in screened wards and treated as if they were actually suffering from the disease. There is no question that the situation at present is thoroughly under control by competent health officers, and so long as they are given a free hand and the government does not cut down the appropriation for sanitary purposes, there is no reason to apprehend a return to the old conditions. The danger is, as we have maintained, that the needs of the politicians may hamper the work of the health department and impair its efficiency. What has happened before may happen again if those in control of the government forget their responsibility in sanitary matters. It is not in Cuba only that the lawmakers are sometimes short sighted in this respect, but it happens that just now, and for the hot months to come, it is this country that will suffer if the Cuban authorities are not alive to their duty to themselves and to us.

News of the Week.

Officers of the American Medical Association.—At the final meeting of the House of Delegates, on Thursday, June 10, the following officers were elected: *President,* Dr. William H. Welch, of Maryland; *First Vice-President,* Dr. Robert Wilson, Jr., of South Carolina; *Second Vice-President,* Dr. Charles J. Kipp, of New Jersey; *Third Vice-President,* Dr. Alexander Lambert, of New York; *Fourth Vice-President,* Dr. Stanley P. Black of California; *General Secretary,* Dr. George H. Simmons, of Illinois; *Treasurer,* Dr. Frank Billings, of Illinois. *Trustees*—Drs. C. E. Cantrell, of Texas; Malcolm L. Harris, of Illinois; T. W. Councilman, of Massachusetts, and A. C. Dougherty, of Indiana. St. Louis was selected as the place of meeting of the association in 1910.

Commencement Exercises.—The first commencement of the Fordham University School of Medicine was held on June 9 in the college auditorium. Eleven graduates received the degree of Doctor of Medicine from the Dean of the school, Dr. James J. Walsh.

Sixty-one students were graduated from the Cornell University Medical College of New York on June 9. Of the graduates fifty-four have already received hospital appointments. Prof. J. F. Crane, Dean of the Cornell University Faculty, conferred the degrees and made an address to the graduates.

The degree of doctor of medicine was conferred upon forty-eight graduates of the Washington University Medical School, St. Louis, on May 27, by Dr. David F. Houston, Chancellor of the University.

Twenty-nine men were graduated from the Army Medical School at Bangor, Maine, on May 29. The diplomas were delivered by Secretary of War Dickinson and the address to the graduates by Dr. Roswell Park.

The College of Physicians and Surgeons of Chicago conferred the degree of M.D. on a class of 131 students, on June 5.

Rush Medical College of Chicago graduated a class of fifty-seven on June 1. Dr. Edward J. James, President of the University of Illinois, addressed the class.

New Marriage Law.—The new law governing marriages and the issuance of licenses to marry in the State of Washington, which went into effect on June 10, provides that applicants must undergo medical examination. It is thought that the chief effect of the law will be to send many couples desiring to marry over the border to Canada where the laws are less stringent.

The Philadelphia Medical Club gave a reception on June 11 to Dr. William C. Gorgas, the retiring president, to Dr. William H. Welch, the president-elect of the American Medical Association, and to Dr. George W. Wagoner, president of the Medical Society of the State of Pennsylvania.

Free Radium.—The Senate, on June 12, passed an amendment putting radium on the free list in the new tariff schedule, on the suggestion that such a step would be in the aid of medical science.

New York's Death Rate.—For the week ending June 5, 1909, there were 1,405 deaths in New York City, an increase of 183 over the corresponding week of last year. The death rate per 1,000 of population was 16.06. Slight increases occurred in

the number of deaths from measles, diphtheria, heart disease, pneumonia, and pulmonary tuberculosis.

Typhoid Fever Epidemic.—Over thirty cases of typhoid fever are reported from Winsted, Conn., with three deaths up to June 9. The health officers consider that contamination of a well on one of the dairy farms is responsible for the outbreak, and the Borough Board has created a new office of milk inspector to investigate all dairies.

Charitable Bequests.—Beth Israel Hospital, the Mount Sinai Hospital, and the Montefiore Home for Chronic Invalids each receives $5,000 under the will of the late Ernest Ehrmann, of New York, for the founding of a bed in perpetuity.

The estate of Mr. E. O. Kindberg, of New York, the value of which is not given, is left by the terms of his will to the Presbyterian Hospital, which institution is named as executor.

By the will of the late George W. Fetter, of Philadelphia, the sum of $5,000 is bequeathed to the Medico-Chirurgical Hospital to endow a free bed in memory of his wife.

The Oklahoma Discrimination Against Tuberculous Physicians.—The Committee on Legislation of the American Medical Association passed a resolution at the Atlantic City meeting recommending that the Association use its efforts to have the Oklahoma law repealed that provides that a physician affected with tuberculosis shall not be permitted to practise his profession within the limits of that State. This law was shown to be extremely unjust in view of the fact that the careful consumptive was in no way a menace to his fellowmen, and further that many of our greatest advances in the knowledge of this disease were the results of the labors of men who were its victims.

New Tuberculosis Hospitals.—New York City is soon to add to the group of buildings on North Brother Island by erecting four pavilions of four stories each, with a total frontage of 114 feet, which will be used for the treatment of cases of tuberculosis. The buildings will be of concrete, roof with copper and slate, and will cost about $140,000.

Dr. Andrew Walker McAlester, professor of surgery and dean of the School of Medicine of the University of Missouri, has resigned from the faculty of the school with which he has been connected since 1873.

New York Neurological Institute.—This institute, the incorporation of which was noted not long ago, will, it is expected, be opened early in September, at 149 and 151 East Sixty-seventh street, for the treatment of nervous and mental diseases. The institute will aim to spread among doctors and nurses the principles of treatment of these diseases, and will receive both free and paying patients. The medical directors of the institute include Drs. Joseph Collins, Pearce Bailey, and Joseph Fraenkel.

The American Laryngological Association.—The recent meeting of this association in Boston was the most largely attended of any in its history. The following were elected officers for the coming year: *President*, Dr. James E. Logan, Kansas City; *First Vice-President*, Dr. Cornelius G. Coakley, New York City; *Second Vice-President*, Dr. Harris P. Mosher, Boston, Mass.; *Secretary and Treasurer*, Dr. James E. Newcomb, 118 West Sixty-ninth street, New York City (reelected); *Librarian*, Dr. Joseph H. Bryan, Washington, D. C.; *Member of Council* (to serve for four years), Dr. Algernon Coolidge, Jr., Boston, Mass. The following were elected to membership: *Honorary Fellows* (transferred from corresponding fellowship), Prof. Dr. B. Fraenkel, Berlin, Germany; Sir Felix Semon, London, England. *Active Fellows*, Dr. Albert C. Getchell, Worcester, Mass., Thesis, "Naso-Pharyngeal Fibromata;" Dr. Burt R. Shurly, Detroit, Mich., Thesis, "An Investigation of Post-Operative Conditions, five to ten years after Intubation;" Dr. Greenfield Sluder, St. Louis, Mo., Thesis, "The Anatomical and Clinical Relations of the Sphenopalatine (or Meckel's) Ganglion to the Nose and Its Accessory Sinuses." The next meeting will be in Washington, May 3 and 4, 1910, in connection with the Triennial Congress of American Physicians and Surgeons.

Chattahoochee Valley Medical and Surgical Association.—The sixth semi-annual meeting of this society will be held at Lafayette, Ala., on July 13 and 14, 1909. An interesting scientific program has been prepared under the direction of the president, Dr. A. L. Harlan, of Alexander City.

Society of Ex-Internes of the Jewish Hospital of Brooklyn.—The organization of an alumni association of the Jewish Hospital, of Brooklyn, was recently effected with the following officers: *President*, Dr. William F. Bozenhardt; *Vice-President*, Dr. August G. Horstman; *Secretary*, Dr. J. Ronsheim; *Treasurer*, Dr. William Lintz.

The Willimantic City (Conn.) Medical Society held its annual meeting on June 2, and elected the following officers: *President*, Dr. F. E. Wilcox; *Vice-President*, Dr. C. E. Simonds; *Secretary and Treasurer*, Dr. W. P. S. Keating.

The Arizona Medical Society, at its annual meeting in Prescott, recently, elected the following officers for the ensuing year: *President*, Dr. R. N. Looney, of Prescott; *Secretary*, Dr. John W. Flinn, of Prescott. It was decided to hold the next meeting at Phoenix in April, 1910. As a result of recommendations made by this society, the Arizona Association for the Study and Prevention of Tuberculosis has been formed with Dr. John W. Foss, of Phoenix as president, and Dr. John W. Flinn, as secretary.

The St. John (N. B.) Medical Society met in annual session on May 26, and elected the following officers: *President*, Dr. J. S. Bentley; *Vice-President*, Dr. T. D. Walker; *Secretary*, Dr. G. G. Corbet; *Treasurer*, Dr. James Christie; *Financial Secretary*, Dr. Warwick; *Librarian*, Dr. G. R. J. Crawford; *Pathologist*, Dr. G. G. Melvin.

The Franklin County (Vt.) Medical Society held its annual meeting in St. Albans, on May 25, when officers for the ensuing year were elected as follows: *President*, Dr. Alan Davidson, of St. Albans; *Vice-President*, Dr. C. A. Pratt, of Enosburg Falls; *Secretary and Treasurer*, Dr. F. A. Hyatt, of St. Albans.

The Arkansas Medical Society held its thirty-third annual meeting in Pine Bluff, on May 18 to 21. The following officers were elected: *President*, Dr. James H. Crow, of Little Rock; *Vice-Presidents*, Drs. Harvey D. Wood, of Fayetteville, F. L. Watson, of Newport, and F. A. Cerv, of Louoke; *Secretary*, Dr. Morgan Smith, of Little Rock; *Treasurer*, Dr. J. S. Wood, of Hot Springs.

Obituary Notes.—Dr. Robert K. Tuthill, of Poughkeepsie, N. Y., died of pneumonia at his home on June 9 aged 74 years. Dr. Tuthill was graduated from the New York Medical College in 1859, and served as assistant surgeon in the Twentieth New York State Militia during the Civil War. He was a member of the American Medical Association, and of the New York State and Dutchess County Medical Societies, and consulting surgeon to the Vassar Brothers' Hospital at Poughkeepsie.

Dr. E. W. Trowbridge, of Watertown, N. Y., died at his home on June 9, aged 60 years. He was a graduate of the medical department of the University of Buffalo, in the class of 1879.

Dr. M. L. Allen, of Cleveland, O., died at his home on June 3, aged 56 years. Dr. Allen was graduated from the medical department of the Western Reserve University in 1888, and had practised in Cleveland until about a year ago, when ill-health compelled his retirement.

Dr. Daniel S. Chase, of Medford, Mass., died at his home on June 3, aged 90 years. Dr. Chase was a graduate of the Jefferson Medical College, of Philadelphia.

Dr. John Alexander Geisendorffer, of Portland, Ore., died in St. Vincent's Hospital, in that city, of meningitis, on May 26, aged 43 years. Dr. Geisendorffer was graduated from the Marion-Sims Medical College, of St. Louis, in 1891, and also received a degree from the Jefferson Medical College, of Philadelphia, in 1893. He was a member of the American Medical Association and of the Pacific Coast Association of Railway Surgeons.

Dr. Leonard C. Whitford, of Seattle, Wash., died at his home on May 26, aged 72 years. Dr. Whitford was graduated from the Bennett Medical College, of Chicago, in 1870, and for nearly thirty years had practised in Seattle.

Dr. Philo D. St. John, of Wichita, Kan., died from accidental carbolic acid poisoning on May 23, aged 57 years. He was a graduate of the College of Physicians and Surgeons, of New York, 1883, and was a member of the staffs of the Wichita and St. Francis Hospitals.

Dr. Edward F. Gage, of Winthrop, Mass., died of pneumonia, after a short illness, on May 31, aged 46 years. Dr. Gage was a graduate of the Harvard Medical School.

Correspondence.

CUBA FREE FROM YELLOW FEVER.

To the Editor of the Medical Record:

Sir:—I enclose herewith a true copy of the recent report rendered to the Louisiana State Board of Health by Dr. Harvey Dillon, president of the Louisiana State Board of Health, and Dr. Hamilton P. Jones, State Analyst, in order that you may see how mistaken was the information that caused the editorial "The Cuban Menace" which appeared in the Medical Record of the 5th inst.

In the next issue of the Official Bulletin of this department, "Sanidad y Beneficencia" (Public Health and Charities), you will find a careful answer to the above referred editorial, which I hope you will reproduce in your journal as an act of courtesy due a colleague, no less than one of justice.

We have no yellow fever in Cuba; you can be assured of that. We have no contagious disease of any importance, except tuberculosis, from which no country is exempt. You can also state that if unfortunately we should find a focus of yellow fever in Cuba, it would be immediately reported, and would be extinguished in the same effective manner as was done by Drs. Gorgas and Kean, assisted by Dr. Guiteras, Dr. Finlay and many Cuban physicians, among them Dr. Agramonte, one of the great Major Reed's associates.

You may rest assured that I have the highest esteem for your journal and a great love for your powerful nation, and it is this feeling which has caused me to set aside a few moments of my busy time to beg you to make this just rectification.

Dr. M. Duque,
Secretary of Public Health and Charities.

Havana, June 10, 1909.

UNAUTHORIZED USE OF A NAME.

To the Editor of the Medical Record:

Sir:—My attention has been called to the fact that a manufacturing concern is advertising a number of preparations said to possess medicinal properties, one of which is called "Expectorant (Hare)"; another "Tonic Comp. (Hare)". I am also told that traveling salesmen employed by these parties are representing that I am responsible for these formulæ and that I have a financial interest in them. Will you kindly state for the benefit of your readers and for my protection that such a use of my name is without any justification whatever. I never heard of the manufacturing concern before today, nor do I know what the compounds contain. It is hardly necessary for me to add that all statements made by anyone to the effect that I have any interest in any pharmaceutical or chemical preparation are absolutely untrue.

H. A. Hare, M.D.

Philadelphia.

THE STUDY OF NEUROLOGY IN PARIS.

To the Editor of the Medical Record:

Sir:—In your issue of April 24 I notice an interesting article by Dr. George Mannheimer on "Post-graduate Study in Europe." In this article Paris is set down as "best for dermatology, genito-urinary work and bacteriology." This is perfectly correct. But may I point out that Paris is, if anything, preeminent in one branch of medical science which Dr. Mannheimer has omitted to mention, viz., neurology. It is only necessary to quote the names of Babinski, Déjerine, Pierre Marie, and Raymond—to mention but a few—to understand that nowhere can better work be done in neurology than under the guidance of these great and original teachers. And the great hospital for nervous diseases—the Salpêtrière—affords unrivalled wealth of clinical material.

I may add that I will gladly give all necessary information to any of your readers who intend going in for postgraduate work in Paris.

Charles G. Jarvis, M.D.

81 Boulevard Malesherbes, Paris.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INTERNATIONAL CONGRESS OF CHEMISTRY—ANTICONSUMPTION LEAGUE—POLYCLINIC—CHRONIC CARDIAC DISEASE—SHOCK—MEDICAL COUNCIL—ITEMS—OBITUARY.

London, May 28, 1909.

Yesterday afternoon the Prince of Wales, accompanied by the Princess, presided over the inaugural meeting of the seventh International Congress of Applied Chemistry. His Royal Highness, as a vice-patron, brought from the King, the patron, a message of hearty welcome to the distinguished delegates from every civilized country and assured them that all must recognize that without a scientific foundation no permanent structure could be raised. "Does not experience teach us," he said, "that the rule of thumb is dead and the rule of science has taken its place?" He then offered cordial greeting to members, earnest hopes that great results may ensue from their deliberations, and declared the seventh congress open.

Sir Henry Roscoe, honorary president, offered a hearty welcome on the part of British chemists to their confrères from all parts of the world and said a formal vote of thanks to their Royal Highnesses was hardly necessary. The great gathering thereupon rose and gave three hearty cheers for the Prince and Princess.

Sir William Ramsay followed with an interesting speech in which he repeated the welcomes to all and, giving brief notices of the previous congresses, seized the occasion to speak of their several presidents and representatives. As to their subject, it was cosmopolitan—science knew no country—and they were favored

with the presence of representatives from every civilized state, and as president he welcomed every one, regarding their presence as proof of friendship to this country and devotion to the science on which they spent their lives.

Representatives of other nations responded in turn to these welcomes and all were received with every token of good will. Dr. Harvey W. Wiley, replying for the United States, spoke of the debt to chemistry of the medical art. Prophylaxis is largely due to chemical science and sanitation, for the most part a chemical problem. In easing suffering, preventing sickness, promoting health, eliminating crime and fraud, science was helping progress, benefiting mankind, and advancing morality.

M. Gautier responded for France, Dr. Witt for Germany, Professor Paterno for Italy, Professor Arrhenius for Sweden, and the proceedings closed by singing "God Save the King."

The British League against Tuberculosis has now been formed as the result of a conference recently held. A strong executive committee has been appointed, as well as a general advisory committee, on which physicians and surgeons are well represented. The League proposes shortly to inaugurate branches in the chief industrial and rural districts of the kingdom. The objects are to instruct the public on the main lines of scientific prevention and treatment by means of demonstrations and lectures and to arouse public opinion on the dangers of communicating disease through meat and milk. Efforts will also be devoted to carry on the propaganda through educational and local government bodies and it is hoped a demand for further legislation will arise.

Dr. J. G. Emanuel of Queen's Hospital, Birmingham, delivered a lecture last week which might well occupy the attention of the new League. "Heredity or infection—which factor is the more important?" he asked, and answered without hesitation, infection. Is consumption always with us because we have an army of tuberculous parents producing tuberculous offspring, or because it spreads from one person to another as cholera, typhoid, variola, etc., are known to do? If by infection it can only be stamped out by destroying the bacillus. Why the hereditary factor, which no doubt exists, falls into insignificance, is difficult to say. It may be that the very prevalence of tuberculosis is a reason. No one talks of hereditary transmission of measles or scarlet fever, though probably these infections have a predilection for certain families. But they are so prevalent that we only concern ourselves with their paths of infection. It may be so with tuberculosis, which may be so prevalent among us that the hereditary factor falls into insignificance. Practically it is the various paths of infection that are of importance to us—not any hereditary predisposition.

You will not suppose that Dr. Emanuel's views will be universally endorsed, for while no one will deny the infectivity of tuberculosis, there are many who still attach great importance to heredity. He is himself conscious of this and mentioned the attitude of life insurance companies on the point. Family history is always carefully scrutinized in proposals for insurance, and certainly there are many instances in which predisposition seems marked, a point, however, which is admitted by Dr. Emanuel. It is in pulmonary phthisis that this is of greatest importance from the insurance and also the preventive point of view. I have known a father to die of phthisis and five out of seven of his children follow him at intervals of one, two, and three years, and house infection could not count, as there had been three removals during the time. The mother lived to old age.

Since I mentioned the troubles of the Polyclinic it seems to have largely overcome its difficulties and is making good progress. At the ninth annual dinner which was held on Monday a cheerful tone prevailed. Professor Howard Marsh occupied the chair and was supported by Sir W. Church, Sir D. MacAlister, Sir J. Hutchinson, and other leaders, as well as by a numerous company. The chairman, in proposing "The Medical Graduates' College and Polyclinic"—to give it its full designation—said it had done much pioneer work and it provided information on subjects which many had not time to work out for themselves. Sir Jonathan Hutchinson, who has all along been the chief pillar of the institution, and who is now giving weekly clinical demonstrations, said he highly esteemed the organization which carried on medical education after graduation, that education could not stop at school or college, was a life-long process, and in a sense only began when the diploma was taken. Captain Hayward Pinch, late Medical Superintendent, was presented with a cheque for 100 guineas and an address numerously signed in recognition of the zeal and ability with which he had served the institution for ten years. A good course of demonstrations and lectures has been arranged for the session, in which the practical clinical reputation of the Polyclinic is sure to be maintained.

The week before the meeting Dr. Wethered gave a lecture on chronic heart disease, in which he laid down, somewhat positively, that all patients who show indications of cardiac failure, though only slight, do so on account of alteration in the walls of the heart. Hence the chief effort should be to sustain the reserve force of the heart's muscle. To do so we need the patient's co-operation, and the question is how far he should be made aware of his condition. Something depends on the personality of the patient. Some who are told they have heart disease become depressed and apprehensive, and Dr. Wethered advised diplomatic reserve and phraseology. As to medical treatment, he said we may sustain the muscular force of the heart by directly increasing the power, by maintaining its nutrition, and by reducing peripheral arterial tension, which is the resistance to the heart. To sustain the force cardiac tonics are less useful than in acute failure and only to be resorted to with caution. We can do better by giving the heart rest—not recommending the life of an invalid, but making the work of the heart more regular. Often irritability is due to irregular cerebral circulation, whether from mental disturbance, anxiety, etc. Some changes in the daily routine of the patient's life may promote the needed rest. To improve the nutrition of the heart it is necessary to insure that the coronary circulation is satisfactory. This also involves a proper regulation of exercise and rest, by stimulating the arterial circulation of all the muscles of the body and so hastening the venous and lymphatic currents, thus activating the whole metabolism, by which digestion and other functions will be improved. With regard to the reduction of peripheral resistance, the lecturer thought this principle had not usually been sufficiently insisted on. Clearly we may attempt to help the heart by reducing its work—that is, by reducing the tension in the peripheral vessels. This has been attempted by drugs, but the action of vasodilators is temporary. Amyl, so rapid and therefore so effective in angina pectoris, has very temporary value and nitroglycerine is not prolonged. When a longer effect is desired sodium nitrite can be given. The lecturer said he had also seen good results from doses of 3 to 5 grains of potassium iodide, combining it with bicarbonate of sodium and potassium and with cardiac tonics. When the tension was high he gave strophanthus. He then reviewed the mechanical treatment by baths and exercises. When faulty digestion is troublesome, he said, beware of the usual "invalid diet," and as to starchy foods mastication is of the first importance. Biscuits help to secure it. If dyspepsia cannot be cured by diet, some drugs must be given. Insomnia sometimes demands hypnotics, but other means are better if they can meet the case. Palpitation may be due to heart or stomach and treated accordingly. The bromides are often effectual in either case.

Shock was lately the subject of a paper at the Medical Society of London by Mr. Malcolm, who agreed with Crile that the tissues were pale, the arteries empty, and the veins dilated, but differed so far as to say the arteries were tensely contracted, while Crile thought the vasomotor centers were paralyzed and the vessels therefore dilated as shock progressed, and should be filled with fluid and if possible contracted. Mr. Malcolm, however, held that the vessels contracted in shock, squeezing out the fluids which were removed in sweat. Hence vasodilators and sedatives were indicated as shock developed and fluids must follow in the stage of recovery. When fluids were withheld after operations patients often remained for hours in profound shock, but since it was recognized that the administration of fluid was all that was needed, recovery has been prompt in uncomplicated cases. When arteries are empty and will not dilate, vasoconstrictors should not be given, but alcohol was useful, the author thought. The better methods of giving anesthetics, the disuse of irritating antiseptics, and the anticipation of possible troubles tended to prevent shock. The greatest danger was in septic cases, in which the vascular changes had begun. Then fluid was urgently required, and that during the operation. It might be given subcutaneously,

even before the operation, to replace lost fluid and fill up vessels that tended to relax.

Mr. Keetley disapproved strychnine injections and said when ether was used shock was less frequent than with chloroform.

Mr. Pearce Gould urged treatment by rest, warmth, and morphia.

Dr. Alex. Morison said the point was to stimulate the heart and recommended amyl nitrite and warmth.

Mr. Warren Low advised saline injections into the veins in bad cases.

Mr. Lockwood considered inhalation of oxygen advantageous.

The General Medical Council has been sitting this week. It began on Tuesday with the usual address of the president, recounting the principal events since the November meeting. Then there was a long discussion on a proposal that an additional direct representative ought to be appointed for England, although the Council is rather numerous and the new universities send new members. Apathy at elections was complained of, but that is only natural while a radical reform is not carried out.

Bristol University is now established, the King having approved the charter, to the great delight of the citizens, displayed by bell-ringing and other demonstrations.

Professor MacAlister of Cambridge spoke at Livingstone College for Training Medical Missionaries. He said it was criminal for societies to send out missionaries to the tropics without some medical training.

Dr. Edward Liveing has resigned the registrarship of the Royal College of Physicians after twenty years' service. A very complimentary resolution was passed recording his zeal, ability, and courtesy.

Dr. Pavy, F.R.S., is receiving the felicitations of numerous friends and pupils on reaching his eightieth year.

Dr. Tatham of the statistical department of the Registrar General's office is to be entertained shortly at a dinner in recognition of his valuable services.

Dr. W. Wotherspoon Ireland has died suddenly at his residence at Musselburgh. You will recognize him as a distinguished alienist, correspondent of your own Medical and Surgical Society, as well as several similar societies in Europe. He was an Edinburgh graduate (1855), served for a time in our Indian army, and wrote a "History of the Siege of Delhi," 1861, followed by "Studies of a Wandering Observer." Later he settled at home and became medical superintendent of the Scottish Institute for Imbeciles, the office which he held for many years. Other appointments also fell to him. He wrote "Idiocy and Imbecility," 1877; "The Blot on the Brain," 1885; "Through the Ivory Gate," 1889; "The Mental Affections of Children," 1900. His literary output also comprised valuable communications to the journals.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 3, 1909.

A Case of Egg Poisoning.—M. V. Tyrode says that some of the cases on record as those of egg poisoning were due to a suggestive element rather than to actual poisoning. He relates the case of a man of fifty-three years who had had severe attacks of toxic poisoning. Similar symptoms followed the eating of eggs. The patient said that the white of an egg when uncooked resembled the juice of an oyster in being slimy and mucilaginous and naturally would poison him, and claimed that he had been thus poisoned many times. The volk never affected him. Upon analysis of the case the author concluded that the patient had had real ptomaine poisoning, from the oysters, but that suggestion and association were chiefly responsible for the subsequent attacks, which increased in intensity and went to another foodstuff, the white of egg, because in the patient's mind it resembled, uncooked, the oyster. The patient was accustomed to follow up these attacks by an alcoholic debauch because whisky had seemed to relieve the first attack of the series. To break up this association of ideas the author made his patient eat for breakfast (after having been for two days on large doses of bromides) a small portion of white of egg, and gradually increased the amount at each subsequent meal for a few days. In two weeks he was apparently cured, but a few months later he had some return of his old trouble.

Extensive Calcification of Pleuritic Exudation Causing Curvature of the Spine.—Thomas Dwight records the findings in a patient who died of uremia, no history being obtainable. A thick layer of adhesions existed between the walls of the chest and the lung, throughout the back, and more or less on the right side of the chest. A flattened piece of what appeared to be bone, some 8-10 cm. long and 1 cm. broad, was found free in the back of the right chest, pressing into the lung. A thin circular bony disk about 2 cm. in diameter was found far forward in the right side of the parietal pericardium, where it was in contact with the right pleura. The chief bar—shown in an illustration accompanying the paper—showed a length of continuous bone of nearly 11 cm. It was flattened with a breadth of 2 cm. at the upper part. It did not lie against the wall of the thorax, but projected inward and it was also convex laterally. When the specimen was fresh, fibers could be seen radiating from the bone in many directions. Examination of the bar showed no true bone, but calcification in dense fibrous tissue. Two smaller pieces of the same material were found free in the chest cavity. Looked at from behind, the right ribs from the third to the ninth were brought near together at their angles and projected strongly backward, while the left ones from the tubercles to the angles extended nearly straight outward, so that the two sides of the chest were extremely uneven. The bodies of the fourth and fifth thoracic vertebræ were much lower on the right than on the left and were fused together. The twisted curvature of the spine was undoubtedly due, in some degree at least, to the pressure of the calcified bar projecting into the cavity of the thorax.

Placenta Prævia.—N. R. Mason and J. T. Williams analyze 155 cases of placenta prævia seen at the Boston Lying-in Hospital during the past thirty-five years. Their conclusions are as follows: (1) Improvement in the results of the treatment of placenta prævia is to be expected not so much from any particular method of delivery as from early delivery. (2) The advantages of early delivery are as great for the child as for the mother. (3) Every patient should be instructed and enabled to notify a competent obstetrician at once of any uterine hemorrhage during pregnancy. (4) Any hemorrhage during the second half of pregnancy demands an immediate investigation of the contents of the lower uterine segment. (5) A routine vaginal examination should be made on every patient at the end of the seventh month. (6) In multiparæ, rapid dilatation, followed by version and extraction, offers a safe and satisfactory method for both mother and child. (7) In primiparæ, at the beginning of hemorrhage, while still in good condition, cesarian section should be the operation of choice.

Exercise in Pulmonary Tuberculosis.—B. Swayne Putts extols the value of "working colonies," such as exist in some of the English sanatoria. The object of these colonies is (1) to bring the patients, under careful medical supervision, to such a physical condition that when they return to work again the change will be so slight that their lungs will not be affected. (2) To instruct many patients in a new (to them) occupation, which they follow after leaving the institution and which promises to be more conducive to health than their previous employment, and (3) to utilize the economic value to institutions by having the patients do work which will bring in returns. In introducing such a system, patients should begin on light work and gradually increase in time spent and in the severity of the work up to the limit of safety. In considering exercise we should consider it with reference to the lungs alone and then with reference to the whole body. We have the right to consider exercise separately, for the reason that we have factors whose effects are limited, essentially, to the movements of the lungs. When we place a patient in bed for a long period we are allowing the muscles to atrophy and are thus interfering with convalescence by destroying part of one of the largest organs and one second only to the liver in the nitrogenous metabolism. Some moderately febrile patients can work with benefit. In some tuberculous patients the heat regulating centers are abnormally sensitive. Besides the actual increase on the lung disease as a cause for fever, we should consider as a potent factor the actual heat produced during exercise by muscular contractions and increased circulation, and as well the chemical changes which normally are the chief source of body temperatures. Each case must be treated individually.

New York Medical Journal, June 5, 1909.

The Flagellation of Leucocytes in the Presence of Chemical Excitants and in Other Conditions.—A preliminary report on this subject is made by E. M. L'Engle, who refers to the recent work of Ross and Macalister. He repeats their technique and confirms their findings. Certain of the cells which, on account of their size and general appearance, are believed to be small mononuclears, may be seen to extrude fine, hair-like projections with a terminal granule. These at first are quite short, but gradually grow longer and are apparently in quite active motion. The length finally attained may exceed twice the diameter of the cell to which they are attached. There may be one or several of the processes on a cell. Ross and Macalister report seeing as many as twenty. The author has not seen more than two on any one cell. This phenomenon may not be seen in every blood smear examined, but one or two, or sometimes more, cells can usually be found in which this process may be followed. The flagella are very easily distinguished from the pseudopodia, which are formed on the ameboid cells. They resemble, in a general way, the flagella seen on bacteria, except in the possession of a terminal granule. After a varying length of time the flagella separate from the cell and swim away as independent bodies. It was not possible in any of his cases to follow the separated flagellum and determine its ultimate fate. Its change of place was very rapid and the gradual drying of the edge of the smear caused disconcerting independent movements of the blood. The occurrences of flagella formation in the blood may be concerned with the formation and multiplication of leucocytes. It may perhaps be a function of certain of the white blood cells in normal or diseased conditions. Ross and Macalister suggest that it may be of some importance in carcinoma, as they have stimulated flagella formation in normal blood by the addition of sera from cases of carcinoma.

Malarial Fever as Seen at Close Range in the Deep Jungle of the Malay Peninsula and in the "Country of the Ghosts."—C. S. Braddock, Jr., believes that the malarial poison is not only inoculated by the bite of the mosquito, but that it originates in water and soil, is carried by the wind and water, and is taken into the system by unboiled drinking water. He bases his views on his experience with the disease in many parts of the world. He has noted that on a jungle trip the men on foot are first taken ill with malarial fever, then the men on horseback, and last of all and very seldom the men who travel on elephants. He attributes this exemption of the men traveling on elephantback to the height they are from the ground. The higher you keep from the ground, whether traveling or sleeping, the more exempt you are from fever. The same varieties of mosquitos exist in the locality where the ordinary malarial fever prevails, as well as where pernicious malarial fever prevails, and as you travel you can smell, without being told by your native guides, the miasma as it rises from the ground, and unless prophylactic doses of quinine are taken you will have fever. Wherever you disturb the earth in the tropics you disturb this great fever giant. This is noticeable in the ruby mines, in the tin mines, and in the digging of embankments and canals, but if you cut off the jungle and let the sun in you can do more good than all the mosquito curtains in the world. General rules for the preservation of health are these: Sleep in the open ground away from the deep jungle. Do not sleep on the ground or near the ground, but as high from it as possible. If wet from tropical rain or fording streams, change clothing as soon as possible. Always drink boiled water. Use a mosquito curtain. Give prophylactic doses of quinine when traveling through the bad districts. If a man will clear away the jungle and let the sun in over one dry season he can dwell with impunity where before was only the trap. If we let the sun in the fever will disappear. The author believes that while the mosquito transmits malarial fever, he acquires it first from the man and the soil. No other explanation can be given for those acquiring it from mosquitoes who have landed on an utterly uninhabited coast where there were no human beings to primarily infect the mosquitoes there, but who have been promptly taken down with malarial fever when they have disobeyed the laws of the jungle, while those who have obeyed these laws have escaped entirely.

Chimaphila in Diabetes.—S. G. Soules highly extols the remedy for the disease named, referring to a previous paper in the *New York Medical Journal* (Vol. LXXXVI., page 929) on the same subject. The dose there published has been found to be too small to produce the best results. Twice as much is infinitely more satisfactory, and an abstract, made by evaporating the fluid extract to the consistency of thick syrup, is the best form in which to give it that the author has found thus far. A dram of this abstract represents approximately four drams of the fluid extract. Of this the dose for an adult is one or two teaspoonfuls twice or three times daily, according to the need of the patient. Of this large dose no one need be afraid: He has frequently taken one-half ounce at a single dose, and twice one ounce in twelve hours, without any inconvenience whatever. He cautions against the "gluten" bread products unless he knows just how much starch they contain. He has seen such bread contain 70 per cent. of starch. He adds a few words about diabetes cramps, which occur usually in the calf of the leg, and before arising from bed in the early hours of the morning. In this case the plantar surface of the foot of the affected side should be placed on the footboard of the bed and the patient should press his foot hard against it, when the cramp will disappear at once. Wherever the cramp is, put the affected muscle in action.

Journal of the American Medical Association, June 5, 1909.

Acute Pancreatitis.—W. F. Cheney discusses certain questions regarding this subject. First, how frequent is the disease? To this one can answer it is certainly not rare, although it seems to have gone undiscovered for many years, like appendicitis and cholecystitis. Since first recognized, cases have multiplied, and no doubt, as time goes on, it will be found that it is still commoner than we at present suppose. The question as to its etiology can be answered in one word—infection. This may occur from the intestine or from the gall-bladder or by direct extension of a duodenitis through the wall of the duodenum or by infected emboli carried by the blood streams from distant parts. Most cases have been found associated with gall-bladder disease, the next largest number with gastroduodenitis, especially that due to alcohol. These cases reported as secondary to general or local infections are best explained by transmission of the infection by the blood. The clinical recognition of the disease as shown by all the published reports is made by the sudden violent onset with pain, vomiting, intense tenderness of the upper abdomen, collapse, hiccough, and, later, the symptoms of localized peritonitis with low fever and irregular chills. The laboratory evidence is not diagnostic. There is quickly a high leucocyte count with an increase of polymorphonuclears. The urine rarely shows sugar at first. The absence of indican is an important point in differential diagnosis, and we may have the Cammidge reaction. Taking all the facts, however, there is no absolutely certain way of clinically recognizing pancreatitis. There is no medical treatment for the condition. It demands surgical treatment unless the shock should be considered too risky. Morphine for pain and stimulants to tide over the crisis of imminent collapse may be used in the beginning of the symptoms. While there is no certain diagnosis possible, we can promptly arrive at a conclusion limiting the diagnosis to a few conditions, all of which require operation, and the only question really remaining is how soon to operate. Osler gives the mortality of unoperated cases as 90 per cent., while of patients operated on more than 50 per cent. recovered.

Postoperative Ileus.—W. H. Wathen defines ileus as the operative or postoperative paralytic obstruction of the bowel and says that the word ileus should be eliminated from surgical nomenclature. The primary paralytic form of obstruction may be caused (1) by violent inhibitory impulses transmitted to the muscle walls of the intestine from the central nervous system by the splanchnic nerve through the sympathetics; (2) by impairment or destruction of the nervous and muscular energy of the intestines by the poisonous action of bacterial enzymes from the intestines or peritoneal cavity on the nerves or muscles or bowel walls or from traumatism, or (3) by the combined action of both. The mechanical preoperative and postoperative intestinal obstruction may be caused by adhesions, constricting bands, volvulus, intussusceptions, hernia, etc. Unless it is relieved promptly, the bowel above the obstruction becomes dilated and paralytic, and the ileus caused then be distinguished from the primary paralytic form. He explains in detail the anatomy, physiology, morbid

and bacteriology of the intestinal tract and explains normal and abnormal peristalsis, while shock may have an influence in most cases of severe or fatal paralytic obstruction, this is the result of and is associated with the absorption of bacterial toxic products from the bowel or peritoneal cavity into the intestinal walls and tissues of the body. This is shown by the fact that when we remove the obstruction the patient may collapse from the rapid absorption by the comparatively healthy bowel below, of the toxic substances, the epithelial resistance being quickly impaired. We cannot often decide when an operation is necessary until it is too late to do good, but in such cases as can be diagnosed the obstructing cause, whatever it be, should be promptly removed with as little delay or rough handling of the intestine as possible. In some cases we shall get better results by relieving the distended bowel of its contents by enterotomy or even enterostomy, and a subsequent operation can be performed to remove the obstruction and restore normal conditions. In operations for mechanical obstruction it may be better not to enter the abdomen through the original incision, but to select a point where the obstruction can be reached and removed with the least possible exposure and injury to the viscera, and he gives some special directions on this point. In the absence, however, of any evidence of the seat of the obstruction it is better to enter the abdomen in the median line below the umbilicus. There is no department of surgery for which a knowledge of the embryology, anatomy, physiology, bacteriology, pathology, diagnosis, and surgical technique is needed more than for this, and in addition the surgeon should be a surgical mechanic. In true paralytic postoperative obstruction without peritonitis, surgery is contraindicated, and the treatment should be preventive rather than curative. We may sometimes have a recovery of an apparently severe case without surgical treatment, but in other cases a severe toxemia or general peritonitis may result, resistant to all treatment. Purgation is contraindicated, and neither food nor liquid should be given by the stomach. The general belief that we should give remedies in any form to establish intestinal peristalsis has no scientific basis, and it is positively contraindicated in cases in which there is peritonitis, inflammation of intestinal walls, or injury to the nerve plexus or muscles of the bowels. Such medication could be useful only when the cause of the obstruction is in the inhibitory action of the splanchnics with little injury to the nerve plexuses and muscles of the bowel. We may expect such patients to recover, however, without medicinal treatment if we employ stomach lavage and use saline solution in the colon as recommended by Murphy, or an occasional large enema as the conditions indicate.

Gastric Symptoms of Arteriosclerosis.—H. L. Akin discusses the frequency of this condition and gives the histories of some personal cases. He reviews the mechanism of the production of the symptoms as explained by Pal, Ortner, and others, and states that in making a diagnosis it is of the utmost importance not to be led astray by the patient's complaints of indigestion, pain in the stomach, distention, and belching, and so neglect to make a careful physical examination. He emphasizes particularly the importance of examining the vascular system thoroughly. In treatment he advises a restricted diet, and states that in this, as in all other arteriosclerotic conditions, the iodides are the most valuable drugs.

Cholelithiasis and Pancreatitis.—C. N. Smith states that the prevalence of cholelithiasis and of infections of the biliary tract as the essential feature in the production of pancreatitis demands thoughtful consideration. He enumerates the early symptoms: Pain, shortness of breath, liver tenderness, chills simulating malaria, etc. There is frequently a history of previous typhoid fever. The one great stumbling block in the way of an early diagnosis of gallstone disease, he says, is the allurement of jaundice, which seems to have bewitched the judgment of so many medical men, in that they demand its evidence before admitting the presence of gallstones. Jaundice, however, is an infrequent and inconstant event in gallstone disease, and when present is as a terminal rather than as an inaugural one. Too frequently, indeed, does jaundice announce the advanced stage of a secondary chronic pancreatitis. It is high time that the medical profession should break away from the fetish of jaundice; that it should recognize the presence of gallstones by their inaugural symptoms; that it should appreciate the gravity of gallstone complications and sequels, and that it should forestall such complications and sequels by the institution of operative procedures immediately following the establishment of a diagnosis.

The Lancet, May 9, 1909.

Tracheotomy Cases in the Course of Which There Were Long Periods of Inability to Dispense with the Tube.—Brief histories of three cases are given by D. Forbes and R. M. Courtauld. Feathers were used for the removal of membrane and secretion from the trachea. No case is known of prolonged retention of the tube in which these were avoided and tracheal forceps used. After operation neither feathers nor forceps are likely to be required if a sufficiently large tube is used. The smaller the tube in relation to the lumen of the trachea, the less the effective expulsive power of the cough. The authors say that the cases indicate (1) that considerable patience must be exercised in the treatment; (2) that if the patient remains in hospital there is every chance of his final recovery; (3) that it is doubtful if active interference has any beneficial result; (4) that the amount of obstruction varies from time to time and that the removal of the tube should be undertaken when this is at a minimum; (5) that only occasional attempts to find out the degree of obstruction should be made—not more than once in three weeks or a month in prolonged cases; (6) that the principle of early removal of the tube is right—an attempt to remove finally should be made some 48 to 72 hours after the operation; (7) that the use of feathers should be avoided; (8) that no advantage seems to be gained by the replacement of a metal by a rubber tube; (9) that fenestration of the tube, allowing the passage of air through the larynx, is not found to lead to improvement.

Autoinoculation and Reinfection of Syphilis.—This subject is considered by J. Hutchinson, who says that it would be strange if it were true that autoinoculation was impossible after the sore had existed but a few days. The time limit is probably not more than ten days in this respect and mercurialization of the patient may render autoinoculation, even during this period, impossible. He refers to several instances of autoinoculation by natural contact, as penis and scrotum, penis and inside of the thigh, the two labia majora, etc. Of course, such conditions are explainable on the theory of simultaneous infection in two places by the spirochetes. The author refers to one case which proves that even after secondary symptoms have appeared a typical fresh chancre with bubo may develop. In regard to the question of reinfection, he says that many histories of such an occurrence are lacking in vital features of evidence, so as not to make the stories absolutely credible and reliable, yet he has been able to collect undoubted instances. Some of these he adduces with the following captions: Interval between the two infections seven years; second attack the more severe and protracted, especially the eruption on the skin and mucous membranes; interval less than three years; both attacks mild and amenable to treatment; interval twelve years; second attack the more severe; interval eighteen months, the shortest on record; secondary symptoms in both attacks yielding well to treatment, etc. His general conclusions are as follows: (1) Efficient treatment by a continuous course of mercury for one or two years is the surest way of rendering a patient susceptible to second infection. With this proviso he may contract syphilis again within two or three years of the onset of the first attack. The treatment of the first attack in all the seven cases was by a steady mercurial course lasting from one to three years. (2) The interval between two attacks of syphilis may be so short a time as 18 months, *i.e.* the patient may no sooner have finished his course of treatment than fresh exposure may produce a complete fresh attack. The average interval has been in his experience six years. (3) The second attack may be slighter or more severe than the first; nothing positive can be laid down on this point. If the symptoms on the first occasion have readily yielded to mercury they will probably do so in the second. (4) There is no reason why the same patient should not go through even three attacks of syphilis provided the first two have been well treated.

British Medical Journal, May 29, 1909.

Perforated Gastric and Duodenal Ulcers Treated Successfully Without Suture of the Perforation.—E. M. Corner and W. Bastion relate two cases. They sub-

mit the following propositions: (1) If stitches cut through at an operation, no further time should be wasted in trying to close a perforation. (2) Such perforation should be covered by omentum anchored in place by one or two sutures. (3) A gauze drain should be conducted to the perforation and removed under an anesthetic in forty-eight hours. (4) The chance of recovery under this treatment is unlikely to be less than if the ulcer is sutured. (5) The remote results of these cases as regards pyloric obstruction are no worse than when the ulcer is closed. (6) In these, as in many other cases, a primary gastroenterostomy is unnecessary for the recovery of a majority of cases. Both of the cases described in the paper recovered.

Treatment of Severe Cases of Chronic Colitis.—P. L. Mummery says that cases of chronic colitis naturally divide themselves into two classes: First, those which, if carefully treated by a suitable dietary, proper regulation of the bowels, and perhaps one or more visits to some suitable spa where proper lavage of the bowel can be carried out, get well and stay so, and, second, those in which, in spite of prolonged careful medical and spa treatment, but little if any improvement follows, and in which relapses quickly occur. The latter forms one of the worst classes of chronic invalids and chase after all forms of quackery. The first task of the physician should be to find out the real cause of the symptoms. The term "chronic colitis" should be reserved for those cases in which there is a chronic inflammatory condition of the colon mucosa. They should be made out easily with the sigmoidoscope, as the sigmoid flexure is practically always involved. Such cases do well on lavage and the Plombières douche. In some of the cases with this class of symptoms there is, instead of a lesion of the mucosa, some chronic obstructive lesion, such as adhesions from a previous peritonitis or perimetritis. Cancer of the colon may cause symptoms of chronic colitis. In another group of cases we find a chronically inflamed appendix. In still another group there is no inflammation of the mucosa, but the whole colon is lax and atonic and there is a marked tendency for the upper portions to prolapse into the latter, and there is generally well-marked ptosis of the stomach and the transverse colon. Here lavage would be harmful. Those cases which medical measures fail to relieve may call for appendicostomy. The most difficult cases to treat are those in which there is a general atony of the bowel combined with ptosis of the colon. Stitching up the colon is quite useless, as it is unreasonable to expect stitches to hold up the stomach and transverse colon permanently when the natural supports have not been able to do so. In such instances very satisfactory results follow appendicostomy and the fitting of a belt to support the abdomen. The object of operation in such cases is to prevent the stagnation of the fecal contents of the colon and at the same time by the introduction of peristaltic stimulants to improve and restore the muscular tone of the bowel wall.

The Prevention of Parotitis During Rectal Feeding.—W. S. Fenwick notes that the necessary prohibition of food and water by the mouth after severe hematemesis is often followed four days later by inflammation of the parotid glands, the side first affected being the one most frequently in contact with the pillow. The impossibility of keeping the mouth sterile leads to the infection of the glands through Stenson's ducts. After the usual experience of rectal feeding with large nutrient enemata of peptonized milk and trusting to the usual methods of cleansing the mouth, the author had a very large number of cases of suppurative parotitis. An effort was then made to promote a continuous secretion of saliva, with the object of irrigating the ducts, and thus of preventing an ascending infection, and with this object the patients were directed to chew horseradish, pellitory, or pieces of raw meat at intervals, or to keep a pebble constantly in the mouth. Eventually it was found that an india rubber teat about two inches in length met all the requirements of the case, and that patients were quite content to suck it for hours at a time, with the result that the mouth remained quite clean and moist. When not in use the teat is kept in a weak solution of Condy's fluid. Since this simple device was adopted he has treated more than 300 cases of hematemesis by rectal alimentation, lasting from ten days to seven weeks, without being troubled in a single instance by parotitis. It is only in hospital practice, where the mouth is very foul at the time of admission, that the gland occasionally becomes inflamed before any measures can be taken to prevent it.

Secondary Parotitis Due to Oral Starvation in the Medical Treatment of Gastric Ulcer.—H. D. Rolleston and M. A. Oliver discuss this subject, the former having seen nine cases in eleven years in the course of general hospital practice. In St. George's Hospital there were 1,000 cases of gastric ulcer in twenty years treated by medical measures. In this number there were twenty-three cases of parotitis, all in women. Of these 23, complete oral starvation was employed in 21; the two remaining cases were on rectal feeding, but in addition were allowed to suck ice. In other words, the percentage of secondary parotitis in 470 cases treated by rigid oral starvation was 4.5, while in the 530 cases allowed something, even though only water, by the mouth it was 0.4. Hematemesis had occurred, either before admission or while in the hospital, in 16 of the 23 cases of gastric ulcer complicated by parotitis. It is thus clear that exclusive rectal feeding, or rather oral starvation, is a much more constant antecedent than hematemesis. Attention is drawn to this point because Hone attached more importance to antecedent hematemesis than to oral starvation as a factor in the causation of this form of parotitis. Probably hematemesis is likely to be a factor in the production of parotitis only in so far as it leads to treatment by oral starvation. There is no evidence that secondary parotitis depends on the occurrence in the parotid gland of thrombosis such as might be favored by a posthemorrhagic leucocytosis. In all, the authors collate 34 cases of parotitis and it would appear (1) that secondary parotitis may complicate cases of gastric ulcer treated medically by oral starvation; (2) that it occurs ten and a half times more frequently in such cases of gastric ulcer than in cases allowed fluid by the mouth; (3) that it is an outcome of the dry condition of the mouth, and that mouth washes do not prevent its occurrence; (4) that it is more often unilateral than bilateral; (5) that suppuration occurs in about one-fourth of the cases, and that this constitutes a grave complication.

Berliner klinische Wochenschrift, May 10, 1909.

A Rare Granuloma from a Foreign Body.—K. J. Schopper reports the case of a young man who had a discharging tumor on the eyebrow. It began as a red, painful nodule the size of a pinhead, but rapidly grew to 3 cm. in diameter and broke down. One gland was enlarged. The diagnosis was difficult. Syphilis was considered, but lack of general adenitis spoke against it. The Wassermann reaction was negative and no spirochete could be found. Ringworm was thought of, but no trichophyta could be discovered. Tuberculosis was ruled out. Finally an exploratory incision was made and a fragment of chaff 3 mm. long was removed. This was supposed to have worked out from a straw mattress and to have entered the patient's skin while he slept.

Diazo Reaction in Yellow Fever.—Vargas and Seidelin studied the diazo reaction in twenty-two cases of yellow fever. In nine it was positive, in thirteen negative. The reaction varied greatly from day to day. It was more apt to be positive early in the disease than late. The reaction was of no great value in diagnosis, but was considered suggestive of the disease when occurring early and associated with albuminuria. The authors could draw no definite prognostic conclusions from the reaction. Of the nine positive cases four died, while of the thirteen negative ones two died. The reaction was usually weak, though in one or two cases it was as strong as in typhoid fever.

Munchener medizinische Wochenschrift, May 11, 1909.

Roentgen Rays in Gynecology.—Albers-Schönberg says that in gynecology the following may be attained by the use of the *x*-ray: (1) The cessation of the menses. By this may be accomplished (*a*) reduction in size of myomata. Intramural tumors are more amenable to treatment than subserous or pedunculated ones. Old calcified tumors do not respond to the *x*-ray. In some patients the tumor decreases rapidly, though a complete absorption has not been observed. (*b*) Disappearance or reduction of hemorrhage caused by myomata, both menstrual and intermenstrual. This effect is not immediate with menstrual bleeding. The first effect of the radiation is an increase in the hemorrhage, sometimes with pain, sometimes without. The decrease in hemorrhage comes on gradually. In intermenstrual hemorrhage the initial in-

crease is not seen. (*c*) The relief of pain dependent on myomata. Not only the local pain, but the general discomfort, nausea, vomiting, dyspnea, edema, discharge, and habitual constipation are relieved with remarkable rapidity. (*d*) The relief of preclimateric hemorrhage and pain not depending upon myomata. (*e*) Sterilization for gynecological reasons. (2) The relief of postclimatic hemorrhage. (3) The reduction and cure of the untoward symptoms of myomata without bleeding at the post climateric age. Both the hemorrhage and other symptoms are more amenable to treatment after the menopause than in younger patients. (4) The relief of painful menstruation at any age when possible without sterilization, when not, with sterilization. The author has no personal experiences with this last. He says, however, that with care a permanent sterilization is hardly to be expected in a young woman.

The Effect of the Injection of Salt Solution into the Intestines on the Gastric Secretion.—V. Benczur reports a series of experiments on a dog. He cites the work of Cohnheim and Dreyfuss, who showed that if solutions of $MgSO_4$ or NaCl were injected into an intestinal fistula in a dog, that a test meal placed in the stomach remained there longer than when no intestinal injection was made, and also that the $MgSO_4$ caused an increase of gastric acidity, while the NaCl caused a reduction thereof. V. Benczur raises the question whether these apparent hyper- and hypoacidities are due to an increased or reduced secretion of gastric juice or to a secretion of a gastric juice of an abnormal acid content. He, therefore, repeated the work of Cohnheim and Dreyfuss, except that where they experimented on a stomach containing a test meal he worked with the empty stomach, and so obtained pure gastric juice. His results showed that while the injection of the $MgSO_4$ caused an increase and the NaCl a diminution in the amount of gastric juice in the organ that the acidity per cent. is not altered by either. He, therefore, concludes that the effect of the injection into the intestines of the salts is a quantitive and not a qualitative one on the gastric juice.

Sclerosis of the Abdominal Aorta.—Rossbach reports a case of a woman of 43, who for several years had been ill, complaining of cramp-like pains in the abdomen. This had steadily grown worse, so that she was hardly able to work. The pain was frequent and severe and had no relation either to menstrual period or diet. Further complaint was of giddy sensation, pain in the legs, tiring easily, headache, and occasionally vertigo, black spots before the eyes, sinking attacks, sweating, and great anxiety. She had had nine premature children, but denied syphilis. The patient was under observation for months. Whereas in 1907 the heart was of normal size and the sounds clear, in 1908 the apex was two finger breadths outside the mammary line and had a heaving impulse. Over the aortic area a loud systolic murmur and a snapping second sound developed. The blood-pressure was high. A trace only of albumin appeared in the urine. The abdomen showed nothing abnormal. The patient died of a cerebral hemorrhage. The points of interest in the autopsy were as follows: The heart was generally enlarged. Both ventricles were dilated and the walls thickened; the left atrioventricular orifice admitted two fingers; the ascending aorta and arch were normal; the descending aorta slightly cloudy, and the abdominal aorta below the diaphragm was a rigid tube 3 mm. thick, while the interior and media were calcified. The calcification extended to the superior mesenteric and common iliac arteries. The femorals were normal. Microscopic examination of the kidneys showed no nephritic changes. The heart, liver, spleen, brain, and kidneys showed no capillary sclerosis. The author compares this condition of angina abdominalis with angina pectoris and intermittent claudication. He believes the muscle of the walls of the vessels to be sensitive and that the abdominal pain of the patient to be due to spasmodic contraction of the vessels secondary to the increased blood-pressure, caused by the resistance of the schlerosed and narrowed abdominal aorta. He quotes several authors who consider that hypertrophy of the heart is especially liable to follow schlerosis of the splanchnic vessels.

Deutsche medizinische Wochenschrift, May 13, 1909.

Are There Cases of Dystrophy Which Recover?—Jendrassik raises the question of whether true progressive muscular dystrophy ever recovers. He cites four cases reported by others and then reports in full two cases which he has observed. Case I. A girl of ten when first seen in 1898 had a negative family and personal history. First child and normal birth. She first walked at two years, but fell frequently. Had had no illnesses except dysentery, at one and a half years of age. During the summer of 1898 the gait grew rapidly worse. On October 10, when seen by the author, the diagnosis of dystrophy was definite. The tendon reflexes were absent; there was free movement of all the joints and the spine; the muscles of the legs, especially the thighs, were very weak. The abdominal and back muscles and arms were weak, but the face muscles normal. The generative organs, bladder, and rectum were unaffected. The patient at this time was bedridden. The muscles became flabby, but there was no fibrillary twitching. After six months in bed the movements of the legs improved. At eleven years of age the child was almost completely developed, though menstruation had not begun. The gait was waddling. She could not sit up from the dorsal position. The reflexes were still absent. At twelve the reflexes could be obtained by reinforcing. She was menstruating and looked strong and blooming. From this time on the improvement was steady and the reflexes returned. In November, 1908, the patient was strong, reflexes present, though weak, gait waddling. Pes planus and left peroneous longus still weak. The girl is able to go on long excursions and mountain climbs. In Case II. there was a strong hereditary history, the boy's uncle and sister suffering from typical dystrophy. The symptoms in the boy appeared early. At six he had a tenotomy performed. The course was, however, arrested, not involving the arms, and gradual improvement occurred. The characteristic waddle disappeared, the child was able to rise without help and steadily increased in strength and control. In 1908 there is a slight scoliasis, but the patient appears strong, hunts and walks well. He has just been accepted for military service. Jendrassik considers these two cases to be undoubted dystrophy and therefore concludes that such cases may recover.

Treatment of Laryngeal Tuberculosis by Means of Sunlight.—Theodor Janssen says that during the past ten years our ideas of the prognosis of laryngeal tuberculosis have changed and that an aggressive therapy has replaced the symptomatic and expectant. The inhalation methods are mostly expectant. Surgical methods consist of curetting, caustics, puncturing, and tracheotomy. Specific treatment with tuberculin has been reported on favorably. During recent years, however, the treatment has turned more to the application of the sun's rays. The author reports a series of cases treated at the sanatorium at Davos. Many were completely cured and remained so for years. The patients were placed with their backs to the windows. By a specially devised apparatus, consisting of a mirror on a stand, resembling a music stand, with three-way hinges, the sunlight was reflected into the mouth, and by use of the laryngoscope to the larynx. The patients soon learned to hold the laryngoscope themselves. They knew when the sunlight was falling on the diseased part by seeing in the stationary mirror the image of the larynx. The treatment was kept up from thirty minutes to an hour at a sitting. In the mountains a plane mirror was used, whereas in the lowlands, owing to the weaker sunlight, a concave mirror of a 40 cm. focal length may be used. In order to get the effect of the light rays and as few heat rays as possible the treatments were carried out either early or late in the day.

Method for the Prompt and Easy Demonstration of the Reticular Structure of Nerve Cells.—C. Golgi states that the internal reticular structure of the nerve cells described by him has been little studied hitherto on account of the difficulty of demonstrating it by staining agents. He describes a new method of staining that is easy of execution and gives excellent results, and that has been made use of for a year in his laboratories. It consists of a modification of the silver reduction method. It includes fixation for from six to twenty-four hours in arsenious acid, 1 per cent. solution, using 50 parts of the solution, 40 parts of distilled water, 0.5 to 20 parts of alcohol, and 21 parts of formalin. Next the tissue is placed in 1 per cent. silver nitrate solution for some hours. The third step is to develop it in hydrochinone. Sections are made after embedding in celloidin or parafin. Fixation of the sections in chloride of gold and hyposulphite of soda follows, and the sections are bleached by Veratti's method; successive coloration of the nuclei ends the process.—*La Riforma Medica.*

Book Reviews.

Dr. Jessner's Dermatologische Vorträge für Praktiker. Diagnose und Therapie des Ekzems. 2 Auflage. Diagnose und Therapie der Syphilide. 2 Auflage. Von Dr. S. Jessner, Königsberg i. Pr. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1909.

Dr. Jessner has made his name well known by publishing a series of small monographs on dermatological diseases. The two on eczema and on syphilis appear in second editions. Although questions of diagnosis are considered at sufficient length by the author, most stress is laid upon the treatment of these two diseases, which between them comprise such a large percentage of all skin affections. The therapeutic directions are extremely practical in character, prescriptions, and courses of treatment, such as have proved useful in the extensive experience of the author being given with all detail. We heartily recommend these useful pamphlets to the general practitioners as well as to dermatologists; indeed, the whole series of Dr. Jessner's monographs should prove a useful addition to the physician's library.

The Therapeutics of Radiant Light and Heat and Convective Heat. By William Benham Snow, M.D. New York: Scientific Authors' Publishing Co., 1909.

The use of both light and heat as therapeutic agents harks back to the time of the ancients. But with the discovery of the *x*-rays and their application in treatment, a new impetus was given to the investigation of both phototherapy and thermotherapy. In the present volume there is much of interest and value to one who would keep abreast of the times, even though he cannot secure the facilities for direct study of the observations here recorded. It is worth while to know, however, what can be done without the very great outlay of money which the purchase of appliances in this field demands. To this end the section on convective heat and the application of dry and moist heat is well worth careful study. The poultice, the hot-water bag, the koalin cataplasm, the hot-water bath, the Turkish bath, and the hot box are all agencies which, when properly used, are of decided value. Helpful suggestions are given by the author in applying the above to the treatment of quinsy, felonotitis media, furuncles, inflammatory conditions of the pleural and abdominal cavities, etc. This volume will prove an addition to the rather small amount of comprehensive literature dealing with light and heat therapy.

A Textbook of Genitourinary Diseases, including Functional Disorders in Man, by Dr. Leopold Casper, Professor at the University of Berlin. Translated and Edited with Additions, by Charles W. Bonney, B.L., M.D.; Assistant Demonstrator of Anatomy, Jefferson Medical College, formerly Surgeon to the Southern Dispensary, Philadelphia, etc. Second edition, revised and enlarged. With 230 illustrations and 24 full page plates, of which 8 are in colors. Philadelphia: P. Blakiston's Sons & Co., 1909.

Those whose knowledge of German does not suffice for studying the original of this work certainly are under obligations to Dr. Bonney for his most excellent rendition thereof into English. The book, however, is singularly incomplete in some instances, as, for example, in the technique of cystoscopy. In this connection no mention is made of the fact that Casper was the first to devise a method of giving the urethral catheter the necessary varying curves within the bladder, to render practicable ureteral catheterism in almost all cases. Without this enormous advantage, for which Casper paved the way, ureteral catheterism might still be the rather crude process it was when first attempted. It therefore seems false modesty that Casper did not emphasize his epoch-making improvement in this work. Serious exception may be taken to the fact that only thirty pages are devoted to nonspecific and gonorrheal urethritis, to chronic gonorrhea and its sequelæ. In this curt disposal of the disease which causes 80 per cent. of all affections of the genitourinary apparatus, the question of the marriage of gonorrheics is discussed in but three paragraphs. In these it is held inacceptable in practice to deny permission to marry while the last remnant of discharge persists. It is declared (p. 99) "if we were to forbid all such to marry, they certainly would not obey us; and if they did, the number of unhappy mortals would be greatly increased, the list of neurasthenics and hypochondriacs would become larger, and mankind would be in danger of extinction." Anglo-Saxon mode of thought shrinks at the idea of exposing an innocent girl to matrimonial infection, rather than that the man who, though infected, would marry her, become an unhappy mortal, a neurasthenic, or a hypochondriac. While it is true that many women seem to be immune to gonorrhea, and consequently escape infection, the gynecologists' sad records warn against assuming the risk. The paragraph in which the momentous question is discussed conclude with: "If all examinations are negative, the urethra is irritated by natural and artificial means (cohabitation, free use of strong alcoholic beverages, irritant injections like nitrate of silver), if the increased secretion thus produced shows no gonococci, then marriage may be permitted. Possibly this course may result in an occasional mistake, but in the present state of our knowledge we possess no other criteria of infectiousness, and so are obliged to choose the lesser of two evils." Were this teaching not offered by so eminent an authority as Casper, it might be passed without heed, but coming in a work of such transcendental importance to the general practitioner and specialist, it demands at least passing comment. It is unlikely that any American practitioner will recommend coitus with all its moral and physical risks, for the purpose of irritating the urethra, so that the results may be used to decide upon the propriety of the applicant's marriage. There are also among us many who would refuse to attempt provocation by the free use of strong alcoholic beverages; this, however, is less a question of morality than of personal sentiment, and to be governed by the feasibility of such course in each individual case. The reviewer would warn the practitioner, however, against dispensing with all tests to determine the safety of marriage to a man who harbors residual gonococci, because "the course advocated may result in an occasional mistake." We can but use the justifiable means to this end that are within our knowledge.

Despite the shortness of the division on gonorrhea, the author has at least mentioned all the means and instruments employed in its treatment, and has carried it to so late a day as to depict and describe Frederick W. Robbins' ointment applicator, demonstrated at the June meeting, 1908, of the American Urological Association. One of the especially fine chapters in the book is that on stricture. In the author's terse way he has managed to give a thorough, albeit brief, conspectus of all the general practitioner needs in an up-to-date treatise on the subject, which the translator has faithfully reproduced. The author emphasizes that more than 90 per cent. of strictures are of gonorrheal origin, and that (p. 142) "gradual temporary dilatation is the proper procedure for nearly all strictures." Fully one-third of the book is occupied by diseases of the bladder and prostate. No attempt to review these 200 pages could do them justice. It may suffice to say that almost every line thereof contains an important lesson. The publishers present the work with an elegance suitable to the valuable text.

Rotunda Practical Midwifery. By E. Hastings Sweedy, M.D., F.R.C.P.I., Master of the Rotunda Hospital, and G. S. Wrench, M.D., Late Assistant Master. London: Henry Frowde and Hodder & Stoughton, Oxford University Press, 1908.

This book does not pretend to compete with the larger works on obstetrics. It has been written for the practitioner and student who have not had the advantages of a practical obstetrical training. All theoretical discussion has been omitted, and the authors have limited themselves to the consideration of the conditions which the practitioner is likely to encounter. They have mentioned only the treatment which they have found most efficacious in the management of their cases at the Rotunda Hospital, Dublin. Although we do not agree with them in every particular, yet their methods of treatment are in most cases similar to those which we in America are accustomed to. We would take some exception to their treatment of eclampsia. To control the convulsion, Dr. Sweedy gives hypodermic injections of morphine sulphate grain ½, with atropine sulphate grain 1-200. If necessary, the injections are to be repeated every two hours, as much as two grains being administered in twenty-four hours. He claims that chloroform depresses the heart, so he does not use it. Neither does he use chloral or the bromides. We on the other hand place a good deal of dependence on chloroform and chloral to control the eclamptic convulsions. The nomenclature of the presentations is different from ours. For instance, L.O.A. is called vertex number 1; R.O.A., vertex number 2; R.O.P., vertex number 3; L.O.P., vertex number 4. The other presentations are designated in the same way, as breech number 1, etc. The chapters on the symptoms, signs, and diagnosis of pregnancy, and the treatment of the normal labor and puerperium, are excellent. There are short chapters on the care of the healthy baby, on the care of the unhealthy baby, and on the insanities of the reproductive period.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

223d Regular Meeting, Held April 2, 1909.

DR. E. G. JANEWAY, PRESIDENT, IN THE CHAIR.

Caisson Disease.—Dr. M. ALLAN STARR read this paper. (See page 1047.)

Dr. E. G. JANEWAY said that several years ago he reported a case of gas emboli following the use of hydrogen peroxide. His patient was a man whose pleural cavity was being irrigated with the substance and on one such occasion he fell suddenly unconscious and developed hemiplegia and aphasia. He recovered completely after a long illness. Dr. Janeway thought that the oxygen liberated from the hydrogen peroxide was in some manner carried to the brain in this case and produced a condition quite similar to caisson disease. French writers had reported a number of such instances. Of course, instead of oxygen of the hydrogen peroxide it might have been plain air that caused the mischief, for the tearing of some adhesions in the pleural cavity could have allowed the air to enter the blood-vessels, as the full inspiration which the patient is apt to give and the presence of blood in the pleural washings suggests.

Fibrosarcoma of the Eyelid in a Child.—Dr. CHARLES S. BULL reported the case of a boy, aged nine, whom he first saw on March 8, 1909. There was a tumor of the left upper lid, extending from the ciliary margin of the lid upward to the superior orbital margin, and involving the outer half of the lid. The skin was freely movable over the growth, but the tumor itself was firmly attached to the tarsus at its base. It was slightly lobulated, quite hard to the touch, and entirely painless and non-sensitive. The eyelid covered the entire eye and sagged outward toward the temple. The mother had noticed, when the child was about two years old, a small pimple or swelling in the lid. This remained unchanged in position and size until about eight months ago, since which time it has grown rapidly, but has occasioned no discomfort except a feeling of weight in the lid. On March 12 the tumor was removed. An incision was made horizontally through the skin and the skin and fibers of the orbicularis muscle carefully dissected from the surface of the growth. It was found to be encapsulated and firmly adherent to the tarsus at its base. It was very hard, so that a sharp hook could with difficulty be forced into it. The cavity was carefully irrigated and the wound in the skin closed by five small sutures. It healed promptly and the boy was discharged on the third day.

The tumor was given to Dr. George S. Dixon, the pathologist of the Eye Infirmary, who reported as follows: "The tumor removed from the lid of the boy proved to be a fibroma growth with a large number of spindle cells, and a little glandular tissue on one edge. The blood-vessels were comparatively few in number and all had very thin walls; even the larger ones carried but a single layer of endothelial cells. There were no signs of irritation and no indications of rapid growth present. It was encapsulated, but the capsule was very thin. Diagnosis: Fibrosarcoma; large spindle-cell variety."

Prostatectomy and Calculi of the Bladder.—Dr. L. B. BANGS showed forty-four uric acid calculi removed from a patient's bladder. The patient had an enlarged prostate and catheterized himself frequently. A cystoscopic examination showed the presence of three stones and a fourth one was suspected. Curiously enough, another physician to whom the patient went after being cystoscoped by Dr. Bangs likewise saw three stones and was somewhat doubtful of the existence of the fourth. Prostatectomy was done and, the number of stones found behind the prostate at the operation simply showed that most of them were hidden from the cystoscope by the upper layer. Another feature of the case was that the patient had no pain whatever, and beyond the cystitis and the recent appearance of blood in the urine, no symptoms were caused by the stones.

AMERICAN MEDICAL ASSOCIATION.

Sixtieth Annual Meeting, Held at Atlantic City, N. J., June 8, 9, 10, and 11, 1909.

(Special Report to the MEDICAL RECORD.)

SECTION ON MEDICINE.

(*Continued from page* 1044.)

Diverticulum at the Pylorus.—Dr. ALLEN A. JONES of Buffalo reported the case of a young man aged 21. When 18 years old he had attacks of severe pain in the stomach after eating. When Dr. Jones saw him he complained of pain two inches above the umbilicus, radiating a little to the left. There was no history of vomiting of blood. Free hydrochloric acid was found to be present, and after considerable retching there came through the stomach tube a small quantity of blood-stained water and a fragment of mucous membrane. There was no food stagnation. After several months of complaining, vomiting, gastric pain, flatulency, loss of weight, etc., operation was decided upon. Adhesions were found about 4 cm. from the pylorus on the anterior stomach wall, between it and the transverse colon and gastric omentum. Between this point of adhesion and the pylorus, just inside the pyloric ring on the stomach side, was a diverticulum consisting apparently of serous and mucous membranes only. Recovery was uneventful. It was probable he had had a gastric ulcer when 18 years old, and this ulcer destroyed the muscular coat of the stomach, and in healing this coat was not restored, the pyloric wall in that region consisting chiefly of the serous and mucous coats, the latter having undergone regeneration. This thin and weak portion of the pylorus gradually stretched and formed a diverticulum.

Diet in Typhoid Fever.—Dr. WARREN COLEMAN of New York read this paper, and said that the conclusions he had reached concerning the food requirements of the typhoid fever patient were based upon studies on the protein metabolism of the disease which had been carried out in collaboration with Dr. P. A. Shaffer during the last two years. He believed that the essential problems of the typhoid fever diet would be found in the correct answers to two questions: (1) Shall the typhoid fever patient be given enough food to meet his energy requirements? (2) How much food might be considered necessary to fulfill these requirements? The history of diets in typhoid fever clearly indicated a steady, but very slow, tendency to increase the amount of food allowed to the patients. There was strong experimental and clinical evidence in favor of giving typhoid patients sufficient food to meet their demands for energy. The loss of weight in typhoid fever had been attributed to two causes, to the temperature, and to the so-called toxic destruction. The loss in both of these causes they found could be prevented by a high-calorie carbohydrate diet. The diet they used consisted in the main of milk, cream, milk sugar, and eggs. In addition they allowed small slices of stale bread or toast, with as much butter as the patient wished. The daily quantities of these foods were about 1½ quarts of milk, 1 to 2 pints of cream, ½ to 1⅔ pounds of milk sugar, and 3 to 6 eggs. He believed that the foods men-

tioned must form the basis of the ideal diet for typhoid fever patients, but much remained to be done in working out details. In conclusion he said: (1) The practice of partial starvation, at present followed in the treatment of typhoid fever, was highly detrimental to the patient's welfare. (2) It was not only desirable but necessary that the typhoid patient be given sufficient food to cover his energy expenditures. (3) The amount of food required for this purpose would vary with the different patients, but might be estimated approximately on the basis of 40 calories per kilogram of body weight per day.

Dr. Clayton of Washington said that for the past five or six years he had been feeding his typhoid fever patients, and he agreed with Dr. Coleman that if one once watched the effects of feeding these patients one would never go back to the starvation diet. He believed the patients were more apt to make a recovery if fed. They were made happier; one of the most trying experiences one had in dealing with this disease was with hunger. Instead of being reduced to skin and bones, they were in good condition and were able to return to work much earlier, a very important thing to the working man. As a result of feeding he had not seen a larger number of cases of hemorrhage or perforation than when he employed the starvation treatment.

Dr. Arthur K. Stone of Boston reported a series of 50 cases of typhoid fever treated last Summer on the so-called Shattuck diet with but one death.

Dr. A. Jacobi of New York thought that Dr. Coleman should be congratulated upon his results which Dr. Jacobi said he would not expect with such a diet. It was impossible to expect a healthy person, far less a typhoid fever patient, to digest so much milk and cream. He had never seen more disorders of the intestines, with indicanuria, acetone, and diacetic acid in the urine, than he had in patients, or at least in persons, who had consumed a great deal of fat in that shape. It was impossible for the average stomach to digest an unmixed cream to that extent. An adult or child, healthy or diseased, would tolerate milk that was diluted with cereals better than when not so diluted, especially in fever cases where the gastric secretion was lower than in health. He did not believe that most of them would be willing to give fat in that quantity unmixed, or even raw milk in that quantity. He cautioned those present that they should be very careful with fat feeding to the extent that Dr. Coleman had proposed to them.

Dr. James M. Anders of Philadelphia thought it was a significant sign that the general profession no longer advocated the starvation diet. Dietetic principles should be kept in mind in dealing with typhoid fever patients, more particularly since the lesions were situated in the intestinal tract. All the energy represented by protein substances was not utilized by the system. Too much proteid in the food favored putrefaction in the intestinal tract, and, so greatly increased the gravity of the case, especially in the direction of local symptoms. On the other hand they should recollect that the energy represented by carbohydrates and fats were utilized in their entirety within the system. It should be remembered that one object of the dietetic treatment was to preserve the tissues of the body and to prevent more or less emaciation, which otherwise would occur. Fats did not preserve the proteid constituents of the body, but carbohydrates did. He believed the secret of Dr. Coleman's success was in allowing the use of carbohydrates which were easily digested, and particularly the use of milk sugar which he recommended. Preservation of the tissues of the body could only be done by the use of available carbohydrates.

Dr. Walker of Philadelphia was much interested in Dr. Coleman's paper, because he felt that this increased feeding of typhoid fever patients had gone too far. He was pleased with Dr. Coleman's suggestion, but he accepted Dr. Jacobi's criticism. Although Dr. Coleman's results were thoroughly honest and true, yet he did not believe that so much cream should be allowed. He advocated the use of calves' foot jelly, and protested against too liberal feeding in typhoid fever.

Dr. Parker of Detroit said that they should get back to the natural mode of living, in so far as the patient's condition would permit. Salt should be given, and more time should be allowed between feedings.

Dr. Woods Hutchinson of New York said that Graves' epitaph was "He fed fever." Before Graves' time very little food was given patients, they were deprived of water, even cold water was not allowed; they were bundled in blankets, and the windows were shut. The sufferings of the patient were as much due to the treatment he received as to the disease itself. Ten years ago he had an opportunity of treating a number of cases of typhoid fever; the patients were placed upon more liberal feeding, and the results obtained were similar to Dr. Coleman's, although he did not go to the extreme. He gave an abundance of meat jellies, crackers, ice cream, etc., and the results were excellent, not only as to keeping up the weight but also the strength of the patients, preventing the condition of collapse and the violent appetite, that terrible craving for undigestible articles of food. With regard to the damage to the intestine, he thought they thought too much of typhoid fever as an intestinal disease exclusively; it was a general disease.

Wednesday, June 9—Second Day.

Observations on Indicanuria and Its Significance.—Dr. Judson Deland of Philadelphia stated that indicanuria was the presence of a perceptible quantity of indoxyl sulphate of potassium, not merely a trace, in the urine. It was derived from anaërobic bacterial putrefaction of proteins. Normally from five to 20 milligrams of this substance were excreted daily and abnormally from 50 to 150 milligrams. After having tried most of the tests recommended for the determination of the presence of indican in the urine the test advised was to filter 10 cc. of urine, add a 1 per cent. solution of postassium chlorate, then 5 c.c. of chloroform and lastly 10 c.c. of pure hydrochloric acid of a specific gravity of 1.19. After thorough mixing the indican thus set free was dissolved in the chloroform, to which it had imparted a blue color. The maximum coloration was secured in ten minutes. Clinically, a quantitative idea of the amount of indican present might be obtained by noting the depth of the blue color of the chloroform. If the urine contained iodide the chloroform would be colored violet; this color might be removed by adding a 5 per cent. solution of sodium thiosulphate. In order, therefore, that indican might not be overlooked, it was necessary to obtain urine for examination at different times during the day or week, or under conditions produced by variations in food and exercise or during the presence of the most marked symptoms. The urine first passed upon retiring and rising, as well as that taken from a 24-hour specimen, should always be examined. Sometimes indican was only observed after the ingestion of certain articles of food. Clinically, indicanuria might be mild or severe, acute, chronic, or recurrent and occurred as an independent affection or as a complication of other diseases. Indicanuria was significant of the absorption of the products of putrefaction, which was usually situated in the intestinal tract, but under exceptional circumstances might be situated in other parts of the body. The test for indican was so simple and that for other putrefactive processes so difficult, that indican had assumed the position of an indicator of absorption, not only of indoxyl, but of any one or any combination of the bodies produced by the decomposition of proteins. Indicanuria might be absent

when protein decomposition was present, and it was conceivable that intestinal toxemia occurred in the absence of indicanuria. Indicanuria, clinically, occurred more readily when the hepatic function was disturbed. It was unsafe to assume in the light of our present knowledge that indicanuria produced no harm when symptoms were absent, conservative prudence dictated the prevention of its formation. The conditions which favored indicanuria were numerous. They might be morbid conditions of the teeth, oropharynx, nose, and sinuses connected therewith. The production of indol might be due to simple excess of proteins in gourmandizing, insufficient mastication, too rapid eating, paralyzing or lessening gastric, intestinal, or colonic peristalsis, or interference with the normal secretions of the stomach, intestines, pancreas, or liver. Hernia, ileus, appendicitis, local, general, acute, or chronic peritonitis, and intestinal stenosis also favored the growth of putrefactive bacteria. Indicanuria had been observed in nearly all pathological conditions of the intestinal tract and deep importance was attached to its recognition in typhoid fever. After thoroughly discussing indican as an indicator of toxemia, Dr. Deland discussed in turn the various effects of toxemia. These results were manifested in the blood and might be the remote cause of arterial sclerosis. Chronic intestinal toxemia might induce or complicate cases of neurasthenia and again toxemia was a common complication of mental disease. Attacks of intestinal toxemia frequently interrupted the favorable course of many cases of tuberculosis. It aggravated catarrhal inflammations of the respiratory tract and the amelioration of this symptom greatly benefited eczema, pruritis, acne, rosacea, and malodorous perspiration and breath. Intestinal toxemia was a common disease and its removal was very frequently followed by remarkable and prompt amelioration or disappearance of many distressing symptoms.

The Diagnostic Value of Stained Specimens of Stools in Cancer of the Stomach.—Dr. Philip King Brown of San Francisco said that they were continually confronted with the accusation that they did not send cancer cases to the surgeon soon enough, but he had made the mistake of sending cases to the surgeon with the diagnosis of cancer when no cancer was found. The differential diagnosis of these cases was very difficult. He said he had seen four cases of single or multiple ulcer of the stomach, in all of which the ulcers had undergone cancerous degeneration; in all of these the stomach contents did not indicate the ordinary conditions appearing in cancer at all. The total acidity was practically normal in two of the cases, while free hydrochloric acid was present in all. The stools were examined in all the cases and were gram-positive; this was the only clinical sign by which the condition of cancer might have been surmised. The test was so easily made that it should be used more often.

Resorption of Proteins, Fats, and Carbohydrates in the Chronic Alcoholic.—Dr. Alexander Lambert of New York presented this paper, in which were reported the results of an examination of a series of cases of chronic alcoholism with regard to their resorption of protein, fat, and carbohydrates. The changes which took place as the result of chronic intoxication with alcohol were those which induced a catarrhal condition of the stomach, usually with increasing anacidity, accompanied by cirrhotic conditions of the pancreas, liver, and small intestines; not infrequently the kidneys were affected with interstitial changes. Hence it seemed not improbable that a careful examination of resorption and excretion might be useful from a diagnostic point of view. In all the cases examined hitherto the loss of fat by the feces did not fall below 5 per cent. Most investigators of resorption in pathological conditions had found difficulty in fixing normal standards, but one found that with certain exceptions the loss of nitrogen in the feces rarely exceeded 10 per cent. The fat loss varied greatly, but on general diet did not as a rule exceed 7 per cent. The loss of carbohydrates had not been studied so carefully, but such as had been given lead one to induce that, with ordinary diet, there was a loss of about 3, or at highest 4 per cent. The patients examined were placed on a diet which Dr. Lambert had tabulated in detail, and which consisted of 23.8 nitrogen, 177.5 fat, 237. carbohydrates, and amounting to 3091 calories daily. The urine and stools were collected each day, separation of the stools at the beginning and end of the experiment being effected with charcoal. Nine experiments in all were made, extending over from five to six days. The results of the resorption tests were given in tables showing the percentages resorbed and the percentages lost. A remarkably good resorption was shown in all cases, and in one case it was distinctly better than the average in normal cases. In no case was the carbohydrate resorption at all impaired, a condition which one would not suspect from the supposedly catarrhal condition of the intestines. The percentage of loss of nitrogen ranged from 6.1 to 8.9, except in one case in which it was 3.3, while the normal loss of nitrogen was 10 per cent. The normal loss of carbohydrates was 4 per cent., while in this series it varied from 0.6 per cent. to 1.3 per cent. The loss of fat varied in the cases examined from 1.9 to 7.8, while the normal loss was 5 per cent. It was a matter of interest to note in this series that on the diet given very notable quantites of nitrogen were stored up. The tabulated results showed that the balance stored up ranged from 14.4 to 43.1 per cent. except in one case in which it was but 0.9 per cent. In every case the patients gained weight on the diet, though on the whole they were not in a state of undernutrition when the experiments were begun. Another method which appeared to promise something toward the diagnosis of obscure affections of the digestive system was that of testing the hourly excretion of nitrogen. In a patient receiving an adequate amount of food a large quantity of nitrogen in the form of meat was given at a definite time, and every hour thereafter the urine was collected separately and the samples analyzed for total nitrogen. Although experiments on normal persons were not very numerous, they knew that after the injection of 500 grams of finely minced meat the height in the curve of elimination was reached about the seventh hour after the intake of food. Experiments of this type were performed on these patients and in no instance did the curve of excretion correspond with the somewhat regular steep steps which were observed in normal subjects. It appeared that in the curve of digestion a delay occurred leading to gradual ascent in the course of the excretion of the nitrogen. In this respect the chronic alcoholic reacted in an abnormal manner. Much credit was to be given Dr. C. G. L. Wolf of Cornell University for what he had done in assisting with this work.

Dr. E. P. Joslin of Boston said that absorption in alcoholics was good, a very important thing for them to remember. Lack of assimilation was only a catch phrase and would not hold water. Most of these patients were starved and it was necessary that both the acute and convalescing alcoholics be fed. They should not be discharged from the hospital until they had recovered from their delirium; they should be kept in the hospital and fed up just as one would in typhoid fever convalescence. He thought that both Dr. Lambert and Dr. Wolf were to be congratulated upon the work they had done.

Dr. John A. Lichty of Pittsburg said that absorption must have been very good in Dr. Lambert's cases, cases which were supposed to have a very much disordered digestive system.

The Uses and Limitations of Examinations of the Stomach Contents.—Dr. Charles G. Stockton of Buffalo read this paper. He stated that the stomach tube

should not be too small; for an adult it should be from 30 to 35, French scale. It should be capable of supporting its own weight when held in an upright position for the length of twelve inches. It should have as large a calibre as possible without being liable to bend sharply at an angle when pressed upon. It should be about 54 inches long and have no pumping apparatus connected with it. If there was temporary delay in introducing the tube one might expect to find either cardiospasmus or stricture at the cardia. If, after passing the tube about 14 inches, portions of the test meal returned and the food was unmixed with gastric juice there was some kind of obstruction at the cardia. If, in pressing the tube onward, it stopped at the cardia or was held fast, stricture or spasm at the end of the esophagus might be inferred. The best reflow was obtained at a distance of from 21 to 22 inches from the teeth, provided the patient was of ordinary stature and his stomach in normal position. If, after aspirating the stomach contents found at from 20 to 22 inches and pressing the tube further on, after a little resistance, it apparently got into another cavity from which stomach contents of a different character were removed an hour-glass stomach might be suspected. If, after passing the tube the usual distance an unusually large amount of the test meal was obtained, moderate motor insufficiency was indicated. If a large quantity of the test meal was found undergoing fermentation and having a musty odor with a large quantity of bacteria and few lactic acid bacilli, there was indication of benign obstruction at the pylorus. If stagnating food of foul odor was found, either with or without free hydrochloric acid, with lactic acid present and Opler Boas bacilli malignancy and obstruction were suggested. The finding of too little of the test meal at the usual time with the presence of gastric juice suggested excessive motor activity. If little of the test meal and no gastric meal were found, excessive motor activity was indicated. A conclusion should not be reached by a single examination. If, on one day, there was an absence of gastric juice, and on the next an excess, on one day food retained too long, and on the next passed on too quickly, they might conclude that the patient was the subject of nervous disturbance. When an acidity above 60 was habitually present hyperchlorhydria might be suspected. This condition was not to be determined, however, by a fixed standard. There were cases of practical suspension of gastric secretory function with symptoms of hyperchlorhydria; these were probably instances of chronic glandular gastritis with exacerbations accompanied by symptoms of irritation. The following findings were given: Over-acidity with delay in digestion of starch was indicative of hyperchlorhydria; a low total acidity suggested a defect in secretion of enzymes; a high total acidity suggested an active secretion of the enzymes; a mass of nummular sputum indicated that the mucus had been swallowed and was not of stomach origin; occult blood was evidence of hemorrhage; blood with mucus and pus cells suggested ulceration or degeneration of the gastric mucosa and probably malignancy; food remaining after washing for a considerable time was evidence of tony and probably dilatation; the stomach holding a large quantity of fluid was indicative of dilatation. The slow change of albumin showed that the gastric digestion was retarded. The presence of the odor of fatty acids was evidence of fermentation. Too much importance should not be attributed in stomach examinations to the disturbances in secretion. The greatest importance should be attributed to evidence of disturbance in motion. The diagnosis of stomach disease should not be made solely by examination of the stomach contents, but by the results of this method considered in connection with the symptomatology and with the estimation of all the facts in the case. The stomach tube was important in diagnosis; in treatment it was often useless or harmful.

X-Ray Evidence in Gastric Cancer.—Dr. A. W. CRANE of Kalamazoo, Mich., said that the diagnostic factors presented were size, form, position, clearance, and indication of pain-marker. The form of the stomach might be designated as normal, tubular, globular, drain-trap, and deformed (indentation, adherent, and contracted). An analysis of these diagnostic factors presented by stomach skiagram showed that three of five major factors might give information concerning gastric cancer. They were form, location of lead marker, and clearance. In the case of ulcer the alteration was confined to the contracted type; the indentation stomach was the type distinctive of cancer. The problem of differential diagnosis might require a careful consideration of all available evidence in the case. When they found a deformed gastric outline they had to discriminate between an indentation from the pressure of other organs or growths, a local contraction of the stomach wall, an invasion of the stomach wall by a growth, and the presence of adhesions, due to disease of contiguous organs. Also, when they found low clearance and a globular form and established the fact of pyloric narrowing, they then had to discriminate between the narrowing due to the scar tissue of ulcer, that due to growths in the walls of the antrum or pylorus, that due to the pressure of growths of glands outside the pylorus, and that due to the binding of adhesions. In order to make these discriminations they should study the stomach under normal conditions so as to be able to recognize a departure from normal outlines. Air or bismuth within the stomach gave certain outlines. The following points should be considered: Patient, position of the body, degree of stomach distention, contents of stomach and immobility. Bismuth: kind of salt, quality, how suspended, how taken, how distributed. Time of day for exposure of plates: relation to meals, time elapsing between ingestion of bismuth and exposure of plate, number of plates and time between.

The Determination of Trypsin in the Stomach Contents After Oil Test Meals.—Dr. CLIFFORD B. FARR of Philadelphia read this paper. The experiments reported were based on the work of Boldireff and Volhard. The former in experiments on dogs found that the introduction of oil into the stomach caused regurgitation of duodenal contents, in which the presence of pancreatic ferments could be demonstrated; the latter devised a new method for demonstrating the presence of trypsin and applied Boldireff's discovery to clinical uses. His first object was to substantiate the observations of others as to the ease and frequency with which duodenal contents might be obtained after the oil meal. The second was to decide which of the methods proposed was best suited for detecting trypsin in the specimens secured. The third was to discover what, if any, clinical value was to be attached to the findings thus obtained. The following conclusions were deduced: (1) The duodenal contents might frequently be obtained after the oil test meal, though sometimes there was doubt as to the character of the fluid aspirated. (2) On this account it might be possible to exclude atrophy of the pancreas, but only under very unusual conditions could they demonstrate its presence. In a number of diseases the examination had yielded suggestive results. (3) The observation of Boldireff was of mere interest from the point of view of pathological physiology than of diagnosis, for example, in gastric ulcer and in achylia. (4) The casein method of Volhard was a delicate qualitative test for trypsin, but for this purpose needed simplification. (5) The regurgitation of the alkaline intestinal juice induced by oil might explain the therapeutic value of the latter in some cases of hyperacidity.

The Diagnostic Importance of Examination of the Feces.—Dr. CHARLES P. EMERSON of Clifton Springs, N. Y., gave a brief review of all that might be learned of a case from careful study of the stools, and told of the

methods which were of value in clinical work. He made a plea for gross and microscopical examinations at the bedside whenever possible, and gave a review of the importance of information which could be gained in this way.

Oration in Medicine: Tropical Diseases; America's Opportunities and Obligations.—Dr. James B. McElroy of Memphis delivered this oration. He said that the race for empire from its beginning had suffered more from disease and pestilence than from the implements of war, and this fact had furnished many examples of stimulation to medical research. None was more striking than that given to the study of the diseases of warm climates as a result of the struggle for the possession of the tropics. The discovery by Ross of the mosquito as the intermediate host of the malarial parasite might be said to have stimulated renewed interest in the onslaught on tropical diseases. Sir Patrick Manson had pointed out that the "peculiarities of tropical diseases were etiological rather than pathological." Passing certain conditions which were the direct result of climatic and meteorologic influences found in warm countries, certain diseases were encountered which were the result of toxic substances taken in with the food, peculiar to these climates. As examples of these might be mentioned ergotism, lathyrism, pellagra, and possibly beriberi. In the list of tropical diseases it was customary to include certain bacterial infections, such as Malta fever, bubonic plague, leprosy, bacillary dysentery, and cholera; these diseases, however, could flourish in any climate and had no real claim to be regarded as strictly tropical diseases. Certain pathogenic agents either required high atmospheric temperature for their successful passage from host to host, or required an animal intermediary which flourished only in high temperatures. In view of the extensive use of the proverbial "hoe-cake" as food in the South, it was rather surprising that pellagra should have so long escaped the notice of physicians. The report of its epidemic occurrence in some of the Southern States made the study of the disease a matter of great importance. The specific cause of beriberi remained unknown. The clinical syndrome, which was commonly known as dysentery, had been shown to be due to three distinct diseases, amebic dysentery, bacillary dysentery, and catarrhal dysentery. Studies on Malta or Mediterranean fever had shown that this disease had a wider distribution than was formerly supposed. It had been shown that the *Micrococcus miletensis* was constantly present in the blood of patients suffering from this disease; that it escaped from the body chiefly through the urine; that it was found at times in the urine of perfectly healthy individuals. The march of the "black death" had advanced and was now lodged in Asia, Africa, Europe, Oceania, North and South America. Fifty-one countries of these continents had been infected and millions of lives had been destroyed. The Plague Commission which was sent out in 1905 gave the following conclusions: (1) Pneumonic plague was highly contagious, but being rare (less than 3 per cent. of all cases) played a very small part in the spread of the disease. (2) Bubonic plague in man was not infectious and was entirely dependent on the disease in the rat. (3) The infection was conveyed from rat to rat, and from rat to man, solely by means of the rat flea. (4) Plague was usually conveyed from place to place by rat fleas brought by people in their baggage or on their persons. The outbreak of plague on the Pacific Coast in 1907 was suppressed by the efficient work of those under the direction of Dr. Rupert Blue. One of the most far-reaching results which had come about as a result of the increased interest in tropical diseases was the importance which attached to protozoology and helminthology as fundamental medical sciences. Among the most interesting advances were the discoveries which had removed trypanosomiasis far beyond the mere economic importance which it hitherto had maintained. The discovery of a peculiar, wormlike, actively motile body in the blood of a patient by Forde in 1901, and named *Trypanosoma gambiense* by Dutton, stimulated investigations with respect to this organism as a pathogenic agent. The spirochetæ, a genus closely allied to the trypanosomidæ, had been the subject of much study. Malaria, of all tropical diseases, was the most widespread, the most disastrous in its effects, and the one concerning which their knowledge was most complete. It should be noted, however, that the introduction of eosinated methyl azure stain and thick dehemoglobinized smears had facilitated the diagnosis of malaria. The results of the researches of the Medical Commission of the United States Army to investigate the cause and mode of transmission of yellow fever were well known, and the application of this knowledge had been successful in the control of many outbreaks of the disease. Dengue was probably dependent on the mosquito for its spread. The work on hook worm disease had only begun. The establishment of a biological laboratory in Manila as a part of the Government Laboratory, and the high class of work which had eminated therefrom, had reflected great credit upon American medicine. The record of ten years of sanitation in the Philippines justified the statement of Musgrave that "America has made Manila one of the cleanest and healthiest and most attractive cities under the flag." As regards the triumph of America in the canal zone it had been said that "of one credit history can not rob the United States." The names of no greater heroes than the names of Reed, Carrol, and Lazear would be recorded in the annals of American history. With regard to amebic dysentery, the record of the Johns Hopkins Hospital showed that 182 cases had been in that institution from 1889 to 1908, the vast majority coming from the State of Maryland. The large number of cases of abscess of the liver in some Southern hospitals indicated its wide prevalence. This furnished a rare opportunity for investigation. It had been shown that the prevalence of malaria cost the State of Texas in 1900 in loss from labor alone $533,320. In the United States it was estimated that malaria produced 12,000 deaths and 3,000,000 cases of fever annually. The recent researches of Stiles had shown that 12.6 per cent. of the employees of the cotton mills of the South were affected with uncinariasis; that of this class, 13 to 15 per cent. of those of maternity age were in a condition which prevented them from properly nourishing babies; 5.8 to 20 per cent. of those of possible military age were in a condition which would materially decrease their military efficiency; 48.1 per cent. of the children were suffering from an anemia producing disease which would naturally inhibit their usual capacity for study. As a natural corollary it followed that the present and growing opportunities for the study of tropical diseases must impose the obligation of affording better facilities for teaching them and research work in them. The growing sentiment in this country of the obligations of the Federal Government to the public health was propitious, and this sentiment needed the fostering care of physicians more than any other class.

Transmission of Malarial Fever in the Canal Zone by Anopheles Mosquitos.—Dr. Samuel T. Darling of Ancon, Canal Zone, Panama, read this paper and emphasized the following points: *Anopheles albimanus,* the common white hind-footed anopheles, was the host for estivo-autumnal and tertian malarial parasites in the Canal Zone at this time. *A. malefactor,* notwithstanding its name, did not transmit malarial fever. *A. pseudopunctipennis* was only slightly concerned in the transmission of malarial fever. In the efforts at mosquito destruction, the extermination of *A. albimanus* was of paramount importance. Patients having crescents or tertian gametes in their peripheral blood should not be discharged from the hospital, nor should treatment be discontinued until gametes had

been reduced to a noninfectious minimum. The destruction and prevention of development of the sexual parasites in man was of great importance and might be accomplished by (1) appropriate quinine treatment for all gamete carriers entering the hospital; (2) by the occasional quinine treatment to destroy latent malaria; (3) by the periodical blood examination of laborers in quarters where there was a high malarial rate for the destruction of gametes carriers and latent malaria in order to carry out appropriate treatment; thirty grains of quinine sulphate in solution daily was an efficient dose for the purpose.

The Present Status of the Serum Therapy of Epidemic Cerebrospinal Meningitis.—Dr. Simon Flexner of New York said that it was now about three years since the serum was first introduced and used therapeutically in this country, and gradually its employment had extended until now it was being used in Great Britain, France, and Germany, as well as in the United States and Canada. He presented a tabulation which had recently been prepared based on 712 cases of the disease, in which the bacteriological diagnosis was made and which were treated with the serum. In the first table the cases were subdivided according to certain age periods; in the second table the total cases of each age period were further divided according as the serum was injected in the three arbitrarily chosen periods of duration of the disease. The first table brought out several points of interest. The highest mortality was shown to have occurred in the first two years of life. But contrary to the rule under the older forms of treatment in which the mortality was 90 per cent. or over, in this series it was 42.3 per cent. The second period was from 2 to 5 years, in which the mortality was 26.7 per cent. The third age period embraced children from 5 to 10 years of age, and gave the lowest mortality of all, namely, 15.9 per cent. The next period, from 10 to 15 years, gave a mortality of 27.7 per cent. The next period, of from 15 to 20 years, showed a considerable rise in mortality, 32.7 per cent. The second table was instructive in bringing out the importance of early injections of the serum. The results in the first two years of life were especially noteworthy. The extraordinary figures given under the first period of injection, namely in the first three days of the disease, could hardly be maintained. But the influence of period of injection was shown by the rapid rise in mortality in the subsequent two periods. The rule of the effects of early injection was preserved in the age periods up to the period of from 15 to 20 years, when it disappeared. The total figures did not, however, fail to indicate that the early injections were more effective than the later ones, as was shown by the percentage mortality in the first to third day period of 25.3, in the fourth to seventh day period of 27.8 and the period later than the seventh day of 42.1.

Dr. Thomas Morgan Rotch of Boston reported his experience with the disease in his wards at the hospital during the past ten years averaging 20 cases a year. The cases treated were in the first 12 years of life. During the years 1902, 1903 and 1904 the treatment was by repeated lumbar punctures and the mortality continued from 60 to over 70 per cent. During the year 1905 all the cases were treated with diphtheria antitoxin, with a mortality of about 80 per cent. During the year 1906 the patients were treated with vaccines, and the mortality still remained up to about 80 per cent. From November, 1906, to November, 1907, the Flexner serum was employed and the mortality immediately fell from 80 per cent. to 18 per cent. Since then the mortality had never gone above 25 per cent.

Dr. Philip King Brown of San Francisco told of the remarkable results obtained in some of the smaller towns of California by the use of the Flexner serum.

Dr. William Litterer of Nashville, Tenn., said that there had just been an epidemic of cerebrospinal meningitis at Nashville, the cases numbering 20, all confirmed by bacteriological examination. The first three cases in which the serum was not used properly died. Out of 17 cases in which the serum was used, 10 recovered and 7 died, and two of these were in a moribund state when injected.

The Retention of Alkali by the Kidney, with Special Reference to Acidosis.—Drs. Herman M. Adler and Gerald Blake of Boston undertook certain investigations in order to determine, first, whether any variations occurred in acidosis between the amount of ammonia and the amount of base excreted; secondly, whether such variations, if they occurred, would give information in regard to the acid-neutralizing power of the organism; thirdly, whether the method employed was of sufficient accuracy to make it of use in the clinical laboratory. The following were the conclusions: (1) The amount of base excreted in the urine in acidosis, while following in general the variations in the amount of ammonia, might show differences which were of importance in estimating the power of the organism to resist intoxication. (2) Whether the amount of base excreted varied with the amount or not, it was important to determine both quantities as they represented two distinct mechanisms of defense. (3) The method employed in this investigation was of such simplicity as to recommend itself as a valuable aid to the clinician.

Amebic Dysentery.—Dr. Sidney K. Simon of New Orleans said that in certain regions of the South conditions were almost ideal for the prevalence of amebic infection. During the past two years he had been able to collect 50 cases from New Orleans. The average duration of all the cases was about nine months. The average age was 37 years. There were 42 whites and 8 negroes. Only 6 of the 50 cases were females. Among the cases, 25 were common laborers, 3 were farmers, 4 merchants, 2 bakers and 1 was a rabbi. Fifty per cent. of the cases were born in Louisiana and had never lived in any other State or country. The longer the infection had continued, the greater probability there was of serious complication. Seventeen, or 28 per cent., of the 50 cases died. Extensive ulceration of the bowel was found in practically all, but in nine instances this was found to be the sole cause of the fatal termination. There were six cases of liver abscesses recorded, five solitary and one multiple. With regard to treatment he said he had been impressed by the weight of high authority, especially that born of long experience, and ventured to employ ipecac in his cases during the past two years and he was ready to acknowledge now his thorough conversion to the sanguine views of Manson and other English authorities. The drug should be exhibited in pill form, coated to the extent of about an eighth inch with salol. The patient must be put to bed for the first two weeks' treatment and his diet restricted to liquids or, at least, light solids. Castor oil might be given as an initial purgative and then each evening, after a three hours' fast, the salol-coated pills were administered. A start might be made with 40 or 60 grains, depending upon the length and severity of the infection, but each subsequent evening the dose was reduced five grains until the limit of 10 grains was reached. Following this he had been in the habit of continuing with 10 grains for the next two weeks. Opium was no longer required. The modus operandi of ipecac had never been satisfactorily explained. Bowel flushes might or might not be employed in connection with the ipecac treatment. The comparatively simple operation of appendicostomy had found many advocates in this country in recent years.

Dr. T. B. Futcher of Baltimore said he had collected 119 cases that had been in the Johns Hopkins Hospital; of this number 95 had never been out of the State of Maryland. There were 27 cases of amebic abscess of the liver, 22.6 per cent. Nine of these liver abscesses ruptured into the lung, causing pulmonary abscesses; one of these subsequently ruptured into the pleura, producing a pyopneumo-

thorax. Three of the liver abscesses invaded the inferior vena cava, and one was quite remarkable in that a thrombus extended into the right auricle; this case had been reported by Dr. Flexner. In three cases there was a perforation of the bowel and peritonitis. He thought these cases were more prevalent than generally suspected. They could only be recognized by a careful and systematic examination of the stools.

Dr. George Dock of New Orleans said that the geographical distribution of amebic dysentery was certainly great, and south of the latitude of Louisville it was a common disease. The disease should be looked for in every case where there was a chronic disturbance of the intestines. He called attention to some of the details in the practical examination of such patients, and especially of the examination of the stools. He agreed with what was said in regard to the ipecac treatment according to the method of Roberts.

Dr. H. A. Hare of Philadelphia said that recently he had received from Dr. Rogers of the British Medical Service a paper which practically reiterated the facts already published in regard to the value of ipecac not only in curing amebic dysentery, but as a prophylactic against amebic abscess of the liver. Jefferson Hospital in Philadelphia, one of the largest in the country, had received but three cases of amebic dysentery in eighteen years, the time Dr. Hare had been connected with it. It seemed strange that they had so few cases compared to Johns Hopkins Hospital which was only distant 100 miles.

Dr. Hugo A. Freund of Detroit, Mich., said he wished to bear witness to Dr. Simon's statement regarding the widespread prevalence of amebic dysentery in this country.

Dr. James P. Tuttle of New York said he would not recommend the operation of appendicostomy until they had tried ipecac, Epsom salts, etc. He did not advise operation until local treatment had failed. In New York they had treated 125 cases of amebic dysentery with but one death; this man died of acute miliary tuberculosis after appendicostomy. An appendicostomy opening he never closed under six months, and, in the majority of cases, he left it open permanently. Operation he advised only as a last resort.

SECTION IN SURGERY AND ANATOMY.

Wednesday, June 9—Second Day.

Analgesia and Anesthesia by Means of the Electric Current.—Drs. Dudley Tait and Raymond Russ of San Francisco read this paper. They described its effect as noted on rabbits, dogs, and man. There was a different reaction in each. The chief difficulty had been in adjusting the electrodes properly so that there should be a constant resistence, for sudden changes of potential were dangerous. The size of the electrodes should be the same, viz., about that of a silver dollar, and they were most satisfactorily plunged into wet clay, which had previously been applied to the shaved part. The instrument was patterned after that of the French experimenter, and everything possible was done to make the current constant and give the method a fair trial. There were in general three stages observed—irritation, anesthesia, and death, or at least, electrocution. In man the results had been unsatisfactory. In 24 cases there had been one good result. It was in this series early demonstrated that respiration was dangerously interfered with if the positive pole were put lower than the nape of the neck. Sensations in the head of a most disagreeable kind frequently terminated the experiment at its very beginning. Any sudden break resulted in great shock and was to be carefully avoided.

Dr. Geo. E. Brewer of New York said that the results accorded closely with those obtained two years ago at the Surgical Research Laboratory of Columbia.

Dr. Louise G. Robinovitch said that when repeating some phases of her experiments on electric anesthesia, Drs. Tait and Russ worked in the face of difficulties that they did not suspect; the interrupter that they used the speaker had discarded three years ago as a dangerous instrument; the motor they used should never find its way into a laboratory where electric anesthesia was practised; the electric source they used (mercury batteries) should never be used in this work; accumulators of large capacity and voltage should be used. She hoped her colleagues would repeat these experiments, using the proper apparatus.

The Operative Treatment of Fractures.—Mr. W. Arbuthnot Lane of London, England, read this paper. He said that a long study of the joint and other disabilities resulting from the invariable malposition after the usual method of treatment had led him to the positive conclusion that, with but very few exceptions, all fractures, whether open or not, should be treated by open operation and the application of metal splints. Pegs and all other methods were futile; traditions should be broken loose from and the entire matter of fractures both as to treatment and as to teaching should be reviewed. As to technique, it required admittedly a certain moiety of manual dexterity, but this could be acquired by anyone. The locality of the incisions was of much greater import in the upper than in the lower extremity, for here the soft parts were much more easily injured. Not even the gloved hand should be allowed to touch the wound, for in the presence of the foreign body the most absolute asepsis was imperative. All the instruments were made with long shanks, so as to keep the hands isolated.

Operative Treatment of Fractures.—Dr. William Darrach of New York read this paper. He said that the report comprised the work of the late Dr. C. P. Flint and members of the staff of Roosevelt Hospital, as well as his own. It also included the fracture cases observed during the past five years which were too bad to expect any treatment to be followed by a good result. He classified the fractures regionally and gave the indications for and against operation in each. The most disappointing series was that in which there was fracture of the upper shaft of the humerus, accompanied by dislocation of the head of the bone. Sixteen fractures of the olecranon had been sutured with excellent results. The condition was comparable to the patella. Of the 174 cases there were 2 deaths—each from delirium tremens; there were seven infections. As to appliance, good results had followed the use of phosphor-bronze wire as well as the medullary aluminum dowels. The best results were obtained if opertion were not postponed beyond seven to ten days after fracture.

A Plea for the More Careful Diagnosis of Fractures and Their Treatment.—Dr. E. D. Martin of New Orleans read this paper. The bad results which undoubtedly did follow the usual treatment of fracture were attributable to two factions. First, it was wrongly taught in the medical schools, and second, it was assigned to the young and incompetent hospital interns. As a matter of justice to the public and safeness to the profession in the matter of suits for malpractice, this should cease. The orthopedic men should be called upon to prevent deformity rather that to correct it; it was high time they had the entire care of fractures; the general practitioner and the operating surgeon should at once cease to take part in the treatment of fractures.

Dr. Scudder of Boston, in opening the discussion, said that all observers believed in the operative treatment of some fractures, and it seemed probable the union was in some way promoted by operation, and it resolved itself into the difficult question. When to operate? He could not agree with Mr. Lane that this was easily answered, for it was not to be doubted that in the hands of competent men, even bad fractures could be so treated by the accepted

methods as to give both functionally and anatomically good results. He thought the importance of anatomical results were exaggerated, for indeed, it was the functional rather than the anatomical return which was most to be sought.

Dr. Wills of California exhibited a new silver-plated Lambotte fixation apparatus, which he had used successfully.

Dr. Ochsner of Chicago agreed that the results after fracture were, up to date, bad. The results of Lane's operative treatment were, in his hands, wonderfully good. Fractures on the whole were placed in inexperienced hands for treatment, but if accepted principles were properly followed the results would uniformly be good.

Dr. Freeman of Denver showed an external bone clamp of steel, wood-lined, which was of the Lambotte type.

Dr. Murphy of Chicago spoke of the importance of reduction in Colles fracture.

Dr. Powers of Denver gracefully acknowledged the indebtedness of the section to Mr. Lane for his able presentation of the operative treatment of fractures. It would undoubtedly result in the broader application of the technique. At the same time he thought that the utmost conservatism should be employed for the results of properly treated, ordinary closed fractures were undoubtedly good. He agreed with Scudder and Ochsner that there had up to date been too much attention paid to abdominal work and too little to fractures. Operations on long bones should be exceptions rather than the rule.

Dr. Estes of Pennsylvania said that the middle course, as usual, was the safe and wise one. An observation of 2,000 cases had taught him always to operate on the shaft of the tibia, and also over the course of the musculospiral nerve.

Dr. Matas of New Orleans said that we should be careful not to go to extremes. What was to be done in case of lack of union where perfect apposition had been maintained? He had had welcome results from the use of orthopedic splints and medical therapy.

Dr. De Forest Willard of Philadelphia said that the *x*-ray only added to the danger of malpractice suits, for the public now expected cosmetic as well as functional perfection. The *x*-ray was only a shadow and could lie as well as any other shadow. He advised ivory screws, which were absorbed and eventually replaced by bone. They were really not a foreign body.

Dr. Thomson of Scranton said that had Mr. Lane used the same skill in non-operative work as he had in the operative, his results would surely have been quite as good as those he had demonstrated by *x*-ray. He considered Buck's extension the worst device imaginable. In some cases of long bone fracture, which would not be held, he allowed some time to elapse and then used the callous as a splint.

Dr. Robert F. Weir of New York said that the usual methods had in his hands given very good final functional results, and he thought too radical treatment should not be rushed into without full deliberation.

Dr. Binnie of Kansas City said that the result of the meeting would undoubtedly be to increase the number of operations on bones. Lane was a master mechanic and possessed an almost miraculous touch in the management of broken bones and the application of his splints that no ordinary surgeon could hope to approach.

Mr. Lane, in closing, said that the prognosis of fracture depended on whether or not you studied your own results or those of others. The treatment of all fractures except by operation he considered very unsatisfactory.

Dr. Darrach, in closing, said that in the studies of old fractures in the anatomical department of Columbia, less than 100 serious deformities had been encountered in a study of many thousand cases of fracture. So far as indications went for operating, the results so far obtained in 174 cases at Roosevelt Hospital, and which had been most carefully selected from 3,500 cases had shown operation to be indicated in a very small class of cases only.

The Hypophysis Cerebri; Clinical Aspects of Hyper- and Hypo-Secretion of the Gland.—Dr. Harvey Cushing of Baltimore read this oration. The present knowledge of the ductless glands was in large part a triumph of the experimental methods in medicine, although other branches had contributed their share. He reviewed the anatomy and embryology of the hypophysis, stating that since 1839 it had been known to consist of an anterior or epithelial part, an intermediary part, and the posterior lobe of neutral origin. Physiologists had shown that the secretion of the gland entered the body through the tubular connection with the third ventricle. The secretion contained a blood-pressure raising element which was also diuretic and which in some ways was akin to adrenalin. Repeated injections had been shown by Crowell in the Hunterian Laboratory at Hopkins finally to produce a fall in the blood-pressure. Boiling did not influence the action so that extracts might conveniently be sterilized. The posterior lobe secretions if injected continuously produced characteristic changes in the liver and other organs, and this was a warning that organo-therapy should be very carefully undertaken. As for the technique of hypophysis removal, it was most conveniently practised via the lateral subtemporal route in the dog and transsphenoidally in man. Age had a marked influence, for young individuals survived total ablation better than adults. Total removal led to death, which was preceded by a train of peculiar and very characteristic symptoms. Did these come from the anterior or posterior lobe secretions? The posterior lobe could more easily be removed. The anterior had to do with the deposition of fat, and probably exercised important control over sexual organs both as to growth and to function. A most important consideration in all these matters was the close interrelationship of all the ductless glands, what affected one usually affected all. The clinical symptomatology. Acromegaly might be considered as definitely shown to be due to hypersecretion, and two recent surgical human cases added strength to this belief. The condition may be regarded as a manifestation of gigantism development late in life. Hypersecretion was accompanied by a small stature; by infantile genitalia and by unusual deposition of fat. Some dogs after removal had gained one-third original weight in fat, and had suffered diminuation in size of external genitals. As for therapy, at present the crude measures of surgery only were available because organotherapy was not yet standardized. Neither were the differing secretions of the two lobes as yet separated. In operating, just as in the case of the thyroid, it was necessary to do only a hemisection of the anterior lobe. Without doubt there were many cases of primary disease of the gland, but as yet lesions were recognized only in conjunction with associated cerebral tumors.

The Pseudoperitoneum.—Dr. A. F. Hertzler of Kansas City read this paper. The peritoneum was not a lymph space, and is in no sense the mesentery. Peritoneal adhesions were of several types and were absorbed or were permanent according to the character of the primary deposit.

The Early Symptoms of Upper Abdominal Disease.—Dr. J. B. Deaver of Philadelphia read this paper. He said that the physiology of the parts had only just been made clear. A careful history was of the greatest importance. Gallstones were really never quiescent, only we had as yet failed to diagnose gallstones, they being usually mistaken for dyspepsia. Early diagnosis in all three upper abdominal lesions was the only hope for progress.

Dr. Haggard of Tennessee spoke of the great frequency of these lesions—that too often no diagnosis was made.

Pancreatitis.—Dr. A. J. Ochsner of Chicago read

this paper. He emphasized the importance of relative lesions in the galliducts and stated that acute hemorrhagic pancreatitis was usually accompanied by an injection of infected bile. Cammidge's test was of use only in the hands of a trained chemist. As to symptoms, he said duodenal ulcer might be ruled out by the relation of pain to eating. In pancreatitis there was sometimes subscapular pain, as was shown by Fitz twenty years ago. As to treatment, it was compassed in one word—drain. This was the last and final conclusion of all studies in pancreatitis.

Dr. Gilbride of Philadelphia said that the Cammidge reaction was positive in 25 per cent. of all cases of pancreatic disease. Some form of permanent drainage was absolutely necessary.

Hypertrophic Stenosis of the Pylorus in Infants.—Dr. Stanley Stillman of San Francisco read this paper. The frequency of the condition was much greater than generally supposed. Pylorospasm was to be strictly differentiated from hyperplasia, for it represented an effort on the part of Nature to keep the bowel empty, and this should not be defeated by the performance of gastroenterostomy. The condition was undoubtedly a truly congenital one—was accompanied by a palpable tumor, which should be sought for under an anesthetic. The operation of choice was posterior gastrojejunostomy and the results of surgical treatment if instituted before the child was moribund from starvation was infinitely better than those reached by medical treatment.

Report of Twenty Cases of Perforated Gastric and Duodenal Ulcer.—Drs. J. H. Gibbon and F. T. Stewart of Philadelphia read this paper. Twenty-two cases were reported; 15 on the anterior wall of the stomach and 7 on the anterior wall of the duodenum. All perforations were probably minute to start with, enlarging gradually. The symptoms were always urgent—pain and board-like scaphoid abdomen. There was no distention at first. The pain may spread to the lower abdominal quadrant as peritonitis progresses. Collapse is not important, being of too variable occurrence. The same was true of arrested peristalis. Leucocytic count was variable and of no value. Vomiting and gas eructions were very important signs; the age and sex had no bearing—men happened to predominate in this series. Success of treatment depended on time elapsed from perforation to operation. All had died when operated on after 24 hours. No ulcers had been reached, but simply turned in and sutured. Drainage was necessary at site of perforation and at the pelvis as well.

Dr. W. J. Mayo of Rochester, Minn., in opening the discussion, said that the lesson to be learned from these papers was that mortality arose, not from the operation *per se*, but from delay in performing it. Posterior gastroenterostomy was undoubtedly the operation of choice in infantile pyloric stenosis. There were two types of ulcer, but the acute was almost unknown. Refractions were best treated by simple suture without gastroenterostomy. Perforating ulcer nearly always was self-healing.

Dr. Jos. C. Bloodgood of Baltimore spoke of the usefulness of the low median incision as an aid in diagnosis. Certain lesions, fat necrosis for example, were more easily distinguishable here than in the upper quadrant. A further point was that in traumatic perforations of the stomach a double lesion was common and the division of the transverse mesocolon was useful both to afford a view of the posterior gastric region and to permit of pancreatic drainage as well.

SECTION ON DISEASES OF CHILDREN.

Wednesday, June 9—Second Day.

The Relation Between the Science and Art of Infant Feeding.—Dr. Henry Dwight Chapin of New York read this paper. He stated that there was a great deal of discussion during the past few years relative to what had been considered scentific infant feeding. Much that had been written referred more to the art rather than the science of infant feeding. The art of infant feeding consisted in the various manipulations required to make the different milks acceptable to the infant's stomach. Before any of these details were accepted as scientific rested entirely as to whether they were in accordance with biologic laws. Biology finally decided the possibilities and limitations of every method that was advanced.

Heubner's System of Infant Feeding, Expressed in Calories and Energy Units.—Dr. E. Lackner of Chicago presented this paper. He said that normal feeding in children was established between the fourth and sixth week. The amount of protein ingested depended on the individual infant, its peculiarities and needs. Cow's milk was hard to digest, since it contained nitrogenous substances. This system of feeding infants served as a check toward overfeeding, and was beneficial in controlling the weight and development of the child. The average food values were established by weighing the child before and after feeding for four months, as the actual number of calories required were only determined by this procedure.

Infant Mortality: The Factors Which Compose It and How These May Be Influenced.—Dr. L. Emmet Holt of New York presented this communication, which was based upon a study of the subject of mortality occurring in infants in the large cities of this country and Europe. His conclusions were as follows: (1) The greatest reduction in the mortality had been in children under five years of age. (2) During the past twenty-five years there had been a marked reduction in the mortality of infants. (3) Sixteen per cent. of all deaths within the first year of life were due to prematurity of birth. (4) Artificial feeding was still the most important factor. (5) Among the diseases, gastroenteritis caused more deaths than any other affection. (6) Tuberculosis played a much larger part than was generally supposed. (7) The most important agency in reducing infant mortality was education of the medical profession on the subject of infant feeding and infant hygiene.

A Convenient Method for Determining Calorie Values of Formulas Based on Percentage Feeding of Infants.—Dr. Henry J. Bowditch of Boston read this paper. He said that a more convenient method of feeding was formed by a combination of the caloric system and the percentage system. By this plan he claimed it was useful in computing the caloric value of foods used in any formula employed in infant feeding. He stated that methods of infant feeding were by this arrangement much easier understood by the student body.

The Transmission of Bovine Tuberculosis to Children.—Dr. Henry L. K. Shaw of Albany read this paper, and concludes as follows: (1) There were two types of the tubercle bacillus, human and bovine. (2) The statement made by Koch in 1901, and reiterated in Washington last fall, that the human race was but rarely infected by the bovine type raised a momentous question. (3) A study of the literature seemed to sustain Koch's decision. (4) An authenticated instance of pulmonary tuberculosis due to the bovine bacillus had not as yet been reported. (5) The bovine type of the bacilli had been found in tuberculous lymph nodes, and that this was of great importance in early childhood. (6) He claimed that a determination of the type of bacillus was necessary in every case where heredity and environment were excluded as etiological factors.

Dr. William H. Park of New York said that the records showed that the annual mortality from bovine tuberculosis in children under five years in the city of New York was one and one-half per cent.

History of Two Cases of Congenital Pyloric Spasm, with Remarks on the Treatment and Etiology of the Condition.—Dr. D. J. M. Miller of Atlantic City presented this paper. He said that this condition comprised about one-half of 1 per cent. of all the diseases of children,

and believed that many cases of supposed ordinary spasm were in reality congenital in origin. The principal symptom observed in the two cases reported was vomiting after the ingestion of food, next to which was gastric distention. This type of pyloric spasm was caused by a congenital defect of the circular fibers of the pylorus. The treatment consisted in the withdrawal of all milk mixtures. To control the acidity, lime water was used. Drugs accomplished very little. Regulation of the diet was the most important factor in the treatment, and feeding was permitted only when the stomach was empty. Rarely it was necessary to advise surgical interference.

The Treatment with Living Lactic Acid Bacilli of Summer Diarrheas Due to Intestinal Fermentation.—Dr. Carles Hunter Dunn of Boston read this paper. His classification of summer diarrheas was: (1) those caused by nervous influences, (2) those caused by indigestion, (3) those caused by bacterial fermentation and (4) those caused by bacterial infection. He stated that the lactic acid bacilli were antagonistic toward the organisms in fermental diarrhea. He had studied 120 cases of diarrhea and the treatment consisted in feeding the patients unpasteurized buttermilk which contained large quantities of living lactic acid bacilli. The result was that 74 out of the 120 cases showed marked improvement, the diarrhea ceased and the patients gained in weight.

Dr. Thomas Morgan Rotch of Boston said that the use of unpasteurized buttermilk in the diarrheas of children was a step toward lessening one of the great causes of infantile mortality.

Dr. John Lovett Morse of Boston thought it was not wise to employ the form of buttermilk unless the exact nature of the cause of the diarrhea were known, and, advised that a careful study of the stools was necessary.

"Post Hoc Ergo Propter Hoc"; Cases in Children Illustrating Conditions Mistakenly Attributed to Injuries.—Dr. J. P. Crozer Griffith of Philadelphia presented this paper. His article detailed a number of cases of different conditions, in which the symptoms at the outset seemed undoubtedly the result of injury, but in which on further study it was evident that trauma had no bearing. He emphasized the necessity of care in determining conclusions regarding the influence of injury, as many of these cases were quite misleading. He cited several examples of such cases that had lately come under his attention.

The Treatment of Epidemic Meningitis with the Flexner Serum.—Dr. Frank Spooner Churchill of Chicago presented this paper which was based upon a study of 41 cases. He summarized as follows: (1) In all suspected cases lumbar puncture was advised. (2) If the fluid withdrawn was turbid 30 cc. of the serum was at once injected. (3) It was useless to give the serum subcutaneously. (4) The serum was not intended for any form of this disease except the epidemic type. (5) The dose was repeated every day in severe cases for about four days. The patient was then allowed one day's rest and treatment was again instituted as before. (6) Epidemic meningitis was best treated in hospitals. (7) Results of treatment were favorable and limited the duration of the disease.

The Treatment of Anemia in Infancy with Citrate of Iron Subcutaneously.—Dr. John Lovett Morse of Boston read this paper. He said the subcutaneous administration of iron in infancy was superior to the usual method of having it administered by the mouth. It prevented gastric disturbances and acted more promptly. The dose was 3/4 of a grain of the citrate of iron in an aqueous solution and it was given every other day.

Sea-Water Treatment, Given by Subcutaneous Injection, with the Results Obtained in Children.—Dr Theodore Le Boutillier of Philadelphia presented this communication. He stated that the administration of sea-water subcutaneously was superior to ordinary saline solutions. The water was obtained from the Atlantic Ocean, and when ready for use consisted of 83 parts of pure sea-water to 190 parts of sterile water. The dose was from 10 to 60 c.c. and it was usually administered subcutaneously over the gluteal region. Three doses were given weekly and continued for several weeks. The treatment was indicated in all forms of disturbed nutrition, such as marasmus, inanition, etc. The series of cases treated by this method showed a gain in weight of about one ounce daily.

Middle-Milk Mixtures.—Dr. Alfred F. Hess of New York read this paper. He said that he employed this modification of infant feeding for the past year with success and concluded as follows: (1) Experiments proved that in bottled milk bacteria not only rose with the cream, but that they were present in greatest number in its uppermost layer. (2) The upper two ounces of cream were therefore discarded, and, in this way many pathogenic bacteria were removed. (3) Milk deprived of the upper two ounces was called "middle-milk" and the preparations obtained from such milk were termed "middle-milk mixtures." (4) By this method the same fat and protein percentages were now prescribed as in the popular "top-milk" preparations.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Wednesday, June 9—Second Day.

The Pathology of Eclampsia and Toxemia of Pregnancy.—Dr. J. E. Welch of New York City discussed the condition in the light of fourteen cases in the New York Lying-In Hospital, that came to autopsy. Four of the cases were diagnosed clinically as toxemia of pregnancy and ten as eclampsia. The essential symptoms of the eclampsia cases were the convulsions, which were not present in the toxemia cases in which nausea, vomiting, headache, etc., were more prominent. In the two sets of cases the pathology was extremely similar. There were hemorrhages into the liver lobules, necroses of the liver cells, thrombi in many other organs, edema of the brain, hemorrhages into the brain, general bodily edema, and all common to both conditions; so that it seemed fully justifiable to consider the two as one disease, having a group of symptoms represented by the headache, visual disturbances, petechiæ in the skin and mucous membranes, nausea, vomiting, jaundice, and edema. The blood examination showed a reduced hemoglobin (50 to 60 per cent), red blood cells down to about 3,000,000, leucocytes about normal. There was a distinct hemolysis; the blood pressure was usually increased, the coagulation time was normal. To take one case of toxemia as an example, the patient had complained of dizziness, headache, and then suddenly developed coma, which steadily deepened until death. On examination the brain showed the ventricles full of fluid and a hemorrhage into the brain substance. The liver showed hemorrhages into and about the portal spaces. The kidneys showed sloughing of the epethelium of the lobules of the cortex; there was a very mild jaundice. The hemorrhages into the liver, which have been considered characteristic of the conditions, were no more constant than the hemorrhages into the other organs, and seemed dependent on cell destruction in the endothelium of the blood vessels, and that was only a part of a general cell destruction. There was a marked hemolytic effect of the blood serum. The cerebrospinal fluid did not have the same action. The headache and eye symptoms seemed dependent on intracranial lesions. The petechiæ were due to destruction of the blood-vessel walls. The nausea and vomiting might be explained either as due to elimination through the stomach or irritation of the vomiting center. The edema was due

to the blood-vessel or blood cell destruction or irritation, and the jaundice to the destruction of the liver cells and increase in the bile pressures. The whole condition then seemed dependent on the autolysis of the body cells, and this was probably due to some enzyme in the blood.

A Study of Eclampsia, with Results in Two Hundred and Fifty Cases, from the Wards of the Lying-In Hospital of New York City.—Dr. Ross McPherson of New York City brought out the extensive mortality of eclampsia and the unsatisfactory methods of treatment. The author considered eclampsia as a toxemia of convulsive type. In the hospital cases it occurred in one out of every sixty cases, which was due to the fact that those particular cases were sent to the hospital. In the out patient department of the same hospital it occurred only once in a thousand labors, and the later was nearer to the conditions of private practice. Convulsions appeared antepartum in 56 per cent of the eclampsia cases, postpartum in 34 per cent., and intrapartum in 10 per cent. It was more frequent in primipara. The maternal mortality was about 31 per cent. and the fetal about 44 per cent. Of the deaths, 62 per cent. were in the antepartum cases. 31 per cent. in the postpartum, and 7 per cent. in the intrapartum cases.

The treatment of the eclampsic condition should be primarily only prophylactic. In the cases of headache and dizziness, where there was faulty elimination, but the patient was up and walking around, elimination should be aided in every way, and if the condition grew worse or a single convulsion appeared the uterus should be emptied immediately. Every convulsion decreased the chance of recovery of the patient, for the convulsions did not appear until the absorption of the toxines was greater than the elimination. All expectant treatment was useless. The method of emptying the uterus was the only point left for consideration. In the cases where version was performed, the maternal mortality was 35 per cent., the infantile great. In the deliveries by forceps the maternal mortality was 20 per cent., the infantile 44 per cent. When labor was induced, 42 per cent. of the mothers and 28 per cent. of the children died. The best results were gotten from the abdominal cesarean section, where 28 per cent. of the mothers were lost, but none of the children. The mortality was high not merely on account of the eclampsia, but largely on account of the delay in emptying the uterus. The vaginal cesarean section had its good points, but was not as safe as the abdominal section. After the uterus was emptied it was time to control the convulsions and increase elimination. For the control of the convulsions chloroform was used, and also scopolamine and morphine. Elimination was increased by rectal irrigation.

Dr. Wetherill of Denver said that he did not agree that the eye changes could not be relied on, but thought that the ophthalmoscope showed great changes, and allowed the diagnosis to be made at an early stage. That a neuroretinitis or hemorrhages appeared before other symptoms in many cases. He also objected to the use of chloroform to control the convulsions, since it had been shown that the late effects of chloroform were just those characteristic of eclampsia, and the chloroform would augment the trouble already present.

Dr. Cohen of Buffalo agreed with Dr. Welch as to the cause of eclampsia, and it made little difference just what the nature of the toxine was, there was the constant autolysis of all the tissues. No matter just what the source of the toxine was, it was dependent upon the presence of the living fetus *in utero*, and whether the toxine came from the fetus, the placenta, the fetal products in the uterine cavity, or the liver of the mother, in any event the autolytic products caused the general cytolysis. Even in the early cases inefficient working of the liver could be demonstrated in the mother, and the only satisfactory treatment was the early emptying of the uterus.

Dr. Lawrence of Columbus told of two cases of eclampsia, both with marked anemia as an early sign. He thought that an early blood count would be a great aid in diagnosis.

Dr. Frederick of Buffalo said that, while he believed fully in prompt emptying of the uterus, that before such could be done at times it was necessary to control convulsions, and for such he had found chloretone most efficient. At times, too, it had to be used after the uterus was emptied before efficient elimination had been established. He objected to the use of chloroform, and had found chloretone very satisfactory given in thirty grain doses dissolved in oil per rectum, or, if the patient was able to swallow, in fifteen grain doses by mouth in water.

Dr. Bacon of Chicago thought we ought to consider eclampsia as a disease preceding convulsions and having the convulsions only as a crisis. The early diagnosis was not satisfactory if dependent on the urine examination alone or on the eye symptoms. He considered general edema of the body as very significant, and the blood pressure as the best criterion. He had never seen a case with a blood pressure below 160 millimeters of mercury, and most of the cases had a pressure above 180. He considered that one indication sufficient evidence to warrant inducing labor. He did not believe in treatment by vaginal cesarean section.

Dr. Fry of Washington, D. C., said he considered the treatment of eclampsia just as imperative as that of placenta previa. In both cases the mother's life was threatened in the one by hemorrhage, in the other by toxemia. He would not have anything delay the emptying of the uterus, which was the only method of treatment that gave results with a maternal mortality below 10 per cent. That this was the most rational mode of treatment was confirmed by the mortality statistics. The lowest death rate was in those cases with convulsions coming on during labor. If the convulsions came on before labor the mortality was highest. The convulsions coming on after labor also had a somewhat higher mortality than the intrapartum cases, but here the death was due to changes that had already started before labor. The text books were very far behind the times in not urging the emptying of the uterus as the only cure of the condition. As to the method of emptying the uterus, the abdominal cesarean section was excellent for the child, but the maternal mortality was high. The vaginal section was better, but more difficult to do, and also should be done by a surgeon.

Dr. Peterson of Ann Arbor approved of the vaginal section, but did not think it adapted to the use of the general practitioner. However, the country practitioner in cases of eclampsia with an undilated os had to do something immediately, and could not wait for a surgeon miles away. Manual dilatation of the cervix was to the country practitioner a prolonged operation, very liable to add infection to the existing trouble, and the vaginal hysterotomy was certainly no more dangerous. It was easier than a high forceps extraction.

Dr. Welch, in closing, said that the unsatisfactory results of ophthalmoscopic examinations were based on the statement of Dr. Knapp of New York, who had examined fifteen cases for him. The urine examinations did not give a satisfactory diagnosis. The albumin and urea examinations often led to unnecessary production of abortion. The nitrogen content of the urine also was not a safe criterion on which to base an abortion; neither was the presence of leucin and tyrosin. The blood pressure usually had been high, but was not always above 160. An early and certain means of diagnosis was urgently needed. He thought the obstetrician should be a man of great experience, and that this society should do what it could to stop the practice of allowing midwives to be the judge as to when so many of the cases needed the attentions of a physician.

Dr. McPherson, in closing his portion of the discussion, said that he objected thoroughly to the use of chloroform, and that scopolamine also was objectionable. He did not agree that edema was a critical condition, for he had seen many cases with general edema go through labor without bad effect. The vaginal cesarean section he did not consider difficult if the physician knew the technic of the operation, but most men did not understand the operation, and the bleeding was often extensive and the upper sutures hard to place, so that he did not believe in its indiscriminate use.

A Method of Complete Nephroureterectomy in Women.—Dr. Bovée of Washington, D. C., described an operation devised by the author, which insured rapidity of procedure, facility of drainage, and a minimum amount of traumatism. It consisted in primary vaginal incision in the vaginal wall at the interuretal ligament. The terminal portion of the diseased ureter was caught in a hook and pulled down, then cut free from or excected from the bladder, its end tied and the bladder sutured by one or more layers of catgut. The patient was then put in the supine position and a transverse incision made in the loin after the method of König. The ureter was then dissected free by the finger and could easily be pulled into the wound and removed *in toto* with the kidney. In the cases where it was necessary, drainage gauze was pushed from the kidney incision out into the vagina and pulled out through the vagina later. If it was also thought desirable to drain the kidney bed, such was done by a stab wound posteriorly and the loin incision closed completely. The author reported four cases operated on by this method.

Some Factors Which Contribute to Low Mortality in Abdominal Surgery were described by Dr. Simpson of Pittsburg. He said that to induce a patient to submit to operation the surgeon should be able to promise that there would be no excessive danger, complete relief from the condition, that no other line of treatment or operation would give better results, that no other disease would be substituted for his present one and that the result would compensate for the risk, time, cost, etc. To attain this end it was essential first to know the pathology of the condition and the course of the disease, to determine the patient's margin of reserve strength, to adapt the time of the operation to the individual needs of the case, to use the minimum quantity of anesthetic through the coworking of a skilled anesthetist, and to attain the greatest possible speed of operation consistent with precision by working with the same set of assistants and under the same surroundings so as to develop the most efficient team work. He considered that 30 per cent. of his mortality had been due to anesthetic conditions, including the postoperation metabolic disturbances. He considered that rigid asepsis was essential for the best work and without it no elective operations should be undertaken. He believed in the use of sterile gloves and constant uniform cleanliness of the hands. By working always in the same surroundings it was possible for the operator to devote all his attention to the one part of the operation.

Dr. Reed of Cincinnati said that operative celerity was of tremendous importance and that this association should publicly express its disapproval of leisurely operating, and thus avoid the additional metabolic disturbances of the anesthetic. All unnecessary time spent in operating only gave an added danger to the patient.

Dr. Carstens of Detroit emphasized the importance of keeping the patient busy until the hour set for the operation, then bringing the patient quickly to the anesthetic room and promptly putting her under gas. Such an expeditious course saved a great deal of shock because the patient had gone to sleep before she had time to think and be frightened. Personally he believed that speedier work could be done without gloves than with them. So he kept his hands always clean, never allowing them to come in contact with any contamination and wore gloves for all work that might lead to the soiling of his hands.

Dr. Boldt of New York believed in making a most careful diagnosis before operation. He had ceased to give operative surgical clinics and taught his students only surgical diagnosis. The treatment would follow after the diagnosis.

Dr. Bacon of Chicago said that recently legislation had been attempted providing a special examination for all operators who certainly needed special technical training. The question remained only how to frame a law to cover these cases.

Dr. Lawrence of Columbus endorsed all suggestions tending to care in diagnosis and speed in operating. One factor contributing largely to sepsis was trauma such as was gotten by rubbing gauze over the peritoneum or using heavy retractors. It would be much wiser to work as if the patient were conscious of all that went on and felt the pain caused by the rough manipulations. He personally rarely needed retractors in the wound. To develop an infection, devitalized tissue was necessary so that it was always desirable not to lower the vitality of the tissues. Germs also needed moisture to grow in. Hence it was always desirable to work in a dry field.

Dr. Robert T. Morris of New York City said that surgery had now passed through the heroic and anatomic stages, was completing the pathologic stage in which the aim of the surgeon had been to remove diseased tissue and was entering on the stage of physiologic surgery, which aimed to conserve all the natural resistance of the body and make it cure itself by its own opsonius and normal methods. Therefore it was essential to avoid shock which inhibited the production of the protective bodies—to avoid multiple incisions, gauge packings, etc. In the septic cases there was still a great deal of time frittered away in attempting to avoid infection. His technique would be different in fixation of a floating spleen from what it was in opening an appendix abscess. In the clean case all must be kept aseptic. In the abscess it made less difference whether the surgeon's hands were clean than whether the patient's protective powers were kept at their best. In every case it should be remembered that there were two parties to the operation—the surgeon and the patient.

To be continued.

High Death Rate in Diphtheria.—The Department of Health of Chicago gives three major causes for the present high death rate from diphtheria—delay in seeing the case, too small a dose of antitoxin, and neglect of an early repetition of antitoxin.

Tonsillitis in the Navy.—Past Assistant Surgeon B. F. Jenness (U. S. N.) has called attention to the prevalence of tonsillitis in the navy, and recommends that "all cases of tonsillar hypertrophy in recruits should be treated by tonsillotomy or by freely opening the crypts, depending on the amount of enlargement."

Arthritis Deformans in a Child.—A. S. Hershfield reports the case of a girl of ten who had always been well until five years of age, when, after sleeping on the moist ground, had pain and gradual swelling of the right ankle. After four weeks the acute condition subsided, but left the ankle enlarged and disabled. The right ankle soon followed the same course, and for three years the inflammation was frequently repeated in one or the other joint. At eight years of age both wrists became involved, as did various knuckles. The elbows and knees were painful, but not swollen. On examination the heads of the ulna and radius were enlarged. The wrists were much enlarged and crooked. There was enlargement of nearly all the joints of the fingers, and the little fingers were contracted. The case differed from those described by Still in having no enlargement of the spleen or lymph glands. The hip joints were not involved. The knees and ankles were much swollen and contained fluid. The author thinks that the history suggests a neurotic origin to the condition.—*Pediatrics.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Illinois State Board of Health.

January 18-20, 1909.

ANATOMY.

1. What are the Graafian follicles? What is the discus proligerus?
2. With what bones does the inferior turbinate bone articulate?
3. Give origin, insertion, action, and nerve supply of the brachialis anticus muscle.
4. What is the commencement of the innominate artery? What is its length? Where and into what does it bifurcate?
5. In the adult, which is the smallest and which is the largest branch of the celiac axis artery?
6. In "Pott's fracture" you will find the foot everted. What muscle produces the eversion?
7. Name the openings in the diaphragm. What nerves supply the diaphragm?
8. How many pairs of cranial, and how many pairs of spinal nerves are there?
9. Briefly describe the ventricles of the brain.
10. Name the muscles attached to the lower end of the femur.

PHYSIOLOGY.

1. Discuss sleep.
2. Trace the blood from the time it enters the heart from the vena cava until it leaves by the aorta.
3. Define reflex action. Describe a reflex arc.
4. Name the important centers in the medulla.
5. How would digestion be affected by obstruction of the ductus choledochus communis?
6. Explain why the gastric mucous membrane is not digested by the gastric juice. Give the constituents of gastric juice.
7. Describe the disturbances of function of the digestive system produced by excessive use of alcohol.

NEUROLOGY.

1. Give diagnosis and treatment of chorea.
2. From what artery is cerebral hemorrhage most likely to occur?
3. Give differential diagnosis between the coma of opium poisoning and that from cerebral hemorrhage.

MATERIA MEDICA AND THERAPEUTICS.

1. Write a prescription for an alterative, and give indications for its use.
2. Write a prescription for a cardiac stimulant and another for a cardiac depressant, and give the indications and dangers of each.
3. Name the preparations, therapeutic indications, doses, and dangers of belladonna.
4. To what class of remedies does nux vomica belong? Give preparations, doses, therapeutic indications, and dangers.
5. Define antiperiodic, and give example with dose and indications for use.
6. Name one or more internal antiseptics, and give dose, mode of action, and uses.
7. Define antipyretic, and give two examples, with dose, mode of action, and uses of each.
8. Define diuretic. Give two examples. Explain the physiological action of one, with indications for use.
9. Define oxytocic. Give example with dose and use.
10. Name one diaphoretic, and give physiological action in detail.

CHEMISTRY.

1. Describe a process for the manufacture of sodium carbonate or *soda*, as commonly called.
2. What do the following formulæ represent?

KNO_3; K_2CrO_4; $K_2Cr_2O_7$; $KMnO_4$; HCN.

3. Complete the following equation. Give name of compounds and resultant compounds:

$$NaNO_3 + H_2SO_4 =$$

4. Describe chloroform, giving its formula and the preparation on the large scale.
5. Briefly discuss chemical action in general.

ETIOLOGY AND HYGIENE.

1. Give etiology of neurasthenia.
2. Give etiology of mitral incompetency.
3. Give etiology of angina pectoris.
4. Discuss the prophylaxis of malarial fever.
5. How are impurities in water classified? How can they be detected, and why is the presence of organic material in drinking water considered deleterious?

PHYSICAL DIAGNOSIS.

1. Give the etiology, pathology, and symptoms of spastic paraplegia.
2. Differentiate incipient phthisis from bronchitis.
3. Give the etiology, symptoms, and pathology of tabes dorsalis.
4. Give the etiology, pathology, and symptoms of edema of the glottis.
5. Differentiate between herpes zoster and prurigo.

OPHTHALMOLOGY AND OTOLOGY.

1. Give treatment of chronic otitis media.
2. Give the symptoms, etiology, and treatment of optic neuritis.
3. Give your treatment of contused wounds of the eyeball.

PEDIATRICS.

1. Give the dose of the following drugs for an infant three months old: tinct. aconite, phenacetin, strychnine, morphine, antifebrin, quinine.
2. Give the symptoms and treatment of diphtheria.

PATHOLOGY.

1. Give a description of progressive muscular atrophy, with its pathology.
2. What pathological changes take place in urinary stricture from a prostatic enlargement?
3. What tissue changes characterize interstitial nephritis?
4. Define the term general anasarca, and give the pathology of the lesion which most frequently gives rise to it.
5. Discuss the pathology of cirrhosis of the liver.

BACTERIOLOGY.

1. Give a method for staining the gonococci. How do they appear under the microscope?
2. Describe and give characteristics of bacteria especially connected with pneumonia.
3. What is the method of staining the bacillus of tuberculosis?
4. Describe the comma bacillus, and give manner of its introduction into the system.
5. Describe the microorganism associated with malarial fever.

PRACTICE.

1. Should you be called to attend a case of diphtheria, and find that other children in the family have been thoroughly exposed, state fully what you would do for the patient, the other children, and to protect the public.
2. Suppose you are called to see a case of valvular disease of the heart with broken compensation, what would you do, what would you give, and why?
3. Give the etiology, symptoms, and treatment of peripheral neuritis.
4. Outline the management and treatment of chronic constipation.
5. Give the etiology, symptoms, and treatment of cystitis.
6. Give the symptoms, diagnosis, and treatment of hyperchlorhydria.
7. Give the etiology, symptoms and signs, and treatment of lobar pneumonia.
8. Give the diagnosis and treatment of chronic nephritis, late stage.
9. Give the causes, symptoms, and treatment of ascites.
10. Give the treatment of chronic furunculosis.

OBSTETRICS.

1. Describe the chief differences between the female pelvis and the male pelvis.
2. Give the various diameters of the inlet and outlet of the pelvis.
3. Give a full description of the uterus.
4. Describe the treatment of a lacerated perineum. When would you institute the treatment?
5. What changes take place in the ovum after fecundation?
6. Describe the placental circulation.
7. Discuss the management of brow presentations.
8. Discuss briefly dystocia due to the fetus.
9. What is the uteroplacental souffle? What is the funic souffle?
10. Describe in detail the contents of a well equipped obstetric bag.

SURGERY.

1. Describe and give the varieties of pus. What are the symptoms of suppuration?
2. Describe traumatic gangrene, and give treatment of same.
3. Give the means and agents for the production of local anesthesia?

4. Give the symptoms, diagnosis, and treatment of intracapsular fracture of the femur.
5. Give the symptoms of strangulated inguinal hernia. Describe in detail herniotomy by the method you prefer.
6. Describe the sutures most commonly used, giving their preparation.
7. Enumerate the symptoms of cerebral compression, and outline proper treatment.
8. Give the etiology and symptoms of cystitis of the urinary bladder.
9. Describe the affections of the skin due to syphilis.
10. Give the etiology of aneurysm.

GYNECOLOGY.

1. What is vicarious menstruation?
2. How may vaginismus be recognized, and what is the treatment?
3. Discuss the treatment of tumors of the mammary glands.
4. Describe fully the two varieties of ovaritis.
5. Give the etiology and treatment of an acute general cystitis.
6. Discuss the advantages and disadvantages of the vagina as compared with the abdominal routes in surgical operations.

LARYNGOLOGY AND RHINOLOGY.

1. Give the appearance and effects of the destructive action of syphilis on the larynx.
2. Give the pathology of acute rhinitis.

MEDICAL JURISPRUDENCE.

1. What post-mortem changes occur in the tissues?
2. Describe rigor mortis.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

ILLINOIS STATE BOARD OF HEALTH.

January 18-20, 1909.

ANATOMY.

1. The *Graafian follicles* are little follicles or sacs which contain the ova. They are found embedded in the stroma of the ovaries.

The *discus proligerus* is the heaped mass of cells immediately surrounding the ovum; it is, of course, inside the Graafian follicle.

2. The *inferior turbinate bone* articulates with: The ethmoid, lachrymal, palate, and superior maxillary bones.

3. The BRACHIALIS ANTICUS MUSCLE. *Origin*: Lower half of outer and inner surfaces of the shaft of the humerus, covering insertion of the Deltoid, and intermuscular septa. *Insertion*: Rough depression on the anterior surface of the coronoid process of the ulna. *Action*: Flexor of the forearm. *Nerve supply*: Musculocutaneous and musculospiral.

4. The INNOMINATE ARTERY *commences* near the beginning of the arch of the aorta; its *length* is from an inch and a half to two inches; it *bifurcates* at the upper border of the right sternoclavicular articulation, *into* the right subclavian and the right common carotid arteries.

5. In the adult, the gastric is the smallest and the splenic is the largest of the branches of the celiac axis.

6. The Peroneus longus is the muscle producing the eversion of the foot in Pott's fracture.

7. The *openings in the diaphragm* are: The aortic, the esophageal, for the inferior vena cava, right crural, and left crural.

The *nerves which supply the diaphragm* are: The phrenics, the lower intercostals, and the phrenic plexus of the sympathetic.

8. There are twelve pairs of cranial nerves and thirty-one pairs of spinal nerves.

9. The ventricles of the brain are five distinct cavities, between the first four of which there is an intercommunication. The first two, called the right and left lateral ventricles, are situated within the substance of the cerebral hemispheres; they are separated by the septum lucidum, and communicate with the third ventricle by the foramen of Munro. The third ventricle is situated between the optic thalami, at the base of the brain; it communicates by the aqueduct of Sylvius with the fourth ventricle. The fourth ventricle is between the medulla and cerebellum.

The *lateral ventricles* of the brain are bounded: *Above*, by the corpus callosum. *Below*, by the caudate nucleus of the corpus striatum, the tenia semicircularis, part of the optic thalamus, choroid plexus, and fimbriated edge of the fornix. *Internally*, by the septum lucidum.

The *third ventricle* is bounded: *Above*, by the fornix and velum interpositum. *Below*, by the lamina cinerea, tuber cinereum, infundibulum, corpora albicantia, and posterior perforated space. *In front*, by the anterior commissure and the anterior pillars of the fornix. *Behind*, by the posterior commissure, the iter a tertio ad quartum ventriculum. *Laterally*, by the optic thalami and the peduncles of the pineal gland.

The *fourth ventricle* is bounded: *Above*, by the valve of Vieussens and the cerebellum. *Below*, by the pons and medulla. *Laterally*, by the superior peduncles of the cerebellum, restiform bodies.

The *fifth ventricle* is between the two layers of the septum lucidum, and is therefore between the two lateral ventricles. It is covered over by the corpus callosum.

10. The *muscles attached to the lower end of the femur* are: Gastrocnemius, Plantaris, Popliteus.

PHYSIOLOGY.

1. Sleep is a condition of partial or complete unconsciousness, during which the brain and body can recuperate. Metabolism in general is diminished, anabolism is (relatively) in excess of katabolism. During sleep the respirations are slower and deeper, most of the secretions are diminished, the pulse is slower, the eyeballs roll inward and upward, and oxidation in the tissues is decreased. The cause of sleep is not known. Bradbury (in *Allbutt's System of Medicine*) gives the following as hypotheses as to the causation of sleep: (1) Cerebral anemia; (2) chemical changes in the brain cells or neurons, such as an exhaustion of their intramolecular oxygen, or an accumulation of fatigue products; (3) contraction of the dendritic processes and a consequent break in the transmission of nerve impulses; (4) expansion of the neuroglial cell processes, insulating the nerve processes and producing the same effect; (5) loss of consciousness apart from any physical or chemical change; (6) the most probable hypothesis is that of an altered metabolism of the cerebral cells dependent upon exhaustion and diminished influx of stimuli. Quite recently two new theories have been promulgated; one attributes the causation of sleep to an internal secretion of the pituitary body; the other makes it due to osmosis.

2. The course of the blood is: From the venæ cavæ into the right auricle; through the right auriculoventricular opening into the right ventricle; thence through the pulmonary artery to the lungs; thence by the pulmonary veins to the left auricle; thence through the left auriculoventricular opening into the left ventricle; then through the aorta.

3. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

Example: The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

4. The important centers in the medulla are: (1) Center for mastication; (2) for secretion of saliva; (3) for sucking; (4) for deglutition; (5) for vomiting; (6) for voice; (7) center for expression; (8) cardiac centers; (9) respiratory centers; (10) vasomotor centers.

5. Owing to the loss of bile to the intestinal contents, fermentation and putrefaction are much increased, and emulsification of fats is considerably impaired. Peristalsis may be much accelerated, and diarrhea, with increased amount of fat in the stools, ensue.

6. *Why the gastric mucous membrane is not digested by the gastric juice* is not known, and consequently no explanation can be given. The following "hypotheses" have been given from time to time, but are all unsatisfactory: (1) The "vital principle" in living tissues; (2) the epithelium protects it by preventing the absorption of the gastric juice; (3) the mucus similarly protects it; (4) the alkalinity of the blood.

The *constituents of gastric juice* are: Water, proteid, mucin, pepsin, rennin, hydrochloric acid, salts (sodium and

potassium chlorides, and calcium and magnesium phosphates).

7. Excessive use of alcohol causes an increase in the saliva (both in amount and in total solids; in the gastric juice the acidity, quantity, and total solids are all increased; pepsin is precipitated, albumin is coagulated and proteid digestion is retarded or inhibited; the movements of the alimentary canal are accelerated; vomiting and diarrhea may be produced.

NEUROLOGY.

2. The artery from which cerebral hemorrhage is most likely to occur is one of the lenticulostriate branches of the middle cerebral artery.

3. In *cerebral hemorrhage* there are generally paralysis of the head and upper limbs, and in left-sided lesions there may be aphasia; the pulse is slow and full; the respirations are at first slow, regular, and stertorous, later on becoming of the Cheyne-Stokes type, the pupils are dilated.

In *opium poisoning* the pupils are contracted; there is no sign of paralysis; both respirations and pulse are slow and full.

CHEMISTRY.

1. Sodium carbonate can be manufactured by the Leblanc process, as follows: (1) Sodium chloride is converted into sodium sulphate by the action of sulphuric acid:

$$2NaCl + H_2SO_4 = 2HCl + Na_2SO_4.$$

(2) The sodium sulphate is then mixed with charcoal and calcium carbonate and heated; the sodium sulphate is first reduced to sodium sulphide:

$$Na_2SO_4 + 4C = Na_2S + 4CO.$$

Double decomposition then takes place between the calcium carbonate and sodium sulphide, and sodium carbonate and calcium sulphide are produced:

$$CaCO_3 + Na_2S = Na_2CO_3 + CaS.$$

(3) The product is then purified.

2. KNO_3 represents one molecule of potassium nitrate. K_2CrO_4 represents one molecule of potassium chromate. $K_2Cr_2O_7$ represents one molecule of potassium dichromate. $KMnO_4$ represents one molecule of potassium permanganate. HCN represents one molecule of hydrocyanic acid.

3. $NaNO_3 + H_2SO_4 = HNO_3 + NaHSO_4$. The compounds, in order, are: Sodium nitrate, sulphuric acid, nitric acid, and monosodic sulphate.

4. CHLOROFORM. *Formula*: $CHCl_3$. *Properties*: It is a colorless liquid, volatile, with a sweet taste, and agreeable odor. It is heavier than water; is a good solvent for fats and other substances; it mixes with alcohol and ether, but not with water; when pure it is not altered by exposure to light; it ignites with difficulty.

It is *prepared on a large scale* by the action of bleaching powder upon acetone:

$$2CO(CH_3)_2 + 6CaCl(OCl) = 2CHCl_3 + 2Ca(OH)_2 + Ca(CH_3.COO)_2 + 3CaCl_2.$$

5. By *chemical action* is meant the mutual action of substances upon each other when they are brought in contact under proper conditions. When this occurs, certain changes in composition ensue; the first substances disappear and new substances take their places. The kinds of chemical action are:

(1) *Combination*, or *synthesis;* as when $2H_2 + O_2 = 2H_2O$.

(2) *Decomposition*, or *analysis;* as when $2HgO = 2Hg + O_2$.

(3) *Double decomposition*, or *metathesis;* as when

$$BaCl_2 + H_2SO_4 = BaSO_4 + 2HCl$$

(4) *Atomic rearrangement;* as when ammonium isocyanate is converted into urea:

$$(NH_4)\,CNO = CO\,(NH_2)_2.$$

ETIOLOGY AND HYGIENE.

4. *Prophylaxis of malarial fever.* Individuals should use mosquito netting round their beds and wire gauze in doors and windows, so as to keep out the mosquitos as much as possible. During residence in malarial districts quinine should be taken every morning before breakfast. All pools, stagnant water, etc., where *anopheles* may breed, should be removed. All mosquitos, larvæ, etc., should be destroyed as far as possible. By staying indoors during dusk and darkness, opportunities for infection may be avoided. Occasional fumigation with formaldehyde or sulphur is also efficacious.

PHYSICAL DIAGNOSIS.

2. In *incipient phthisis* "there is no expectoration, and probably no hemoptysis, but a persistent dry, hacking cough, possibly with a slight afternoon rise in temperature and occasional feverish attacks ascribed to colds or influenza; there is slight loss in body weight, and the general health is suffering. The physical signs are mainly defective entry of air into one lung, probably at the apex; slight prolongation of expiration, possibly cogwheel respiration, perhaps impaired movement of the chest on one side, and it may be very slight dullness if the deposit be near the surface. Rapid breathing and a persistently frequent pulse are suggestive of early tubercle. The injection of tuberculin giving pyrexia may be tried as a diagnostic reaction. The *x*-rays, using the screen, may quite early show a lagging of the diaphragm on the affected side."

In *bronchitis* "the temperature does not show in the same way an afternoon rise; one apex does not show more physical signs (crepitations) than the other; there is no dullness; crepitations may extend to the bases, and these are often dissipated or altered by repeated coughing."—(From *Aids to Medical Diagnosis.*)

3. TABES DORSALIS. *Etiology*: Tabes dorsalis is a disease of adult life; is more common in men than in women; is more common in cities than in the country; syphilis is believed to be the most frequent direct cause; alcoholism, injury, exposure to cold and wet, have all been urged as causes, but they are not now assigned so important a place as etiological factors as was formerly the case.

Symptoms: Loss of coordination; characteristic and unsteady gait; tendency to stagger when standing up with feet together and eyes closed; sharp and paroxysmal pain, called *crises;* girdle sensation; loss of knee-jerk and other reflexes; Argyll-Robertson pupil.

Pathology: Tabes dorsalis is a condition in which the posterior columns and nerve roots of the spinal cord are degenerated, and which is characterized by incoordination, loss of deep reflexes, and various disturbances of sensation and nutrition.

The posterior columns of the cord are gray and shrunken and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus.

The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion; the spinal ganglia may be affected.

5. *Herpes zoster* is a nerve lesion; follows, as a rule, the course of a nerve (generally one of the intercostals); is generally unilateral; is characterized by pain and vesiculation.

Prurigo is a local disturbance of the skin; does not follow the course of a nerve, but can occur anywhere; is not unilateral; is characterized by itching rather than pain and papules; it is generally found on the extensor surfaces of the extremities.

OPHTHALMOLOGY AND OTOLOGY.

The *treatment of contused wounds of the eyeball* is thus given by Gould and Pyle: Careful disinfection, the application of ice, eserine or atropine, a bandage, and rest in bed. A bruised iris must be carefully excised. The various complications should be treated as they arise. If there is an extensive rupture of the sclera, conjunctival and scleral sutures may be necessary to prevent complete prolapse of the vitreous. Nothing can be done for iridodialysis except iridectomy. A dislocated lens must sooner or later be removed. Hemorrhage into the anterior chamber and subconjunctival hemorrhages will usually absorb without treatment.

PEDIATRICS.

1. The *dose for an infant three months old* of tinct. aconite, is ♏ 1/10; of phenacetin, is gr. 1/6; of strychnine, is gr. 1/600; of morphine, gr. 1/250; antifebrin should not be given; of quinine (sulphate), is gr. 1/4.

PATHOLOGY.

5. There are two important forms of chronic interstitial cirrhosis of the liver—hypertrophic and atrophic. The following table (from Thayer's *Pathology*) will assist in distinguishing them:

Synonyms. Charcot's Hypertrophic, Unilobular, Hepatogenous, Biliary.	Laennec's, Atrophic, Multilobular, Hematogenous, Hob-nail liver.
Jaundice. Early and marked, bile often absent from feces.	Late and slight, bile usually present.

Ascites. Late and unimportant.	May be early; often enormous.
Spleen. Enlarged early and markedly.	Late and less.
Alimentary hemorrhage, piles. Not common.	Common.
Liver. Large, smooth, mottled, green.	Small, rough, pale or yellow.
New fibrous tissue. In fine lines and strands between acini and cells, involving all parts equally.	In broad bands, making prominent islands in which the single acinus may appear nearly normal; distributed irregularly.

BACTERIOLOGY.

1. To demonstrate the *gonococcus*: On a cover-glass make a smear with the discharge as thin as possible and let it dry in the air; cover it with a freshly made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized, wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismarck Brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes,* which have been *decolorized by Gram's stain,* and have taken the counterstain.

3. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin, red rods, while all other bacteria will appear blue.

OBSTETRICS.

1. The chief differences between the male and female pelvis are thus tabulated in *Morris's Anatomy*:

MALE.	FEMALE.
Bones heavier and rougher.	Bones more slender.
Ilia less vertical.	Ilia more vertical.
Iliac fossæ deeper.	Iliac fossæ shallower.
False pelvis relatively wider.	False pelvis relatively narrower.
True pelvis deeper.	True pelvis shallower.
True pelvis narrower.	True pelvis wider.
Inlet more heart-shaped.	Inlet more oval.
Symphysis deeper.	Symphysis shallower.
Tuberosities of ischia in flexed.	Tuberosities of ischia everted.
Pubic arch narrower and more pointed.	Pubic arch wider and more rounded.
Margins of ischio-pubic rami more everted.	Margins of ischio pubic rami less everted.
Obturator foramen oval.	Obturator foramen triangular.
Sacrum narrower and more curved.	Sacrum wider and less curved.
Capacity of true pelvis less.	Capacity of true pelvis greater.

2. The pelvic diameters.

	Antero-posterior.	Oblique.	Transverse
Inlet	4 inches.	4½ inches.	5 inches
Outlet	5 inches.	4½ inches.	4 inches

3. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits.

9. The *uteroplacental souffle* is a rhythmical, soft, blowing sound, synchronous with the maternal heart beat. It is due to the passage of blood through the enlarged uterine arteries.

The *funic souffle* is a sharp, whistling or blowing sound, synchronous with the fetal heart beat. It is caused by some interference with the circulation in the umbilical arteries.

10. The contents of the obstetrical bag will vary with the requirements and experience of its owner, and the preparations already made by the patient. In any case the following articles should be taken by the accoucheur to a confinement: Tablets of bichloride of mercury, or some other material for making antiseptic solution; forceps; ether or chloroform, with inhaler or mask; fluid extract of ergot; hypodermic syringe, with tablets of strychnine, morphine, etc.; needles, sutures, and needle holder; nail brush and nail cleaner; umbilical scissors; carbolized vaseline; stethoscope; male catheter (rubber); a 1 per cent. solution of nitrate of silver, with eye dropper.

In addition to the above some would also include: A sterile apron or suit; a Kelly pad; solution of cocaine; soap, boric acid, and gauze, all sterilized; absorbent cotton, iodoform gauze; choral hydrate; dilators, and other instruments.

GYNECOLOGY.

1. "*Vicarious menstruation* is a flow of blood from some organ (other than the uterus), recurring at the monthly periods and taking the place of menstruation. It may occur from the hemorrhoidal vessels, the lungs, the skin, the nails, the mammary glands, ulcerated surfaces, and many other parts."—(King's *Manual of Obstetrics.*)

2. *Vaginismus* is a condition of painful and spasmodic contraction of the vaginal orifice, which renders coitus either painful or altogether impossible. The slightest touch causes painful spasms, and examination may be impossible without an anesthetic. Its *causes* are irritable hymen, ulcer, or fissure anywhere in the immediate vicinity, urethral caruncle, caruncle myrtiformes, a long perineum with vaginal orifice placed too anteriorly. The *treatment* consists in removing the cause when possible, tonics and general constitutional treatment, dilatation of the vaginal orifice; local application of a 5 per cent. solution of cocaine will relieve the hyperesthesia and allow coitus. The condition is sometimes incurable.

3. Simple benign tumors of the mammary gland should be enucleated as soon as discovered; malignant tumors require complete removal of the gland with all lymphatics connected, unless the general condition of the patient is such that she cannot stand the shock of the operation, or the diseased condition is too advanced.

5. ACUTE CYSTITIS. (*a*) *Etiology*: Various pathogenic bacteria, foreign bodies, traumatism, retention of urine, unclean catheters, cold.

(*b*) *Symptoms*: Frequent urination, with tenesmus and a burning sensation in the urethra; later on pain in the bladder, hematuria, and the urine contains pus and epithelial cells. Chills, rapid pulse, fever, and headache may also be present.

Treatment: Rest in bed; the imbibition of plenty of milk and water, and the avoidance of all highly seasoned food; laxatives; diuretics; sitz bath; irrigation of the bladder with an antiseptic solution; hot fomentation and vaginal douches are often helpful; sometimes intravesical medication is necessary.

6. The relative advantages and disadvantages of the abdominal and vaginal routes in pelvic surgery are thus summarized by Dudley (*Diseases of Women*):

Advantages of the abdominal route: (1) A larger field is open for operation; (2) the operator may see what he is doing instead of depending largely on touch; (3) diagnosis of unsuspected conditions and complications is much easier; (4) the abdominal section is adapted to large tumors and pus sacs, and to conditions high in the pelvis; (5) the appendages may be removed with better chance of avoiding rupture of a pus sac; (6) there is less danger of wounding intestines, bladder, or ureters and greater facility in the control of hemorrhage; (7) the frequent concurrence of appendicitis and other abdominal lesions with pelvic disease and the impossibility of reaching them by the vagina; (8) it gives more light and more space for conservative work.

Advantages of the vaginal route: (1) It gives better drainage, and is therefore specially adapted to cases of vesical or intestinal fistulæ; (2) it avoids abdominal scar and risk of ventral hernia; (3) it is suitable for cases of small tumors without high adhesions; (4) when properly performed it lessens the danger from shock, and is therefore suitable to cases of extreme pelvic infiltration which are inoperable, because too dangerous, by the abdominal route; (5) it involves less handling of the intestines, and therefore less consequent danger of intestinal adhesions; (6) recovery is less complicated and more rapid.

Unfortunately, the vaginal route is, for at least a very large proportion of cases, impracticable. The long, narrow virgin vagina or the vagina which has become contracted from senile atrophy may render the field of operation almost inaccessible. A very large uterus with exceptionally short, thick, broad ligaments and greatly enlarged appendages, with adhesions extending beyond the reach of the finger, may also be difficult or impossible to manipulate through the vagina. Under such conditions the abdominal route is much safer.

MEDICAL JURISPRUDENCE.

1. The *postmortem changes occurring in the tissues* are: Rigor mortis, lividity, muscular relaxation, change in temperature, formation of adipocere, decomposition.

2. *Rigor mortis* is the condition of rigidity or contraction into which the muscles of the body pass after death. It begins at a period varying from about fifteen minutes to about six hours. It usually begins in the muscles of the eye, neck, and jaw; then the muscles of the chest and upper extremity, and last of all those of the abdomen and lower extremity are affected. It passes off in the same order. It is said to be due to the coagulation of the muscle plasma.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	July 13
Arizona*	Ancil Martin, Phoenix	Phoenix	July 5
Arkansas*	P. T. Murphy, Brinkley	Little Rock	July 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	Aug. 3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	July 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July 13
Delaware	J. H. Wilson, Dover	Dover	Dec. 14
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington	July 13
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov. 10
Georgia	E. R. Anthony, Griffin	Atlanta	Oct 12
Idaho*	W. F. Howard, Pocatello	Boise	Oct. —
Illinois	J. A. Egan, Springfield	Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	July 13
Iowa	Louis A. Thomas, Des Moines	Des Moines	June 22
Kansas	D. P. Cook, Clay Center	Kansas City	Oct. 12
Kentucky	J. N. McCormick, Bowling Green	Louisville	July 6
Louisiana	P. A. LaRue, 211 Camp Street, New Orleans	New Orleans	Oct. 1
Maine	Wm. J. Maybury, Saco	Augusta	July 1
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 14
Massachusetts*	E. B. Harvey, State House, Boston	Boston	July 13
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing	Oct. 12
Minnesota	W. S. Fullerton, St. Paul	St. Paul	Oct. 5
Mississippi	S. H. McLean, Jackson	Jackson	Oct. 12
Missouri	J. A. B. Adcock, Warrensburg	Kansas City	Sept. 20
Montana*	Wm. C. Riddell, Helena	Helena	Oct. 5
Nebraska	E. J. C. Sward, Oakland	Lincoln	Aug. 3
Nevada	S. L. Lee, Carson City	Carson City	Nov. 1
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord	June 29
New Jersey	J. W. Bennett, Long Branch	Trenton	Oct. 19

Wisconsin	J. V. Stevens, Jefferson	Madison	July 13
Wyoming	S. B. Miller, Laramie	Laramie	June 23

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Oklahoma.—The State Board of Medical Examiners of this State will not, in future, issue a license to practise medicine to any person who is suffering from pulmonary tuberculosis. As noted in another column, the House of Delegates of the American Medical Association has seconded a protest against this cruel and absurd piece of phthisiophilic legislation.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending June 12, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	527	180
Diphtheria	270	32
Measles	1,431	39
Scarlet Fever	246	27
Smallpox	2	..
Varicella	197	..
Typhoid Fever	27	4
Whooping Cough	88	7
Cerebrospinal Meningitis	12	2
Malarial Fever	..	..
Totals	2,800	291

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service for the week ending June 11, 1909:

		CASES.	DEATHS.
SMALLPOX—UNITED STATES			
Alabama, Birmingham	May 15-22	1	..
California, San Francisco	May 15-22	4	..
District of Columbia, Washington	May 22-29	1	..

THE CLINICAL DIAGNOSIS OF TUBERCULOSIS OF THE TONSILS.

By LEE M. HURD, M.D.,

NEW YORK.

WITH SOME REMARKS UPON THE MICROSCOPIC DIAGNOSIS.

By JONATHAN WRIGHT, M.D.,

NEW YORK.

The evidence of the physiological relation between the faucial tonsil and the lymphatic glands situated at the angles of the jaw anterior to the sternocleidomastoid muscle, has been proven. [1], [2], [3]. When these cervical glands are enlarged there is always evidence of disease in the corresponding tonsil. This glandular enlargement is due to septic absorption or to the absorption of the tubercle bacillus. Personally, I believe that all these cases of glandular enlargement start from septic absorption, and after the tonsillar resistance has become weakened by disease it easily allows the tubercle bacilli to gain a foothold and soon invade the cervical lymphatics. I also believe that at times this takes place without leaving much evidence of their passage through the diseased tonsil. This has not yet been established as a fact, but the following analogous facts tend to lead me to believe it may be true:

Wood's experiment of once rubbing tubercle bacilli upon a pig's tonsil, later finding tuberculous lesions in its lymph gland, but none in the tonsil.[4] The experiments of Calmette and Guerin on goats[5] showing that tubercle bacilli can pass through the intestinal walls without leaving lesions, and even through the mesenteric lymph glands, making themselves first known in the pulmonary apex.

The clinical diagnosis of primary tuberculosis of the tonsil was made in these selected cases on the condition of the lymph gland that drains the tonsil, as well as the condition of the tonsil.

The faucial tonsils may be divided into two classes clinically. *First*, those that are enlarged, somewhat pedunculated, and most of the tonsil hanging free into the fauces. Such large tonsils are the ones that are usually removed. They are also the tonsils that cause the least systemic harm. True, they interfere with free breathing to a certain extent, but the children that have this class of tonsils are more inclined to be healthy and robust. It seems that the larger and freer the tonsil, the more it resists the invasion of harmful microorganisms; also it is exceptional to find associated with them much enlargement of the lymphatic glands.

The *second* class consists of those tonsils which are more or less buried beneath the tonsillar pillars, and which are prone to chronic inflammation rather than to acute inflammation, although they may have acute exacerbations of the chronic condition. This class causes more systemic effect. These tonsils, when diseased, will regularly cause enlargement of the glands in the deep cervical chain. The children are not robust, but are more inclined to be anemic and languid, and it is in these patients that we find the proper soil for the invasion primarily of the tonsil, and then the cervical gland, with tuberculosis.

On casual examination, these submerged tonsils appear small and insignificant, because the greater portion is in the space between the pillars and crowds upward, sometimes half an inch, above the highest visible portion of the tonsil. It is in this buried portion that the tuberculous evidences are usually found, closely bordering upon the tonsillar capsule. Dr. Wright examined sixty tonsils for tuberculosis, in the days when it was considered necessary to remove only the protruding portion. He did not find it in a single case [5], [6]. This seems to prove two things: First, that the protruding tonsil is rarely attacked by tuberculosis; second, that if it is attacked the lesion is nearly always found just beneath the capsule, at the bottom of the tonsillar crypts.

The tonsil in which we find evidences of tuberculosis is usually pale, the crypts contain cheesy detritus, the edge of the anterior pillar may have a passive hyperemia, and the associated lymphatic gland is usually much enlarged and hard. From this early stage it may progress until any number of glands are involved. The question has been put to me—If the tuberculosis has reached the cervical lymphatics,* why remove the tonsil? There are two very good reasons. First, such a tonsil is allowing microorganisms to take the same route as the tubercle bacillus did, and I believe that this makes it still harder for the lymphatics to overcome the tuberculosis, which they have a fair chance of doing with the tonsil out. This is easily shown by the fact that after removal of the tonsil the lymph glands begin to subside, and if only enlarged from septic absorption will entirely disappear; and in tuberculous adenitis there will be a rapid diminution in the size of the glands to a certain point, which I believe was the increased load placed upon the glands from draining a generally diseased tonsil. Also, when the tuberculous cervical glands are removed, the tonsil remaining is liable to reinfect the remaining glands, as in case No. 2. The most frequent site for enlargement of the cervical glands is at the angle of the jaw and in recognizing the tonsil as the portal of infection, its prompt removal will abort many cases and perhaps other more remote tuberculous lesions.

I would here like to digress long enough to state

*Read at a meeting of the Medical Society of the County of New York, May 24, 1909.

*An enlarged lymphatic gland is not necessarily tuberculous.

that the tonsil must be removed *in toto* in order to get out the tuberculous portion, and also that the stump of a partially removed tonsil is quite as liable to tuberculous infection as if originally submerged. This is probably due to the fibrous cicatrix closing up most of the crypts.

All the tonsils reported in this article were of the submerged variety. From my observations, I would say that the inflammatory enlargements—both septic and tuberculous—of the lymph glands that drain the tonsil, are nearly always associated with the submerged tonsil. The tonsils removed from cases of slight glandular enlargement usually showed microscopic evidences of chronic inflammation, but in one of this class the tonsil was typically tuberculous. The tonsils from cases in which clinically the glands were considered tuberculous or bordering on that condition, had the diagnosis of tuberculous tonsil confirmed by the microscope in eight out of the eleven cases.

I am unable—and this paper is not intended for that purpose—to show the percentage of tuberculous tonsils to the total number removed during the same period. All the cases have been selected with the tuberculous and chronic inflammatory changes of the tonsil in view, and outside of the throat and neck showed no other signs of tuberculosis.

CASE I.—J. H. Male æt. 25. June 29, 1908. Many carious teeth. Large submerged tonsils, with hard enlarged glands at angle of jaw. Clinically considered tuberculous. No other evidences of tuberculosis.

CASES IN WHICH THE TONSILS WERE CLINICALLY CONSIDERED CHRONICALLY INFLAMED BUT NOT TUBERCULOUS.

that the glands in the neck are tuberculous. Later, 10 more slides were examined. In many of them there was the well-marked identical area of tubercle-granulum and epithelioid cells, and in one of these supplemental 10 slides there was in this area a fairly well marked giant cell. Diagnosis: Tubercle of the tonsil. JONATHAN WRIGHT.

"I avail myself of the report of this case to furnish me with an opportunity of making the remarks upon the microscopical diagnosis of tubercle which have so often formed the substance of our informal conversations in the course of the work with which you have been engaged. As you know, some criticism has been expressed at my unwillingness in many cases definitely to declare there were no evidences of tuberculous processes in a given tonsil submitted to me for examination. It is, of course, a familiar rule in making a negative report on a specimen of sputum to remain on the conservative side by saying that no tubercle bacilli *are found*. The limitations of this negative opinion are well understood, but when I have reported that no *conclusive* evidences of tubercle have been found by me in tonsillar structure, the position assumed has not been understood. It is the purpose of these remarks to explain the grounds of this undesirable but, to me, unavoidable uncertainty expressed in the form of speech I sometimes adopt and which it is often so awkward to use in communicating to friends of the patient the result of the miscroscopic examination. This to uninformed minds seems a sort of

CASES IN WHICH THE TONSILS WERE CLINICALLY CONSIDERED TUBERCULOUS

No.	Age	Sex	Class of Tonsil	Condition of Cervical Glands	Microscopic Findings	72.72% Tuberculous

Note large proportion of females, 72 per cent.

Microscopic Examination.—"This tonsil is a good illustration of the grounds I have for calling areas in tonsillar section 'suspicious' of tubercle. In one of the three sections there are granular areas where the proliferation of the round cells are becoming granular and taking the stain badly; near by are some old fibrous areas. Another section shows this

mystic shrine from which to expect the infallibility not inherent in scientific terms.

"Now, in my mind there is often a very large addition of doubt in the negative expression of opinion as to the existence of tubercle in the tonsil, which is not attached to the diagnosis of bacilli in the sputum. With me, this arises from the conviction that the cytolytic emanation of the tubercle bacillus which causes the crumbling of protoplasm may not in lymphoid structure give rise to any of the other structural changes thought to be necessary to the satisfactory identification of tubercle by the microscope. These necrotic areas are not infrequently present in the tonsil, and the most diligent search fails to reveal that they are accompained by other areas in which are present giant and epithelioid cells. Now, in well-recognized tubercle, as in this case, the majority of the necrotic areas do not contain these added characteristics. When areas exist side by side, one containing giant cells and epithelioid cells and connective tissue indications, and the others without them, we do not hesitate to ascribe all to the cytolytic activities of the bacillus. I do not hesitate to believe that such areas of simple protoplasm necrosis *may* be the sole evidence of the tuberculous nature of the lesion, but I hasten to add that they cannot be considered as processes exclusive of other origins. This, I believe is the kernel of doubt that lies at the bottom of the differences of opinion as to the frequency of the occurrence of latent tuberculosis of the tonsil.

"I am convinced that if every tonsil removed in our hospital were examined microscopically (I suppose the number would mount into the thousands every year), and if the accepted evidence of the existence of tuberculosis rested only on the presence of the typical tubercle described by the text-books, the proportion of 5 or 10 per cent. would be found to be a gross exaggeration. On the other hand, were we to accept every area of circumscribed granular necrosis as tubercle caused by the action of the bacillus, without a doubt the proportion would be placed at a higher figure.

"While we are upon this aspect of the subject, I might also remark that the word 'latent' tuberculosis of the tonsil is misleading, as it is most frequently used. I suppose the term 'latent tuberculosis of the tonsils,' when originally used, meant a local tuberculosis without systemic clinical manifestation of tuberculosis there or elsewhere. This strict interpretation of the word 'latent' involves the shrinkage in the number of cases observed under the microscope as the acuteness of diagnostic on the part of the clinical observer rises. These cases which we have been observing, many of them, now present to your trained eyes clinical evidences of tuberculosis which a few years ago the microscope would only have revealed as 'latent.' What becomes of our definition, therefore? We expect tuberculous people to have tubercle of the tonsils, but you suspect or tentatively diagnosticate a case as probably having tuberculous foci in the tonsils because you have followed the reports we have sent you, and are able to appreciate shades of clinical phenomena which a few years ago you could not do. This is a fundamental weakness of all statistics, but nowhere so glaringly evident as in discussions on tuberculosis. The importance of the statistical argument pales before the mature entertainment of such considerations.

"Here, confusion in figures as to the frequency of 'latent' tuberculosis depends upon the definition to be applied to a number of ill-defined terms by observers of different degrees of diagnostic acumen. What is *patent* to you is *latent* to some one else. What is 'tubercle' to me is not the only thing that is 'tubercle' to some one else. All these fundamental differences of opinion and capacity are unexpressed in the discussion of the statistics. I think it would be well to give them what prominence we can.

"To return from this quite excusable digression to the subject of the 'tubercle granulum.' As I have said, I know that not all the crumbling areas I see in the tonsil are tuberculous. Some I believe to be due to autolysis, with the transformation of protoplasm into fat or the substitution of fat for the destroyed protoplasm, a process taking place in the retrograde metamorphosis of the tonsil, and an entirely physiological adjustment of the organism.* Some, possibly, may be due to syphilis, though I am inclined to think this very rare. When occurring, the lesion is usually superficial.

"The difference between these effects of cytolytic ferments—that of the bacteriolysin of tubercle and the autolysin—is commonly ascribed to the efforts the organism makes in the former case to remedy the damage, *i. e.* the production of epithelioid and connective tissue cells in and around the necrotic areas, but I know no reason why the organism should always thus respond. It may be that the turbercle bacillus in passing through from the surface to the deeper lymphatics of the neck has left this imperfect trace behind it, because of its temporary lodgment.. The tonsil, no doubt, is the entry port of a great deal of infection, and if all the virulence of the germs were expended there we should have tonsillar lesions far in excess in frequency to all other lesions of the organs of the body.

"Near these spots of granular protoplasm, representing the regression of the tonsil, we have always more or less low grade fibrous tissue, such again as we have around old healed tubercle at the apex of the lungs. Thus you see why it is that I am undoubtedly often in a state of doubt as to how I am to interpret these spots of granular necrosis.

"I am reminded by some recent literature upon the formation of tubercle that in view of your intention to publish the communication I made you in regard to the problem of microscopic diagnosis of tonsillar tubercle, I should briefly refer to the conception at which I have arrived of the usual sequence of events. Virchow and Arnold, and many of the earlier writers looked upon the formation of the giant cell and the appearance of epithelioid cells as the initial tissue change in answer to the insult of the tubercle bacillus. This they supposed to be due to the confluence of the fixed tissue cells into a giant cell, and the alteration of others into the epithelioid cells. This is subsequently followed by the accretion of leucocytes from the blood-vessels with resulting coagulation necrosis. Many others, Koch, Cohnheim, Metchnikoff, Yersin, among them, believe that the nucleated blood-cells are the mother cells of tubercle, and from them are formed the giant cells and the epithelioid cells. So far as the tonsil is concerned, I am inclined to

*In order to avoid repetition of what you may elsewhere find in print, I refer you to the details of the facts upon which this belief was founded originally, remarking that subsequent observation has only confirmed them: "The Fat Contents of the Tonsils," *N. Y. Med Jour.*, Dec 15, 1906; "Cysts in Lymphoid Tissue; an Exceptional Manifestation of Tonsillar Regression," *The Laryngoscope*, Sept., 1905

think the leucocytes from the neighboring lymph spaces and capillaries first form a cluster around the point of irritation, be it bacillus or foreign body, or tissue altered by the influence of either. Epithelioid cells are soon formed, whether from the leucocytes or the fixed tissue cells I am unable to say, but I am inclined to think they arise from the large and small lymphocytes. By this time, and often before the appearance of giant cells, a certain amount of coagulation necrosis has taken place. The giant cells, when I have been able to detect their genesis, have been arising from the endothelial cells of capillaries in accord with the observations of many histologists. By the confluence of these we have a multinuclear cell with feeble cytoplasmic contents. It seems very probable to me that the sequence of events in the formation of tubercle in general is not always the same. The morphological appearances of tubercle differ considerably, and it is quite probable that the giant cell of tubercle is due, like the giant cell of bone, to the confluence of other cells than those of the capillaries, and this may even be the case in the tonsil, but for reasons which I have partly disclosed in my previous letter to you I do not believe that the giant cell is usually the first step in the process in the tonsil—rather the last, or next to the last, fibrosis being more properly a process of repair. It is not necessary to say anything of the view of the fission of nuclei in giant cells as the sole cause of their existence. While nuclei may divide in them, I suppose, I have never detected it, and I am not disposed to think of them as arising in this way."

Case II.—G. McM. Single; age 19. For the past three and a half years has had enlarged cervical glands. Two and a half years ago had first operation on glands. Subsequently has had ten more operations, making eleven in all. Three years ago had first operation on adenoids; again in four months. Two years ago had still another tonsil and adenoid operation. I found this girl on the sidewalk talking to patient No. 3, and on observing large numbers of scars on her neck, induced her to come into the hospital and have her throat examined. I found large submerged tonsillar stumps, flush with the pillars; no adenoids; two distant cervical glands enlarging since last operation, some two months previously. I induced her to have her tonsils out. She rather thought it was hopeless, as this made the fourth try, but on being informed of their relation to the neck condition she consented, and I enucleated them last April. Dr. Wright found typical tubercle in the tonsillar tissue. Her health has improved so that she has gone back to work, which she has not done in two years. The two glands that were showing a tendency to grow, one in the parotid, the other above the clavicle, have receded somewhat. These two glands cannot be directly connected with the tonsillar drainage, but the removal of the primary tonsillar foci seems to have been very beneficial to the girl's general condition.

Case III.—E. McM. Female, age 22; servant. Perfectly healthy except for broken down gland at angle of jaw. Submerged tonsil that looks suspicious of tuberculous involvement. Admitted to hospital; neck abscess opened; also tonsil enucleated. Neck promptly healed, and tonsil showed following condition: "This is lymphoid material with much subjacent fibrous connective tissue. There are typical Langerhans giant cells and tubercle granulum deep down in the lymphoid tissue."

Case IV.—M. N., Irish, æt. 27; June 3, 1908. For past two years has had glands at angle of jaw much enlarged and gradually increasing in size. In last two months mass acutely enlarged to double former size. Tonsils very small (no history of tonsillitis), entirely submerged. The corresponding tonsil enucleated, and submitted to Dr. Wright, who reported "chronic inflammation," but he remarked that if he saw the same masses of fibrous tissue in a section of the lung he would call it healed tubercle, but was not prepared so to state regarding the tonsil. Seven days after the removal of the tonsil the acute swelling subsided, leaving the old tuberculous glands their former size. These tuberculous glands did not diminish in size, and about four months after removal of tonsil they showed evidence of breaking down, and a month later were a fluctuating mass. They were now entirely removed. One had become fluid, and the rest, about six in all, had cheesy centers. Dr. Wright said: "I presume this is a tuberculous gland, but we have been unable to find typical tubercle in the sections examined." I feel tolerably certain that the tonsil was the port of entry, for the glands first affected drain the tonsil, and there is no evidence of secondary drainage into these glands.

Considering the length of time—over two years—between development of the adenitis and examination of the tonsil, it seems to me logical to believe that the tonsillar lesion had healed. The patient had the most pronounced enlargement of the glands, with the longest duration, of any of the cases reported, considerably over two years, she says it might be three, since she first noticed their size, and they had probably then been enlarging for some time.

Case VII.—L. O'R., æt. 8; August 15, 1908. Very small submerged tonsils. Glands moderately enlarged, with tonsillar gland about size of hickory nut. Microscopical report: "Typical tubercle, giant cells, etc." In the six months since operation all the glands have subsided, except the tonsillar, which is hard and about half former size.

February 18, 1909. The tonsillar lymphatic gland removed about 1½ inches in diameter. Its tuberculous condition confirmed by Dr. J. Wright.

Case VIII.—M. V., æt. 8; June, 1908. Three months before operation, tonsillar gland and others in relation broke down and drained. Small submerged tonsils. Dr. Wright found typical tubercle in corresponding tonsil; now, after period of seven months, glands have entirely subsided.

Case IX.—M. D., æt. 3; May 12, 1905. Submerged tonsils, enlarged glands. Tonsils enucleated. Report: "Sections through tonsils show undoubted evidences of tuberculous process. While there are no typical anatomical tubercules, still the presence of masses of epithelioid cells arranged in groups with central coagulation necrosis and proliferating coagulation tissue fibers, the patchy appearance, nuclear fragmentation, makes the diagnosis fairly positive. In addition to this, the presence of tubercle bacilli can be demonstrated, arranged in clumps." This child's health has greatly improved; the glands have receded, until now, after a period of over three years, they are hardly palpable.

Case X.—L. K., æt. 8. On February 4, 1908. Had tonsils removed, that is, down to the pillars, two years ago. This boy has recurrent O. M. S. A., some adenoid; large tonsillar stumps remain that are submerged and partially covered with cicatricial

tissue. The tonsillar neck glands are enlarged from size of hazel nut down. Tonsils enucleated. Dr. Wright reports as follows: "These tonsils have many fibrous bands of large diameter traversing the lymphoid tissue; near them the lymphoid tissue is undergoing coagulation necrosis with much hyperplasia of the epithelial or large plasma (epithelioid) cells. There are no giant cells, and the degenerated areas are so scattered that I am inclined to regard this rather as evidence of a retrograde metamorphosis than of old tuberculous lesions." Supplementary report: "Sections stained for tubercle bacilli show them apparently in the areas of degeneration. I cannot avoid, therefore, regarding this as a tuberculous lesion." In the year since tonsillar removal the boy's health has greatly improved, and the glands have subsided.

I am very much indebted to the laboratory for the work it has done in these cases. It is out of the question to ask them to convert a suspicious tonsil into sections and examine every section. What has been done, however, is to take the most likely portion of the tonsil and make three or four sections. If these look suspicious, but are not positively tuberculous, a few more sections are made; but in this series it has not been difficult to find tuberculous evidences in most of the tonsils in the first few sections.

I wish to express my gratitude to Dr. Wright for the interest and work he has given the subject. Without his help this article would have been impossible. Not my theories, but his facts make it worthy of your consideration.

ON THE USE OF ATROPINE SULPHATE AND ATROPINE METHYLBROMIDE IN DIABETES MELLITUS.

A PRELIMINARY COMMUNICATION.

By J. RUDISCH, M.D.,

NEW YORK.

VISITING PHYSICIAN, MOUNT SINAI HOSPITAL.

During the past two and a half years I have carried on a series of clinical experiments in the wards of Mount Sinai Hospital and in private practice to determine the value of certain atropine salts in cases of diabetes mellitus. The results of this method of treatment have proved so satisfactory that I desire briefly to record the most striking features in the hope that others may be led to continue these investigations.

No attempt was made to select cases. My series include severe cases as well as mild ones with very varying periods of duration. The ages of the patients ranged from nine to over seventy years. A carbohydrate-free diet was always given at the beginning of the treatment in conjunction with the atropine.

The action of atropine may be summed up under the following heads: (1) Reduction in the amount of sugar excreted; (2) Increase in carbohydrate tolerance.

1. It was uniformly observed that glycosuria disappeared much more rapidly under this combined form of treatment than with the customary antidiabetic diet alone. It is a common experience that while a strict carbohydrate-free diet will usually cause a marked diminution in sugar excretion, traces of sugar will still remain in the urine or appear from time to time. In these cases the use of atropine in sufficient dosage has invariably resulted in a complete suppression of the glycosuria. Interruption in the administration of the drug without change in diet has been followed in many of my cases by the reappearance of sugar in the urine, but this glycosuria could always be made to disappear again promptly by resuming the atropine.

2. The influence of atropine in increasing carbohydrate tolerance is manifested in two ways. I have frequently noted that an amount of carbohydrate sufficient to cause glycosuria in a patient whose urine has become free from sugar but who is not taking atropine, will be perfectly well tolerated as soon as the atropine is administered. Secondly, after the prolonged administration of atropine the tolerance for carbohydrates increases much more rapidly than after a period of antidiabetic diet alone. The appearance of glycosuria in such cases is the signal to resume the atropine, and even without any reduction of the carbohydrates this frequently is sufficient to cause the urine to become again sugar-free.

I have administered the atropine in the form of the methyl-bromide and the sulphate. The former has the advantage of being much less toxic, but its effects are not so prompt as those of the sulphate. Its cost, moreover, limits its use. As the initial dose of the methyl-bromide I have given gr. 2/15 *t. i. d.* to adults, gradually increasing this by gr. 1/15 until gr. 8/15 *t. i. d.* are being taken. In one case three grains were given daily over a short period with no other toxic effect than dryness of the throat. The initial dose of atropine sulphate should be gr. 1/150 *t. i. d.* that may be gradually increased to gr. 1/20 *t. i. d.* Children require a dosage proportionate to their age. My youngest patient, a nine-year-old boy, received an initial dose of gr. 1/250 of the sulphate three times a day, and this dose, in the course of several months, was gradually increased to gr. 1/10 *per diem*.

It is noteworthy that these unusually large amounts of atropine are well tolerated, provided the initial dose is small and the increase gradual. It is not necessary to attain the maximum dose in the majority of cases, however, much smaller amounts often causing the glycosuria to disappear. With the appearance of the first toxic symptom, usually a marked dryness of the throat, the atropine was either stopped entirely, or, more often, the attempt to increase the dosage was temporarily abandoned. It was always possible to resume the drug after a period of rest.

While the tolerance for atropine varies in different individuals, I have not observed a single case in which a peculiar susceptibility totally precluded the administration of one or other of the salts previously discussed. In no instance was an atropine "habit" acquired, nor were there any deleterious effects upon the general health observed from its prolonged administration.

COMPENSATORY ALBUMINURIA;

A CONTRIBUTION TO THE STUDY OF CLINICAL ALBUMINURIAS.*

By HEINRICH STERN, M.D.,

NEW YORK.

Albuminuria is often the only clinical symptom of a functional disorder in some part of the organism. The albuminurias consequential to abnormal function occur without clinically recognizable anatomical changes in the kidneys. That they may ensue in the presence of structurally sound kidneys was conclusively demonstrated by Langstein, who was the first to perform the autopsy of a patient that had been affected with authenticated orthotic albuminuria.†

Ever since albuminuria of the orthotic type was recognized, numerous clinicians deemed it to reflect a peculiar or dormant form of nephritis, while others viewed it as an expression of a transitory disturbance of renal function.

Langstein's autopsy findings have done away with the first assumption for all times; the latter supposition merely substitutes a disturbance of renal activity for an anatomical renal lesion—a very vague conjecture which does not explain anything.

Of course, an albuminuria cannot ensue if the cells of the kidneys are impermeable for the large albumin molecule. That much we know, therefore: The structurally sound renal membranes permit under certain circumstances the passage of albumin from the blood current into the urine. The question now arises: *Is the transudation of the large albumin molecule through the normal kidney membranes to be ascribed to a perverted function or to a compensatory response of the latter?* In other words: *Is the albuminuria due to deficiency or efficiency of renal action, to a renal, mere local, functional incompetency or to ante-renal pathological influences.*

The kidneys regulate the composition of the blood. When their work is not interfered with the amount of the various urinary constituents ordinarily reflects the comparative quantity in which the same substances have existed in the blood. On the other hand, when the renal activity is lowered, be it on account of functional or morphological circumstances, there will be retention of the urine-making substances in the blood-current and a proportional deficiency of them in the renal secretion. Hypertony of the blood plasma in the presence of normally functionating kidneys can only be a transitory occurrence, and if there be a hypotony of the plasma the regulatory function of the kidneys will soon correct it. The kidneys, in other words, endeavor to maintain a more or less definite concentration and osmotic tension of the blood for every period of life. Furthermore, substances contained in excess, or such which are foreign to the blood, always reach the kidneys whence they are eliminated.‡ This fact again demonstrates the blood-regulating ability of the kidneys, and also evinces that the appearance in the urine of certain so-called pathological substances is not due to diseased, but, on the contrary, to healthy and forcefully working excretory organs.

The occurrence of albumin in the urine in the presence of structurally sound and functionally efficient kidneys must be designated as a regulatory act of the latter. By their regulatory capability the renal organs tend to compensate for the insufficiency of those organs which have permitted entrance into the circulation of blood-foreign albumin, or to the incompetency of which is due a peculiar physico-chemical blood composition, demonstrating itself in the deficient power of attaching the absorbed proteid material. In a limited sense, that is as far as the interchange between blood and urine is concerned, we may speak of a regulatory albuminuria; in as far, however, as the blood-foreign proteid or the abnormal blood composition is the outcome of perverse metabolic processes, we are justified in describing the resulting albuminuria as compensatory in character. While, as a matter of course, a non-nephritic albuminuria cannot ensue without renal regulatory activity, the causative factors of compensatory albuminuria are ante-renal in time as well as location, and are entirely independent of the kidneys. The designation "compensatory albuminuria" is therefore much more comprehensive and expressive than either the terms "regulatory albuminuria," chosen by Rosenbach, or "hematogenic albuminuria," propounded by Bamberger. Although regulatory albuminuria corresponds in many respects with compensatory albuminuria, its most distinctive factor is deemed to be the regulatory function of the kidneys, while the conception of compensatory albuminuria sees in the regulatory activity of the kidneys not a selective-voluntary, but rather a compulsatory operation. On the other hand, the rather indefinite so-called hematogenic albuminuria, which does not go beyond an altered condition of the blood as the prime factor in the production of the albuminuric phenomenon, conforms but in few points to the definite and comprehensive scope of compensatory albuminuria.

An albuminuria may be designated to be of a compensatory nature when the quantitatively and qualitatively entirely normal urine contains albumin without the presence of renal inflammatory products, oil globules, connective tissue shreds, casts and of more than a few renal epithelia. The urine in compensatory albuminuria exhibits a normal density and the aggregate of solids eliminated by it is proportional to the intake, if the end-products, which would have been yielded had the albumin not been excreted, be taken into due account. It is evident that the kidneys while responding to corrective demands exert increased activity, and it is also evident that but healthy and strong excretory organs can undertake and perform the task of eliminating unconverted albumin or such which is not sufficiently fastened to the blood. However, if the additional burden becomes too heavy or if the supplementary

*Read at the meeting of the Medical Association of the Greater City of New York, May 17, 1909.

†Die Albuminurien älterer Kinder, Leipzig, 1907.—The patient, a girl ten years old, was under observation from March, 1903, until November, 1905. Although considerable amounts of albumin were excreted, the urine never contained any when the patient remained in the recumbent posture. Renal form elements were never present. Necropsy showed the following: Left kidney, capsule easily striped off, surface smooth, blue-red, tough consistency. Right kidney the same as the left. A few black "Venensterne" on the surface. No pathological changes on the cut surfaces of both kidneys. A most careful microscopical examination of the kidneys demonstrated the absence of any degenerative or inflammatory change whatsoever. A lentil-sized contraction on the surface of one kidney was caused by a relatively fresh infarct which was probably the result of a marantic thrombosis of a small vessel that appeared toward the end of life. A few tubular epithelia, situated in the same area, exhibited minute fatty changes.

‡While water and the normal catabolic products do not alter the constitution of the sensitive renal membranes, blood-foreign material is liable to affect the function of the renal cells and may cause their structural damage if large amounts of it are continuously brought in contact with them through the medium of the circulation.

activity be continued over a protracted period, the kidneys may be rendered functionally insufficient after a time and in some instances may even become structurally affected. The primary changes accruing in the kidneys after excessive renal activity are of a reactive nature, that is, they are due to a more or less marked exhaustion of the secreting apparatus, or, in other words, to trophic disturbances. The excretory work of a set of functionally exhausted kidneys is, of course, proportionally less than that of competent organs. The total urinary solids are diminished to a greater or lesser degree, and this may be also the case with the urinary water. The general relaxation of the secerning renal cells permits the transudation of albumin from the plasma into the urine, an occurrence which prior to kidney exhaustion was accompanied by enforced renal activity.

There may be a period during the enfeebled renal state when the relative and absolute amounts of excreted albumin are actually reduced. This diminution of urinary albumin is generally looked upon as an improvement of the renal condition; in reality, however, it denotes precisely the opposite, *i. e.* renal deterioration. At a later period, when the structural alteration of the kidneys has progressed to a certain degree, the albumin output is again increased, becoming in all likelihood larger than ever before. Still, it is a question whether the structural renal changes following long-continued or excessive excretion of albumin attain the nature of a genuine nephritic process. The inflammatory stage, or what may be considered such, runs very often a mild and rapid course, and the patients may actually feel better while it supervenes than during the period of functional renal insufficiency without organic alteration. It is even plausible that an eventual inflammatory stage after renal exhaustion—a temporary occurrence in many instances—is itself a compensatory process enabling the kidney to resume some of its regulatory activity after the inflammation has run its course.

Alterations in the exchanging membranes in the kidneys may be the mediate result of a protracted compensatory albuminuria, but there is no renal lesion which stands at the foundation of the compensatory albuminuria. The primary cause of the latter is presumably always of a functional nature and is situated in the organs concerned in the general metabolism, and more especially in those participating in the process of blood-making. Elsewhere I have discussed in detail the factors which lead to the compensatory elimination of proteid material by the renal organs. For the present purpose it suffices to know that the immediate cause of the albuminuria is either a surplus of circulating albumin or the inability of the blood to attach to itself certain albuminous material which has entered the circulation. If the binding qualities of the blood for albumin are of a normal degree, and if the albumin is not admitted to the blood-current in too excessive amounts it will be brought to the various tissues whence, after successive stages of oxydation, it will again be taken up by the blood in the form of urea, the normal end product of intrasystemic albumin disintegration. In the majority of instances, therefore, an overabundance of circulating albumin will hardly give occasion to compensatory albuminuria. A peculiar chemicophysical state of the blood, on the other hand, seems to be nearly always the direct cause of the compensatory albuminuric phenomenon. Rosenbach has already drawn attention to this point. Normal blood is unable to bind certain blood-foreign proteids, as egg albumin, casein, albumoses, etc., even if they be introduced directly into the circulation; they are eliminated by the normal kidneys, some quite rapidly, others, like the albumoses, after having accumulated to some degree in the blood. Blood possessing only limited combining qualities for blood-assimilable albumin will lose a portion of it in its native state by way of the kidneys. Such blood cannot transport to the tissues all the albumin which had been admitted to the circulation, although its amount may have been perfectly normal. The natural result of this inability of the blood will be the excretion of a diminished amount of urea, and the urea deficit will be found to stand in close proximity to the amount of urea which would have been yielded by the albumin that transuded through the kidneys in its native state.

There are a number of clinical varieties of compensatory albuminuria, not known as such ordinarily, which bear manifold, often rather vague and meaningless designations. A detailed consideration of these varieties will be found in a forthcoming article.

Compensatory albuminurias are, as a rule, easily recognized and readily differentiated from nephritides. One has to recall that in compensatory albuminuria the excretion of albumin is frequently the only clinical phenomenon, that there are no other exceptional urinary features, and that the physical signs, symptoms and disturbances usually met with in one or the other form of renal disease, are not present. Again, the amount of urinary albumin is not very large; the daily output not exceeding a few grams, hardly ever reaches that noted in the average case of chronic parenchymatous nephritis.

The compensatory phenomenon is of a more or less temporary nature, persisting ordinarily not longer than its underlying causes; it may, however, assume a remittent or intermittent character, especially in its milder forms, but then by the spell-like succession of limited outputs of albumin an apparent chronicity is imparted to it. In nephritic conditions the functional work of the kidneys is more or less interfered with; the renal activity, on the other hand, is not only not lessened in compensatory albuminuria, but ofttimes is even increased. While the hypodermatic introduction of 0.01 gram phloridzin yields a minimum of about 1.6 gram glucose within three and a half and four and a half hours in the presence of normally functionating kidneys, the amount of glucose will be diminished or none at all will be produced, if the renal organs be structurally damaged. In individuals with compensatory albuminuria phloridzin glycosuria can always be induced, and the quantity of glucose often surpasses the minimum amount to a considerable degree. Kidneys rendered less efficient or exhausted functionally by overwork—a condition liable to supervene in protracted instances of compensatory albuminuria—always respond to the phloridzin, but ordinarily yield slightly less glucose and produce it less quickly than do the normal and competent organs. The most potent means of differentiating between a set of functionally deficient kidneys resulting from overwork and one which is structurally affected are the absence from the urine of any specific nephritic elements and the occurrence of a slightly lowered, yet almost minimum phloridzin glycosuria in from five to seven hours.

160 West Seventy-third Street.

THE TREATMENT OF POTTS' DISEASE AT THE SEA BREEZE HOSPITAL.

By LEONARD W. ELY, M.D.,

NEW YORK.

ATTENDING SURGEON TO THE SEA BREEZE HOSPITAL.

Orthopedic surgery in the past has concerned itself too much, perhaps, with details, too much with "straps and buckles," too much with improved styles of braces. It has fixed its attention on the minutiæ of treatment to the comparative neglect of the study of pathology and of the broad underlying principles of procedure.

The mechanical treatment of Potts' disease at Sea Breeze aims at three things: (1) To splint the spine effectually; (2) to keep the children as much as possible in the open air; and (3) to permit them to go about and exercise. We meet these indications almost invariably by two forms of appliance, the Bradford frame as modified by Whitman, and the plaster-of-Paris jacket. All complicated forms of apparatus we have discarded, not so much on account of the trouble and expense inseparable from them, as because we have found them less efficient than the means we have adopted. From what follows it can be seen that there is nothing in the treatment of Potts' disease that prevents its prosecution by any man with an ordinary armamentarium, a little mechanical skill, and a good working knowledge of plaster-of-Paris. This is a great advantage. Children suffering with this disease are usually of the poorer classes, and if they live far from the larger cities must be treated by the local practitioner or not at all. Braces are usually out of the question, and often are worse than useless. They require careful fitting by a skilled mechanic, and frequent adjusting. The need has been for a treatment that can be of general use, and this need our treatment seems to meet.

Recumbency on the Bradford frame. This is our treatment of election for children under three years of age, for those with large deep abscesses or psoas contraction, and for those whose sinuses open in such a manner as to make a jacket impracticable. If the spinal disease be complicated by hip-joint or shoulder-joint disease, the frame will probably be the treatment of choice here also. The child spends the entire twenty-four hours on it, and is never permitted to sit or stand for an instant. Twice a day he is rolled off it on to a table, and his back rubbed gently with alcohol and then powdered. His shirt is the only garment, except perhaps a diaper, between him and the frame. All the rest of his clothes include the frame also. It has an oblong shape, is made from gas-pipe (¼ inch in caliber), and is covered with canvas laced up the back. Its width is the distance between the child's shoulder joints, and its length is the child's height plus about six inches. It is provided with an apron which is buckled to the canvas cover at the sides and holds the child firmly in place, and it is bent backward at the seat of disease in order to superextend the spine at that point. Its head may be rested on a box in order to make it pleasanter for the patient, and if he shows any tendency to roll over and walk off on his hands and knees, a two foot board bound transversely across the bottom of the frame will suffice to keep him quiet. If the medical attendant be at all dubious of his ability with plaster-of-Paris, he can perfectly well keep his little patient on the frame during the entire course of the disease. Children are happy and contented when treated in this way, especially if they have previously had much pain.

Fig. 1.—Frame cases; the patient on the left is A. C., whose history is given below.

In children over three years of age, our customary treatment is by the plaster jacket. If the disease is below the ninth thoracic vertebra and uncomplicated, we usually apply the ordinary jacket, which is too well known to need description here.

If above the tenth, we use the Calot jacket. This jacket was introduced into this country about two years ago, and marks a distinct advance in orthopedic surgery. It is invaluable in the treatment of Potts' paraplegia, is by far the best means of support for upper thoracic and cervical disease, and is excellent in cases of Potts' disease with much deformity. Calot claims that he can reduce the deformity, or cause it to disappear entirely by means of his jacket, but our experience with it has not been long enough to enable us to verify this for ourselves. He claims also that the jacket is very simple of application. Here we differ from him radically. We regard it as by far the most difficult form of plaster dressing. In regard to the manner of applying the jacket, we follow the rules laid down by Calot, with a few exceptions. We found that plaster made with cold water broke down in a few days, and we have substituted warm water. We use also bandages made previously with dry plaster, instead of rolling them in plaster cream. It would be well for anyone who has never applied one of these jackets to follow Calot's advice and practice on a mannikin before putting one on a patient. He will find that three assistants are advisable.

The Calot head sling is a great improvement on the old-fashioned kind, and is made of canvas, six centimeters wide. To a circular piece 168 centimeters in circumference is sewn a tailpiece 15 centimeters long. Measure the child's occipitofrontal circumference and add two centimeters to this. Then measure off this distance on the circular part of the sling and insert safety pins. Into this middle part the child's chin and occiput fit, and the two loops beyond are carried up and hung over the transverse bar. This bar is suspended from a hook and pulleys as in the old-fashioned apparatus, and while the jacket is being applied the child's heels are just pulled clear of the stool on which he stands (see illustration). The tailpiece of the sling starts from the child's occiput and passes up to be attached to the middle of the transverse bar. It keeps the child's head from tilting backward. An assistant holds the child's hands at an angle of 45 degrees with his body.

The patient wears one—or, better, two—buttonless shirts, usually of stockinette, with sleeves. In the "grand" jacket one piece of stockinette reaches up over the head, and has a hole cut for the nose while the jacket is being applied. For the jacket with military collar we sew a collar of corn plaster felt to the top of the shirt. A large triangular pad of cotton batting, about an inch thick, is then held in place by an assistant over the sternum and ribs; the pelvis is also lightly protected with a piece of corn plaster felt, and, if the jacket is to be one with a military collar, one or two plaster bandages are smoothly applied, covering the trunk and shoulders and encircling the neck. The auxiliary pieces are then put on, as described below, and several bandages are applied outside of these. In a "grand" jacket the chin and occiput are also carefully padded, and the plaster bandages include the head also, avoiding the hole left for breathing.

When the plaster has been applied as quickly as possible the surgeon and his assistant give their attention to molding it carefully all over the child's body, especially about the pelvis and shoulders. Through a small triangular opening over the sternum, the cotton padding is then removed and the jacket is trimmed off above and below. Above, with a military jacket, at the junction of the chin with the neck, with the "grand" jacket leaving the ears free and including the chin and occiput. Then the patient may be released from the sling and laid face downward over the edge of a table or bed. A nurse or assistant should watch his breathing for a while to see that it is not impeded. During the next forty-eight hours the jacket should be cut out in front, as shown in the illustration. A window, 6 by 3 inches, should also be cut in the back over the kyphosis, the shirt slit up by two cross cuts, the skin greased with vaseline, and oblong pieces of cotton wadding, a little larger than the window, should be tucked under the shirting, next the skin, by means of a spatula. This drives the kyphosis forward. The shirt is then folded back in place, and the whole thing is held by a bandage—we use several plaster bandages. At intervals of about two months this treatment of the kyphosis may be repeated. A jacket should last about six months.

The auxiliary pieces mentioned above consist of three or four layers of crinoline, impregnated with fresh plaster cream. For the military jacket they

Fig. 2.—Ordinary or old-fashioned jackets. Observe how the jacket on the left fails to control the deformity; both this boy and the one on the right ("Smiling Joe") were afterward put in Calot jackets, and all three have been discharged cured.

are three in number—two aprons, front and back, and a collar; for the "grand" jacket, two aprons, a chin piece, and a piece for the occiput. The aprons are the length of the trunk, plus one-half, and in width are equal to one-half the circumference of the trunk. The anterior one is applied from the sternum to the pubes, and the redundant portion folded up and applied over the lower abdomen. The posterior apron is slit up for almost half its length, making two tails, and these tails are brought over the shoulder and then down in front of the shoulders back under the axillæ. An assistant stands by to nick the aprons with the scissors, if necessary, to make them lie smoothly; and, in fact, the same thing is advisable while the first plaster bandages are being applied. The collar is made about the height of the child's neck, and once and a half its circumference. It strengthens the jacket at this point. The pieces for the chin and occiput in the "grand" jacket should be about 4 by 6 inches, and should run downward from these points.

In disease above the seventh thoracic vertebra, or

in disease at any point complicated by paraplegia, the "grand" jacket is used: in other cases, the jacket with military collar.

Abscesses.—In dealing with these the fact should always be borne in mind that an infected abscess

Fig. 3.—Application of the Calot jacket with "officer's collar"; trimming the jacket. This patient had suffered from paraplegia and incontinence for months, but recovered completely after being put in plaster; he is now almost well and will soon leave the hospital.

means, in the vast majority of cases, the death of the patient—sometimes comparatively soon, sometimes after two or three years with amyloid degeneration and sepsis. They should not be allowed to emerge under Poupart's ligament and enter the thigh. A patient with a psoas abscess should be immediately placed in the recumbent posture on a frame, in order to avoid the effect of gravity upon the fluid. If the abscess be small and high up, it should be left alone, and possibly it may disappear spontaneously. If it be of large size and low down in the iliac region, it should be attacked in this situation and evacuated through a trocar and vacuum bottle. The best place to insert the trocar, the place of election, is just internal to the anterior superior spine and below it. The abscess can be palpated and its location will determine the direction of the trocar. After it has been evacuated, and while the cannula is still in place, about seven to ten c.c of fresh iodoform—ether mixture* should be injected into the cavity by a syringe whose needle is thrust through the cannula. Then a small sterile dressing should be applied to the seat of the puncture. The operation is almost painless. Most children would far rather submit to it under cocaine than to take ether. It should be repeated about every ten days until the abscess ceases to refill. Abscesses in the gluteal region or those that have already entered the thigh are not so satisfactory to deal with, but the earlier they are attacked the better. In all cases scrupulous asepsis should be observed. The instruments should be boiled, the skin should be thoroughly disinfected, and sterile rubber gloves should be worn.

*Olive oil 50, ether 50, creosote 2, iodoform 5.

Our results under this method of treatment have been brilliant. An abstract of the history of the following case illustrates well its advantages.

A. C., seven years, admitted March 15, 1907. She had been under dispensary treatment by us for a year, and during that time had worn ordinary plaster jackets. On admission she was in very poor condition, nervous, fretful, and emaciated. Her gait was unsteady and her knee-jerks absent. Her cervical glands were enlarged. A marked, sharp, kyphosis was present in the lumbar region, and a large abscess could be palpated deep in the right iliac region and above it. On admission her jacket was removed, and she was placed upon a frame, bent backward at the place corresponding to the seat of the disease.

December 1, 1907. Large abscess palpable in

Fig. 4.—Grand Calot jacket. This jacket is not cut out quite enough at the throat, and is too thick about the neck; it was one of our earlier attempts. The patient suffered from cervical Potts' disease and has since been discharged cured.

left iliac region also. General condition excellent. Psoas contraction has disappeared.

September 10, 1908. Child still on frame. Large abscess deep in each iliac region. Abscess on right side aspirated, under cocaine, just below and internal to anterior superior spine. About 100 c. c. thick pus were withdrawn and 8 c. c. of

iodoform-ether mixture injected. From the left abscess about 50 c. c. of pus were withdrawn, through the corresponding spot, and 8 c. c. of the mixture were injected.

September 19, 1908. Abscess on right side aspirated, withdrawing about 65 c. c. of pus; 8 c. c. of usual mixture injected.

October 18, 1908. Right abscess aspirated and 175 c. c. of pus removed. Seven c. c. of usual mixture injected. Left abscess aspirated and 75 c. c. of pus removed. Injected 7 c. c. of usual mixture. Pus somewhat thinner than before.

November 8, 1908. Right abscess aspirated, withdrawing 275 c. c. of pus. Seven c. c. of usual mixture injected. Seventy-five c. c. of pus removed from left abscess and 7 c. c. of mixture injected.

November 25, 1908. A small amount of dark brown fluid withdrawn from left abscess. All these aspirations were done under cocaine.

November 29, 1908. Practically nothing can be felt of either abscess, merely a slight thickening in right and left iliac regions. Calot jacket (military) applied.

December 20, 1908. Child walking quite well. Marked knock-knees. Left abscess barely palpable in iliac region.

March 21, 1909. Child in excellent condition: runs and plays about. Window cut in back of jacket and new padding applied over kyphosis.

Here was an emaciated, cachectic child, with a rapidly destructive process, beginning paraplegia, and a large abscess—about as unfavorable a case as one is often called upon to treat. The prognosis under old methods of treatment was distinctly bad. She is now on the high road to recovery.

We are trying Bier's treatment by passive hyperemia and following Beck's ideas with injection of pastes in some of our cases with discharging sinuses, but we have not yet come to a settled conclusion as to their value.

Only the simplest operations are performed at Sea Breeze. Our facilities for operating are most primitive. For any large operation the children are transferred to some hospital in Manhattan. It is hoped, as soon as our finances allow, to install a modern operating room and outfit, so that the children need not be sent away at all. The operation of "bone scraping" we regard as almost invariably useless. The blind thrusting of a curette into a tuberculous joint and spooning about would not be practised so often were a knowledge of the pathology of joint tuberculosis more widely diffused. The same may be said of scraping tuberculous sinuses. The tubercles are deep in the walls of these sinuses, and the chance of eradicating them with a curette is about one in a million.

In treating Potts' disease one should never forget that he is treating a tuberculosis of the spine and that the mechanical treatment is only part of the problem. These patients need fresh air *all the time*, good food, and careful attention to their general condition. In spite of all that has been said they are still being cooped up in city hospitals, allowed access to a roof once in a while, when convenient, and when the weather is warm and pleasant. Charitable persons are building sanatoria for them which contain beautiful sun-parlors to let in the sun and keep out the air. The lesson has not yet sunk in. It must be emphasized again and again The three essentials in the treatment of tuberculous bone and joint disease are: Proper Surgical Treatment, Fresh Air, and Good Feeding.

THE COMBINED OPERATION FOR THE RADICAL CURE OF INGUINAL HERNIA AND APPENDICITIS.

By ANTHONY H. HARRIGAN, M.D.,

ASSISTANT SURGEON, OUT-PATIENT DEPARTMENT, HARLEM HOSPITAL, NEW YORK.

The subject of appendicular hernia has been treated exhaustively by several writers, notably Jopson[1], Levy[2], and Jacquemin[3]. Their analyses of statistics demonstrate an important clinical relation between appendicitis and inguinal hernia. According to Kelly[4], the appendix is found in the sac in one to two per cent. of all herniæ. These figures, however, are probably too low. Many herniæ which are reducible, for example, are not subjected to operation. On the other hand, in operative cases, the contents of the sac frequently remain undetermined.

Recognizing the frequency of appendicular hernia and appreciating the technical objections to removal of the appendix through the inguinal canal, Dr. Frantz Torek in 1906 reported an operation that combines the principles and advantages of the McBurney intermuscular appendicectomy with the modern hernioplasty of Bassini. Torek[5] describes the operation as follows:

"An imaginary line is drawn from the anterior superior line of the ilium to the umbilicus. A point on this line at a distance equal to one-fourth of its length from the iliac spine marks the beginning of the incision which is carried down from here to the external inguinal ring. The aponeurosis of the external oblique muscle is exposed throughout the length of the incision. This fascia is now incised in the direction of its fibers as is customary in the gridiron operation for appendicitis exposing the internal oblique muscle; but, the incision is prolonged downward so as to terminate at the apex of the external inguinal ring. The aponeurosis of the external oblique is prepared off from the underlying parts in the usual manner, on the outer side exposing Poupart's ligament. Then the hernia operation is proceeded with up to the point where the sac is cut off. Here the hernia operation is intermitted and attention turned to the appendix. The fibers of the internal oblique and transversalis are separated bluntly in the usual manner, the peritoneum is opened, the appendix removed; then the peritoneum, transversalis fascia, and muscles are closed again: in a word, the appendicitis operation is completed except that the aponeurosis of the external oblique is still left open. We now return again to the hernia operation and suture the internal oblique and transversalis to Poupart's ligament according to any of the approved methods, and finally suture the aponeurosis of the external oblique in the entire extent of its incision, so as to close both the appendicitis and the hernia operation. Lastly, the skin is sutured."

The following history is given in detail to emphasize the value of this procedure and its feasibility in difficult cases:

Mr. N. P., age 40 years. Eight years ago had an attack resembling clinically appendicitis. At the time of examination, on January 20, 1909, he was recovering from a second attack, which was characterized by nausea, initial vomiting, pain in the right lower quadrant, and a slight rise in temperature. When examined, there was no appendiceal tenderness. The tongue was coated, and the breath foul. The right internal inguinal ring was large

and loose; the left inguinal canal was normal. Heart and lungs, negative. Spleen not felt. No rose spots. Diagnosis, catarrhal appendicitis. Right inguinal hernia, indirect and reducible.

Operation was performed on January 25, 1909, by Dr. Frederick-Emil Neef and the writer. The incision was two inches long and coincided with the middle portion of an imaginary line passing from the pubic spine to the inner end of the outer one-fourth of the spinoumbilical line. In making the incision, care was taken not to disturb the relation of the skin to the subjacent fascia.

The aponeurosis of the external oblique muscle was exposed. The lower angle of the incision was drawn downward in the direction of the pubes by means of a narrow sharp retractor until the curve intercolumnar fibers appeared and the external inguinal ring defined. A grooved director was passed upward through the ring beneath the aponeurosis of the external oblique muscle and the aponeurosis slit in the direction of its fibers as far as the upper angle of the skin incision.

The aponeurosis of the external oblique muscle was now lifted away from the underlying internal oblique muscle and was followed down by blunt dissection to the shelving border of Poupart's ligament. The internal ring was next exposed. The sac was readily isolated, secured, and anchored with a clamp.

Attention was then given to the appendix. The transversalis and the internal oblique muscles were separated in the direction of their fibers as performed in the classical McBurney operation. Vertical division of the peritoneum revealed the cecum adherent to the anterior abdominal wall, one-half inch external, while the lower end of the cecum, together with the appendix, were in the hernia sac. The adhesion was separated and appendicectomy done by carbolization of the stump and inversion with a purse-string suture of silk.

The vertical peritoneal incision was sutured and the hernia operation resumed. The closure of the sac was effected with a purse-string suture of silk. The redundant portion of the sac was drawn up between the peritoneal and transversalis to the intermuscular separation and sutured to the muscle. The inguinal canal was restored according to the method of Bassini, without transplantation of the cord. No. II—40 day chromicized catgut was used. After the closure of the intermuscular separation, the aponeurosis of the external oblique and the skin were sutured. On the fifth day after the operation, the sutures were removed, and on the fourteenth day the patient was allowed out of bed. Uneventful recovery.

The incision employed in this operation—two inches long—is somewhat shorter than that outlined by Torek. Poupart's ligament is easily exposed and accessible to safe suturing when the incision is accurately placed as described above.

Those who advocate the removal of the appendix through the internal ring maintain that the appendix is always accessible on account of the low position of the cecum in these cases. While this is true, it does not permit the operator to deal adequately with pericecal and appendicular adhesions. In the patient whose history is detailed above, though the cecum was displaced downward, it was relatively immobilized by firm adhesions which could not have been separated through the internal ring.

That it is not always judicious to ablate the appendix through the internal ring, is demonstrated by an unpublished case mentioned by Hutchinson,[6] in which the operator encountered difficulty in securing the stump of the appendix, and the patient died from fecal extravasation caused by slipping of the stump ligature.

An interesting group of cases of which illustrative examples have been furnished by Coley[7] and Wyeth[8] is that in which chronic appendicitis coexists with an inguinal hernia. It is here that the combined operation finds an ideal application.

DERMATOBIA NOXIALIS INFECTION:

REPORT OF A CASE CONTRACTED IN SOUTHERN MEXICO.*

By JAMES D. MANGET, M.D.,

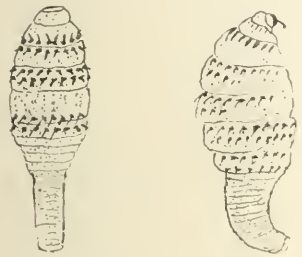
ATLANTA, GA.

J. A. M., age 38, American, resident of Atlanta. Went to Oaxaca, Mexico, in October, 1907, and enjoyed splendid health until March, 1908, when he left the city of Oaxaca and traveled about one hundred miles east, near the boundary of Oaxaca and Vera Cruz. During this trip, which was about two weeks in duration, he went in bathing nearly every day and while undressed was besieged with gnats and flies of which the country is full. Ten days after the first exposure to the bites of these insects he began to complain of general malaise and to have a slight rise of temperature. As soon as he began to suffer with these symptoms, he took full doses of quinine and kept the bowels moving freely with purgatives. He put himself under a physician's treatment about three weeks after the first exposure, when he began to have sharp lancinating pains in his shoulder and back. The pains were limited to four or five points where were located small discharging lesions resembling furuncles. His physician made a diagnosis of malaria and told him these lesions were the "malaria working out." These pains gradually increased in severity and the patient described them as being similar to pain inflicted by a punctured knife wound. The pain would only last a few seconds, but was so severe that he would jump out of bed at night, or while sitting down talking to a friend, he would have to rise suddenly from his chair. His temperature varied from 99 2-5 in the morning to 101 3-5 in the afternoon, being highest usually at 2 P. M. He was confined to his bed continuously for five days and was under "malarial treatment" and on liquid diet. He would occasionally be entirely free from fever in the morning and several times during the two or three weeks of his illness he would walk downtown and remain out of bed several hours, but would spend part of each day in bed, on account of weakness and fever. He suffered from no headache nor backache, no nose bleed nor abdominal tenderness, and no pain except

*Read at the sixth annual meeting of the American Society of Tropical Medicine, held at the U. S. Naval Medical School, Washington, D. C., April 10, 1909.

that already referred to. This pain was no worse at night than in the day, and he states that rarely was there more than one lesion actively painful at a time.

I saw the patient May 12, 1908, about six weeks after the first exposure to infection. An examination of his blood for the malarial parasite was negative, as was also the physical examination of his chest and abdomen. There were present on his back and arm five lesions located as follows: one on the posterior surface of left arm at upper third, two a little internal to the left posterior axillary fold, one over the left scapula at its upper part and one in the left lumbar region. These were situated as can be readily seen where it would have been very easy for the flies to have bitten the patient. These lesions, except the first ones mentioned, were very similar to a rather large furuncle with considerable redness and swelling, and in the center was a small round hole about the size of a pin's head through which there was a slight serosanguineous discharge. There was not the slightest pain on palpating the lesions, and patient said that when the sharp pains would come he would frequently mash them very hard without pain. The one first mentioned differed from the others in that there was practically no discharge and it had the appearance of drying up. It was hard but movable and about



Larva of dermatobia noxialis; enlarged (after Ward

the size of a buckshot, feeling like a bullet under the skin. This lesion had not given him any pain for ten or twelve days before I saw him. I was unable then to diagnosticate the trouble, but decided that the places should be freely incised and drained, but as the lesion just mentioned was so circumscribed, I decided to excise the entire mass and with cocaine anesthesia I dissected out what appeared to be a small fibrous tumor that was very adherent to the surrounding tissue. Before incising the others I cut open the mass and found a small larva which I decided by comparison later was undergoing a chrysalis formation. The other lesions were then incised and with slight pressure there was easily expressed a motile larva out of each lesion. The other larvæ though different in size had the following appearance: on the pear-shaped segmented bodies, which averaged in size that of a pea, there were three transverse rows of dark hairlike projections. The head, which could be thrust out or drawn in at will, was armed with two branched hooklets which evidently caused the intense pain while the larvæ were in their host. The tail was elongated and formed the stem of the pear-shaped body. This part, I was afterward told, sometimes protruded through the small opening in the skin. My patient had no unpleasant symptoms after the larvæ were removed and in a few weeks made a complete recovery.

After a consideration of this case and the literature at our command it would seem that we were dealing with a case of cutaneous myasis caused by the larvæ of the biting fly *Dermatobia noxialis*.

It appeared worth while to report the case (1) on account of the infection occurring to a citizen of the United States. (2) Because of the acute suffering and systemic effect produced by the lesions. In the literature consulted there was found no case that presented the systemic disturbance and distressing symptoms as did our patient. (3) The means of communication between the United States and other countries are continually improving and the number of people who travel in tropical and sub-tropical lands is increasing year by year, consequently the comparatively rare diseases likely to be contracted in these parts should be better known so that travelers may be warned of the dangers of exposure to biting flies and also that other patients who have contracted cutaneous myasis may be spared unnecessary suffering through failure of physicians to recognize the cause.

This report should have been accompanied by the larvæ that were removed, but unfortunately the specimens were lost. The description has been made by one who lays no claims to be a zoologist; the endeavor having been made to be practical rather than scientific.

I am indebted to Dr. J. E. Paullin for his help in enabling me to recognize the nature of the larva and to Dr. O. T. Logan for suggestions and help in looking up the literature on the subject.

SOME PRACTICAL POINTS CONCERNING THE TREATMENT OF FRACTURE OF THE LOWER END OF THE RADIUS.

By ERIC CARL BECK, M.D.,

NEW YORK.

INSTRUCTOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, ASSISTANT SURGEON TO THE ST. MARK'S HOSPITAL AND THE GERMAN POLIKLINIK.

In large cities like New York, where thousands are employed at manual labor, we are liable to find at least three or four cases of fractured radii among the patients that attend the surgical clinics every week. Naturally this particular form of fracture becomes familiar to the physician in charge, and its treatment simple if not systematic.

The first thing we learn is to look upon all injuries to the wrist, even so-called sprains, as suspicious. How many cases of sprain have been permitted to transmigrate into that vast domain of mal-united fractures simply because the examining physician was so sure of his diagnostic abilities that

not even the ensuing osseous deformity and resulting functional disability were able to convince him of his error! The patient will note the appearance of his useless member and, becoming doubtful of his medical councilor's abilities, will seek out his colleague who must necessarily confirm the patient's doubt.

The greatest lessons have been learned by committing errors. Then why should one error excuse another? An honest error is pardonable, and, if the physician is honest, he will admit that error to himself, and learn thereby.

The simplest mode of gaining a definite and exact opinion of any injury involving bones or joints, is by the use of the *x*-ray. But how many physicians are familiar with the intricacies of the apparatus, its moods and caprices, and how many are able to purchase and maintain one? It is still a luxury to many, and but a toy to others. This paper is addressed to those who practice away from the cities, to those who must render assistance far from the possibilities of the *x*-ray. I do not wish to be understood as though the points to follow will always bring about infallible or perfect results, but they are given with the idea of obtaining functional results, the most important detail to the man who who must earn his bread by the sweat of his brow and the toil of his hands.

The main object to attain is the reproduction of the normal, the natural condition. As nature made man, so he is physically perfect. We cannot improve thereon, but we can imitate. That is the key-note of this treatment, the imitation of natural conditions.

A man has fallen on his outstretched hand. It becomes swollen, painful, and discolored. He is unable to move his wrist, unable to close his hand or rotate his forearm. He is liable to come to the doctor, as is usual, with a home-made diagnosis of "sprain."

Examination is painful and reveals no crepitus. The swelling hides the deformity. If the fragments are impacted, it is sometimes impossible to make a positive diagnosis. Then why make a brutal error when it is possible to circumvent one by being rather too careful than otherwise? Treat the injury as though it were a fracture, and even if it be only a sprain the result will be as good if not better, and the few days more of enforced inactivity will not be counted among those lost. The patient will be grateful for his physician's anxiety, and the physician will only gain by the benefit of the doubt.

Sometimes it is possible to diagnose a fracture of the radius by simply everting the hand, as this procedure will magnify the deformity and facilitates digital examination. If the displacement is marked it can easily be felt on the flexor surface of the radius. Even crepitus may be elicited in this position by using the thumb and forefinger and exerting decided counter-pressure.

The patient should be placed on his back. It keeps him and his body quiet, and precludes the possibility of aerial gymnastics on the part of the surgeon. Let one assistant firmly hold the upper arm down upon the table, exerting counter-extension at the same time. This is most easily done by placing the hand over the shoulder into the axilla, where the fist will act as an efficient lever. The other hand can be used to keep the arm upon the table. The second assistant should hold the thumb and fingers of the patient, having first rotated the forearm so that the palm points upward. This rotation serves two purposes. Firstly, it places the ulna and radius in their natural relations to one another, replacing the radius to the position of its greatest length, parallel to the ulna, and secondly it permits of easier manipulation during the procedure of replacement.

The greatest tension should be exerted upon the thumb, as by its means the direction of the head of the radius is best regulated. The thumb should be held between the crooked first and second fingers, as it can be held more firmly and for a longer time. With the other hand the assistant should adduct the fingers toward the ulna. This maneuver projects the carpus and throws the head of the radius still further forward. Thus sufficient play between the fragments is provided so that there is no great difficulty in restoring the continuity of the bone.

While the assistants continue to hold the arm firmly in the corrected position, a plaster of Paris bandage is applied. Starch bandages may also be used—they are not so heavy— but should be applied rather loosely as they have a tendency to shrink and cause extremely painful edema. The application of cotton or gauze bandages upon the skin is not necessary, but simply facilitate the removal of the dressing later on. There is no danger of pressure gangrene or atrophy if the displacement has been corrected. The edema is caused by the ragged edges of the bone and as soon as the normal condition is restored, the injuries to the soft tissues take care of themselves.

A word as to the length of the bandage. It should reach up as far as the second phalanx of the fingers, and back beyond the olecranon process of the ulna at the elbow. As soon as the plaster has hardened at the wrist, it is advisable to mould the palmer end of the bandage so that the fingers are in a state of semi-flexion. This is the position of the hand and fingers during all states of rest and relaxation, and I find that they are consequently more liable to retain their movability after the dressing has been removed.

This bandage should stay on for at least ten days, when it may be removed and a smaller and lighter bandage applied. Passive motion may be begun after seventeen or eighteen days, and the functional result should be complete four weeks after the date of the injury.

If the patient complains of great pain after the application of the first bandage, the probabilities are that the reduction was only a partial one. This is a valuable sign, and should not be taken lightly. The bandage is to be removed and re-applied.

Of course there are cases where periosteal flaps will intervene between the ends of the bone and frustrate every effort of nature toward complete bony union. Then the only rational thing to do is to cut down and suture the fragments together. Sometimes it is sufficient to suture the periosteum over the divided shaft of the bone, and at other times it is necessary to wire the head to the shaft. It is a lamentable fact that after the removel of the wire suture a local necrosis of bone often persists for a long time, and the question is still a mooted one whether to leave the wire in, take it out, or try strong silk. I distinctly recollect several cases during my activity at the Royal Clinic of Berlin, in which Prof. von Bergmann used strong silk in bone injuries and left them there with excellent result. This matter may be left to the discretion of the surgeon.

An interesting point in statistics may be of value. I have found in all cases of fractures, covering a period of six years, that the typical fracture of the radius is extremely rare in individuals below nine years of age. In children below nine both bones of the forearm are usually broken.

CONTRIBUTION TO THE STUDY OF THIOSINAMINE IN OTOLOGY.

By FRANCISCO M. FERNANDEZ, M.D.,

HAVANA.

For the past eight months we have been experimenting with thiosinamine in the treatment of chronic adhesive otitis media, and although our experience is short and the cases few, the results have been so uniform that we feel justified in making some remarks about this drug, which has, with or without reason, awakened widespread enthusiasm in several branches of medicine, but especially in otology.

It is well known that to this drug is attributed the power of softening the cicatricial tissue. This was discovered by von Hebra while he was using it in the treatment of lupus. It has been used with regular success at times, in the treatment of cicatricial contractures of the esophagus and rectum and lately it has been tried in urethral stricture.

Tousey in 1897 first used thiosinamine in otology, and Tapia in 1903 made extensive experiments with the drug. This drug does not give good results in any otitis outside of the adhesive variety, but it has been successful in some cases of the adhesive otitis.

We have, however, used thiosinamine associated to antipyrine (according to Mitchel's prescription) in six cases of adhesive otitis, and the results have been far from satisfactory.

The first three cases were in young, robust men, and able to support the drug pretty well at the beginning of the treatment; but there were lancinating pains in the ears and although the suppuration did not return I did not feel justified in using the drug again. These three cases had been for over three months without suppuration and with no symptoms outside of the deafness which was marked in all of them.

The fourth case was that of a lady of advanced age, suffering from adhesive otitis, of a very chronic character. In her case, after three instillations it was necessary to stop the use of the drug on account of the severe pains which it caused.

Case fifth was that of a young man about 30, who had had no suppuration for six weeks previous to the beginning of the treatment. I began to use the drug, taking especial precautions, and after two weeks of instillation I also practised tympanic massage. One week after, the suppuration was reestablished, and I had to stop the use of the drug on that account, and also because there was some pain in the ear.

The last case was almost identical with case fifth, and the patient is at present under treatment for the suppurative discharge caused by the drug.

As I said before, the results in these experiments were not very encouraging. It is asserted, however, that a combination of thiosinamine and sodium salicylate is less apt to provoke these accidents than when thiosinamine is used alone; I propose to experiment with this combination before rejecting the drug altogether.

Dirty Milk.—It has been estimated that each year the inhabitants of Berlin consume more than twenty tons of cow manure in their milk.—*Good Health.*

Blastomycitic Dermatitis in the Philippines.—Blastomycitic dermatitis, first described by Gilchrist of Baltimore and considered a very rare disease, is very prevalent in the Philippine Islands.

Vegetarianism for Inebriates.—In their Home for Inebriates the Salvation Army provides a meat-free diet. It has been noticed there that animal food tends to increase the craving for stimulants, and that the patients do better on a diet of fruits and vegetables.

The Lower Segment of the Uterus.—Cyrille Jeannin distinguishes the inferior segment of the uterus as the isthmus, or lower third of the fundus. It is of great importance pathologically and normally in pregnancy. Its walls are much thinner than those of other portions of the uterus. In front it is thinner than behind. Its lower limit is the internal os. Its thinness predisposes to rupture of the uterus. Its form varies with the presentation of the fetus. During pregnancy it lends itself to the development of the fetus by stretching. By some it is supposed to be the cause of the beginning of labor. Its dilatation by a rubber balloon is a most efficient means of inducing labor. In the early part of labor it contracts, but later remains inert. During pregnancy the implantation of the ovum on this segment is a frequent cause of abortion and of hemorrhage in placenta previa. During labor the adhesion of the ovum to this segment is a cause of very slow dilatation of the cervix.—*La Presse Médicale.*

Diagnostic Importance of Examination of the Feces for Tubercle Bacilli in Infants with Pulmonary Tuberculosis.—Nicolo Serio-Basile notes the difficulty of early diagnosis of tuberculosis, especially in children who do not cough and expectorate. The author has attempted to examine for the tubercle bacillus in the feces of such infants in the hope of obtaining evidence of their presence in the lungs. He finds that in spite of the technical difficulties of such examination, important evidence of the presence of tuberculosis may be obtained from the feces. The bacilli may pass all the way through the intestinal canal without being altered morphologically or pathogenically. They appear in greater numbers when there is a lesion of the intestinal mucous membrane, and in smaller numbers when the lesion is in the respiratory apparatus. The tubercle bacilli may be absent in the feces of infants who swallow the sputum from pulmonary lesions. This method of examination is of diagnostic value in positive cases, but as negative evidence against tuberculosis it is valueless.—*La Pediatria.*

Nongangrenous Fetid Bronchitis.—E. Gaujoux gives two cases of fetid bronchitis in children, one of which was fatal. He believes that this disease in children differs from that of adults in that there is present no gangrene of the lung tissue. The fetid odor of the expectoration is due to the stagnation of the mucopurulent expectoration, there being no elastic fibers found in it. The disease may be mild and subacute or severe, and finally fatal (in young infants). These infants are too young to cough, and the expectoration is swallowed. High fever ensues as a result of toxins produced, and a septic condition develops with emaciation and cachexia. Gastrointestinal symptoms accompany these cases. Researches have not been made to determine whether there is a specific bacterial action to produce the fetidity. The treatment involves facilitating the expectoration by expectorants and the use of balsamics to disinfect the sputum. General tonic measures and fresh air are necessary to obtain a cure.—*Annales de Médecine et Chirurgie Infantiles.*

Pericardial Adhesions of Tuberculous Nature and Cirrhosis of the Liver in Children.—Hutinel describes a somewhat rare condition in which a tuberculosis of the bronchial and mediastinal glands is communicated to the pericardium, producing adhesive pericarditis. Later cirrhosis of the liver follows, accompanied by ascites, and a fatal issue from heart failure ends the case. He calls it cardiotuberculous scirrhosis. It begins sometimes insidiously with bronchitis and wasting. At other times it is more acute, and begins with a pleurisy. Hypertrophy of the liver follows, the consistency of the organ being firm. Then appear circulatory troubles. The lips become cyanotic and the face violet, as in congenital heart trouble. There is dyspnoea, but no cardiac signs can be elicited. The urine is abundant and albuminous. The tuberculous condition has remained latent, and it is the liver signs that attract all attention. The pleura and pericardium are adherent, and the heart apex does not move with the beat. Treatment has so far failed to prevent a fatal issue.—*Le Bulletin Médical.*

MEDICAL RECORD.

New York, June 26, 1909.

THE WAR AGAINST TUBERCULOSIS IN GREAT BRITAIN.

PROBABLY, although it is practically impossible to obtain absolutely accurate statistics on the subject, there exists more tuberculosis in the British Isles than in any other quarter of the globe. Tuberculosis in all its forms is remarkably rife in the United Kingdom, this condition of affairs being mainly due to the fact that the bulk of the population live in crowded centers, and under circumstances not conducive to the preservation of good health. Urban life is, in the nature of things, favorable to the spread of tuberculosis and when, in addition, ignorance as to healthy living is manifested among the majority of the members of the poor and lower middle classes, as it is manifested in Great Britain, then it can be no matter for wonder that tuberculosis is widely disseminated. While this disease is the cause of a terrible death roll, it cannot be said that British medical men and philanthropists have been unmindful of their responsibilities in this respect. During recent years strenuous efforts have been put forth to stay the course of the disease and, if possible, to stamp it out. The steps taken have been attended undoubtedly with a fair measure of success, but after all it is only a beginning that has been made, and continued and more persistently earnest attempts must be exerted ere the end is in sight.

On June 2, Mr. John Burns, the well-known English cabinet minister, himself born in poverty, and a working man, opened in the East End of London a series of consumption exhibitions, modeled after those with which we are familiar in this country, organized by the National Association for the Prevention of Consumption, which are being held throughout the country for the purpose of educating the nation as to the steps that should be taken to combat the disease. Mr. Burns, who seemed to have the chief details regarding tuberculosis at his fingers' ends, made a telling speech in which he pointed out that during the past forty years the incidence of tuberculosis had decreased some 50 per cent. and that during the past five years the greatest progress of all had been made, by means of the education of the people. Some of the statistics given by the speaker to drive home his remarks to his audience were strikingly illustrative. Among them were the following: Every year the world loses five million people on account of tuberculosis. In London alone there is a yearly death-rate of 9,176, a number larger than the total of the officers and men who fell during the three and a quarter years of the South African War. Consumption preys especially on the lower classes. It is the daughter of ignorance, the offspring of drink, and the product of carelessness. The text of Mr. Burns' speech was that education as to the means of fighting tuberculosis was particularly needed among the poor, and the statement in reference to consumption applies to every civilized country of the world. Mr. Burns said that there were a number of common-sense, homely things which might be done. In the workingman's home his stove register was nearly always shut; it ought to be open to take the air from the floor. In too many houses the windows were never opened. Then there was the enormous danger of the baby's comforter and soother. It was necessary, also, to get rid of the damp and dirty basements which had made so many consumptive servants, and to abolish the one-room tenement.

THE WIDER APPLICATION OF BRONCHOSCOPY.

IN the *British Medical Journal* of May 29 appears some very suggestive correspondence in reference to the application of the methods of bronchoscopy and tracheoscopy for other purposes than for the detection of foreign bodies only, the contributors discussing the value of the procedure in the investigation of cases of limited bronchiectasis of obscure nontuberculous origin. Associated with this is the advisability of making a Roentgen-ray examination of every child presenting limited bronchiectasis. One writer suggests the value of such examination in any case presenting anomalous chest symptoms. Those who have become practised in the use of the new instruments agree in saying that the technique is not difficult to acquire particularly by those accustomed to throat work, needing only a little skill, patience, and attention to details. Perhaps the wish is father to the thought in a statement so phrased, but it is safe to say that the method is not outside the possibility of attainment by the average physician.

One writer calls attention to the fact that a view of the interior of a bronchus by direct inspection affords us much more information than an examination by the indirect method, and he regularly uses the direct method in the investigation of bronchial affections. A case of supposed bronchitis and asthma was thus shown to be due to a new growth. Still another writer says that, rightly or wrongly, some think that no value whatever is to be placed on a negative history as to the ingestion of a foreign body in a young child, and experience confirms this view. Further, many regard it as an axiom in physical diagnosis that in one-sided lung disease with copious foul expectoration (more especially if there are signs of a cavity), the presence of a foreign body in a bronchus or bronchiole should be suspected, and its presence or absence proved by every means available, that is, radioscopy and

bronchoscopy. Some of the conditions in which bronchoscopy has given the greatest assistance, in either diagnosis or treatment, are tracheitis, tracheal papillomata, tracheal and bronchial ulceration and stenosis, adherent diphtherial membranes, inspissated secretions and crusts in the trachea and bronchi, and esophageal growths, aneurysm, thyroid and thymus tumors as causes of dyspnea from pressure on the trachea. A recent case has been reported in which a diagnosis of dilatation of the aorta was proved by tracheoscopy alone, there being no other physical signs. Over and above all remains the fact that in case a foreign body is demonstrated in the air passages or symptoms suggest its presence, immediate action is necessary, first the *x*-ray plate and the direct inspection and removal. Delay is doubly dangerous in case of organic bodies which may enlarge by imbibition of moisture.

MEDICAL EXPERT TESTIMONY.

Much has been said and written on the subject of the medical expert in court, especially from the standpoint of the physician, but the lay and judicial opinions have not as a rule been based on facts and first-hand knowledge. It is, therefore, with great gratification that one reads in the June *North American Review* a concise statement of the matter from the pen of Supreme Court Justice Clearwater, Chairman of the Committee of the New York State Bar Association appointed to consider the regulation and introduction of medical expert testimony. Judge Clearwater's high standing as a jurist gives to his words the full weight of authority, while his responsible position as chairman of the committee above mentioned certainly puts him in immediate command of the facts. All efforts to remedy the present unsatisfactory status of the medical expert have failed, up to the time of the appointment of the commission, because many, both lawyers and physicians, have fought against any change.

One of the existing evils, and the first one named in Judge Clearwater's paper, is the lack of standard as to expertness. This was well exemplified in a recent notorious trial in which one of the medical witnesses proved his incompetence by foolish and ignorant answers to the simplest questions. Still he went on the stand as an expert. Other evils of the present system as named in the Judge's essay are the giving of partisan evidence; contradictory testimony from physicians in equally good standing; unprincipled self-styled experts; trial Judges who are incompetent to pass on the ability of experts or the validity of their opinions; payment of witnesses by the litigant, and consequently the employment of the best experts by the litigant with the longest purse; the contemptuous treatment some experts have received at the hands of rude and unscrupulous lawyers; and most of all trial judges who have sought to draw attention to themselves by their manner of admitting evidence of bad quality. In order that the ends of justice and truth may prevail, "the expert witness should be free from embarrassment, should have no clients to save and no partisan opinions or interests." He should speak judicially as an exponent of the science of medicine, with full knowledge of the highest authorities and of the most recent investigations dealing with his subject. Cross-examination plays havoc with the expert because of his personal embarrassment when he is called as one high in authority, and because of unfair attempts of the opposing lawyer to "rattle" him. Says Judge Clearwater: "Scientific opinion to be of controlling value can be given only under conditions of mental repose," which is seldom possible, we may add, in the witness box.

Some newspaper writers have promulgated false views of the expert's position because of their unacquaintance with judicial proceedings, and first of these is the erroneous statement that the calling of expert witnesses is of recent origin. As far back as 1532 Charles V of England in his published Code gave power to appoint expert physicians and surgeons for the examination of injured patients before the court. And this is probably not the first instance. Then too the ordinary witness and his function is mistaken for that of the expert. "The ordinary witness testifies to facts; the expert witness to opinions." The expert should not form his judgment from the evidence of witnesses, and should not draw inferences from their statements. "The only legal method is to frame a question upon assumption that certain facts are true, and then to ask the witness, assuming they are true, his opinions concerning them. While the hypothetical question seems involved, the method pursued is scientific and calculated to eliminate the element of error so far as it is possible to do so."

Direct examination of the accused and the passing up by the expert of an opinion in writing is not either desirable or tenable. The sixth amendment to the Federal Constitution granting to the accused the right to be confronted by the witnesses against him makes any such provision unconstitutional and would lead to a mistrial. Every party has a right to call witnesses desired and to cross-examine them as seems necessary. In civil actions the deposition of a witness whose attendance in court is impossible may be taken by commission, and on application of the accused may be so taken in criminal actions, but the right to cross-examine remains. The hope is expressed in conclusion that the present efforts of the committee appointed by the Bar Association may prove fruitful. "Medical expert testimony long has been a necessary and always will be an important factor in the administration of justice. It will require time and effort to restore its sullied luster, but the aim justifies the struggle." We commend the reading of Judge Clearwater's paper by all physicians who are interested in the problems of medical jurisprudence.

The Cammidge Test in Gallstone Disease.

A subject about which opinions differ perhaps as widely as any on the border line of medicine and surgery is that of the indications for operation in the milder cases of gallstone disease. Some physicians urge universal operation as soon as the diagnosis of cholelithiasis is made, in order to forestall

serious complications; others prefer to wait until there are definite signs of pus in the liver or gall-bladder before using the knife; while probably the majority of surgeons tread a path between these two extremes and are often in doubt as to the advisability of turning to surgery or continuing with medicinal treatment. In an article in the *Münchener Medizinische Wochenschrift* for May 25, 1909, Kehr discusses at some length the intermediate cases of gallstone disease in which an occasional acute attack is succeeded by weeks or months of mild discomfort. In such cases Kehr lays considerable weight on the condition of the pancreas as shown by the Cammidge test. When this organ is normal he is inclined to trust to nature, rest, baths, and medicine, whereas if the Cammidge test is positive, he advises operation. As to the accuracy of the Cammidge test, Kehr reports thirty-two gallstone cases in which it was used. Of these twenty-five were positive and seven negative. Of the positive cases eighteen came to operation and it was found that seventeen had chronic pancreatitis and one carcinoma of the gall-bladder. In the negative cases four operations were performed and all showed the pancreas to be normal. Only once did the test go radically wrong. In this case, after a negative reaction, an acute suppurative pancreatitis was found. It is quite possible that the Cammidge test, while an accurate indication of chronic pancreatitis, does not apply to an acute inflammation of the organ. Kehr is a man of wide experience in gall-bladder surgery and his opinion carries much weight. The making of the Cammidge test is unfortunately a long, delicate procedure, and is therefore hardly practical outside of a hospital or in the hands of any but a skilled medical chemist.

Simplicity in Treatment.

The ideal of the therapist has always been to select such remedies as would cure safely, quickly, and pleasantly, though it must be confessed that some of our medical forefathers, if we may judge from the concoctions they employed, did not regard so much the third of these requisites as they did the first two. Neither did they appreciate the fact that these three virtues in a remedy often depended upon a fourth, namely, simplicity, and many of their successors seem to be as little mindful of this great truth. This thought is suggested by a brief paper by George Thomas Jackson, in the June issue of the *American Journal of the Medical Sciences*, on the treatment of boils. Many more or less elaborate methods of treating boils are employed, but the most common one is probably the application of heat by a poultice or one of its more cleanly substitutes, followed by an incision and the forcible evacuation of the pus. When a crop of boils follows, as it often does if poultices are used, resort is had to calcium sulphide or some other form of constitutional treatment, or to the latest refinement of an autogenous vaccine preceded by the estimation of the opsonic index. Jackson's treatment is to puncture the boil, when it points, by a sharpened stick wound round with a little absorbent cotton dipped in 95 per cent. carbolic acid; he then washes the surrounding skin with peroxide of hydrogen or a sublimate solution, and applies a salicylic acid ointment. The result is a cure obtained safely, quickly, and pleasantly, because simply. There is no objection, of course, to making a culture from the pus or to taking the patient's opsonic index, and the information so obtained may be useful as a basis for further treatment if the first essay fails; but the simple treatment should not be made to wait upon the results of the laboratory investigation. It does not require much effort to think of other local diseases which may be promptly overcome by equally simple local remedies without recourse to an elaborate and roundabout constitutional attack.

News of the Week.

Examination for Physician (Male) in the Panama Canal Service.—The United States Civil Service Commission announces an examination on July 21, 1909, at the usual places for such examinations, to secure eligibles from which to make certification to fill vacancies as they may occur in the position of physician, at $150 per month, in the Panama Canal Service. Applicants must be citizens of the United States, graduates of recognized medical schools, and have had at least one year's experience as interne in a general hospital. Persons lacking the above qualifications will not be admitted to the examination. Men only will be admitted to this examination. Age limit, twenty to forty-five years on the date of the examination. Applicants should apply either to the United States Civil Service Commission, Washington, D. C., or to the secretary of the board of examiners at any of the usual places for Civil Service examinations, for application Form 1312. No application will be accepted unless properly executed and filed with the Commission at Washington prior to the hour of closing business on July 10, 1909.

Pathologist, Freedmen's Hospital.—The United States Civil Service Commission announces an examination to be held on July 14, for the purpose of securing eligibles to fill a vacancy in the position of pathologist (male) at the Freedmen's Hospital, Washington, D. C., at a salary of $2,000 per annum. Applicants must have had at least one year's experience in a pathological laboratory after graduating from a reputable medical college, and must be qualified to make all kinds of pathological examinations. Application should be made at once to the United States Civil Service Commission, Washington, D. C., for Form 1312.

Commencement Exercises.—Eight students were graduated from the Willamette Medical College, Salem, Oregon, on June 2, the degrees being conferred by President Fletcher Homan of Willamette University. The College of Physicians and Surgeons of Boston graduated a class of thirteen students who had completed a four-year course, the degrees being conferred by Dr. C. C. Farnham in the absence of the president of the college. Dr. Charles H. Hughes, dean of the Medical Department of Barnes University, St. Louis, delivered the address to the class.

Tufts Medical College.—Announcement was made at the annual dinner of the Alumni of Tufts College, Boston, on June 8, of the appropriation of $100,000 by the trustees of the college for the purpose of enlarging and remodeling the school buildings.

Cornell University Medical College.—The board of trustees of Cornell University has announced the following appointments in the medical department in New York: Dr. Frank Sherman Meara, Professor of Therapeutics and Clinical

Medicine; Dr. Charles N. B. Camac, Professor of Clinical Medicine; Dr. William J. Elser, Professor of Bacteriology; Dr. John A. Hartwell, Professor of Clinical Surgery; Dr. William B. Coley, Professor of Clinical Surgery; Dr. Silas P. Beebe, Assistant Professor of Experimental Therapeutics, and Dr. John R. Murlin, Assistant Professor of Physiology.

Brown University Confers Degrees.—Dr. William Crawford Gorgas, a member of the Isthmian Willis G. Macdonald of Albany, members of the Canal Zone, and President of the American Medical Association, and Dr. Charles Value Chapin, Health Officer of Providence, R. I., received the honorary degree of Doctor of Science at the commencement exercises of Brown University on June 16. Dr. Chapin was professor of physiology at Brown from 1886 to 1896.

State Board of Medical Examiners.—The New York State Board of Regents on June 17 appointed Dr. William H. Park of New York City and Dr. Willis G. Macdonald of Albany, members of the State Board of Medical Examiners. Dr. William S. Ely, whose term expires on July 31, 1909, was appointed to succeed himself.

Strange Disease Among Sailors.—A number of sailors on vessels at the port of Philadelphia have been found suffering from an inflammatory affection of the skin attended with the formation of wheals and vesicles. Investigation disclosed the fact that they all slept on mattresses made of straw from several sources, and that the disease could be developed by exposure of the skin to such straw. To determine whether the disease is infectious and transmissible or not, Dr. J. F. Schamberg, assistant diagnostician to the Bureau of Health, has permitted himself to be inoculated with the contents of vesicles developed in Dr. Joseph Goldberger, assistant surgeon of the U. S. Public Health and Marine Hospital Service, and specimens of the straw have been sent to the Hygienic Laboratory of the service for study.

Plague in China.—During the fortnight ending June 14, 131 deaths from bubonic plague were reported from Amoy, China, and much larger figures are reported from some of the interior towns.

Pure Milk.—The New York Milk Committee of the Association for Improving the Condition of the Poor is forming a company for the operation of a "model dairy" and to demonstrate that clean milk can be supplied to the consumer at the present market rates. It is believed that the use of the latest designs of apparatus will effect a saving which will more than offset the increased cost of production under perfectly safe conditions.

Measures to Reduce Infant Mortality.—The Chicago Health Department has inaugurated a campaign to safeguard the lives of infants in Chicago during the summer. One of the first things to receive attention is the milk supply, and food contamination is to be considered. Nurses are to be provided for children who are seriously ill; medical attention is to be urged for the ailing; mothers will be instructed with regard to proper clothing, care, and food of children; day nurseries are to be established, and tent hospitals for babies will be provided in the Eighth, Sixteenth, Seventeenth, Nineteenth, and Twenty-ninth Wards.

Change in Names of State Hospitals.—The State Hospital for the Insane at Bartonville (Illinois), which was first known as the Illinois Hospital for the Incurable Insane, and later as the Illinois General Hospital for the Insane, will now be known as the Peoria State Hospital. Other State hospitals for the insane will hereafter be known as the Jacksonville State Hospital, Watertown State Hospital, Kankakee State Hospital, and Elgin State Hospital.

Beth Israel Hospital.—Dr. Sidney A. Stein, Dr. H. Fred Lange Ziegel, and Dr. David Sheitlis have been appointed adjunct visiting physicians to Beth Israel Hospital. Dr. Eli Moschcowitz has been appointed pathologist to the same institution.

The Chicago Eye, Ear, Nose, and Throat College has completed an annex on Washington street, doubling the capacity of the institution.

Dr. Owen Copp, Secretary of the Massachusetts State Board of Insanity, has been appointed superintendent of the Boston State Hospital, formerly the Boston Insane Hospital.

Dr. F. Kreissl has been appointed attending surgeon to the genitourinary department of the Columbus Hospital.

The Harvey Society Lectures.—The Council of the Harvey Society calls the attention of the medical profession to the permanent value of the lectures collected in the volumes published by the society. Founded to promote the diffusion of such knowledge, it is the aim of the Harvey Society to make its publications accessible to as wide a circle of readers as possible. To further this object the council has decided to invite those in sympathy with it in this endeavor to subscribe to the collected lectures in book form, at a price merely sufficient to defray the costs of publication. Two volumes have already appeared, a third will soon be issued, and a fourth is about to go to press. Subscriptions to the volumes already published or in press may be sent to the secretary of the Harvey Society, Dr. Francis Carter Wood, 437 West Fifty-ninth street, New York.

Rush Medical Alumni Association.—At its tenth annual meeting and dinner, recently held, the class of 1909 elected the following officers: *President,* Dr. Harry C. King, Fort Smith, Ark.; *Vice-President,* Dr. Stephen E. Gavin, Fond du Lac, Wis.; *Secretary-Treasurer,* Dr. John B. Ellis, Chicago; *Historian,* Dr. B. H. Breakstone, Chicago.

American Academy of Medicine.—At the annual meeting of this society, held at Atlantic City June 5 and 7, 1909, the following officers were elected: *President,* Dr. James H. MacBride, Pasadena, Cal.; *Vice-presidents,* Drs. Philip Zenner, Cincinnati; W. Blair Stewart, Atlantic City; Ruth Webster Lathrop, Philadelphia, and H. W. Loeb, St. Louis; *Secretary and Treasurer,* Dr. Charles McIntire, Easton, Pa.; *Assistant Secretary,* Dr. Alexander R. Craig, Philadelphia.

Chicago Surgical Society.—At the annual meeting, held June 18, the following officers were elected for the ensuing year: *President,* Dr. Arthur Dean Bevan; *Vice-president,* Dr. Jacob Frank; *Secretary,* Dr. Frederic A. Besley; *Treasurer,* Dr. Wm. M. Harsha; *Councilor of Chicago Medical Society,* Dr. Carl Beck.

Chicago Medical Society.—The annual meeting of this society was held June 10, when the following officers were elected: *President,* Dr. John A. Robison; *Secretary,* Dr. George F. Suker.

The Maine Homeopathic Medical Society held its forty-third annual meeting at Augusta on June

8, when the following officers were elected: *President,* Dr. John T. Palmer, Portland; *Vice-presidents,* Drs. William H. Kennison, Madison; George H. Rand, Livermore Falls; *Recording Secretary,* Dr. Luther A. Brown, Portland; *Corresponding Secretary,* Dr. Carrie E. Newton, Brewer; *Treasurer,* Dr. William S. Thompson, Augusta.

The Orange County (Cal.) Medical Society at its annual meeting on June 2 elected the following officers for the ensuing year: *President,* Dr. J. L. Beebe, Anaheim; *Vice-president,* Dr. C. C. Violett; *Secretary,* Dr. Ida Parker, Orange; *Treasurer,* Dr. H. S. Gordon, Santa Ana; *Librarian,* Dr. C. D. Ball, Santa Ana.

The Minnesota State Medical Association will hold its annual meeting at Winona in October, 1909.

Obituary Notes.—Dr. Edmond Montgomery Moffett of West New York, New Jersey, died at his home on June 12, aged sixty-one years. Dr. Moffett was graduated from the medical department of the University of New York in 1882, and had practised in this city until about six months ago.

Dr. C. Eugene Gunther of New York died at his home after a short illness on June 12, aged forty-eight years. Dr. Gunther was a graduate of the Long Island College Hospital, class of 1880, and was for some years a professor in that institution.

Dr. Richard E. Haughton of Richmond, Indiana, died at his home from chronic bronchitis on June 4, aged eighty-one years. Dr. Haughton was graduated from the Jefferson Medical College of Philadelphia in 1861. In 1874 he was made professor of physiology in the College of Physicians and Surgeons of Indianapolis, and in 1879 became one of the founders and a professor in the Central College of Physicians and Surgeons. He had been a member of the American Medical Association since 1857, and was also a member of the State and County Medical Societies, and of the Mississippi Valley Medical Association.

Dr. Pliny Rand Watts of Sacramento, Cal., died on June 1, following an operation for appendicitis, aged forty-five years. Dr. Watts was graduated from the New York Homeopathic Medical College in 1887, was at one time president of the California State Homeopathic Medical Society, and was attending surgeon to the Sutter Heights Hospital of Sacramento.

Dr. Valery O. Schayot of New Orleans, La., died on May 29, of pneumonia, aged thirty-nine years. He was a graduate of the medical department of Tulane University, New Orleans, and a member of the Louisiana State Medical Society.

Dr. Joseph L. de Varona of Brooklyn, N. Y., died on May 29, aged twenty-eight years. Dr. de Varona was graduated from Cornell University Medical College in 1905. He was visiting physician to the genitourinary department of the Williamsburg Hospital, assistant cystoscopist to St. Catherine's Hospital, and a member of the staff of St. Vincent's Hospital, Brooklyn.

Dr. Hugh Ferguson of Boston, Mass., died at his home on June 13, aged seventy-three years. Dr. Ferguson was graduated from the medical department of the University of New York in 1858, and immediately returned to Boston where he had since practised. He became a member of the Massachusetts Medical Society in 1858, and was made an attending physician to the Carney Hospital in 1868, a position which he held until he retired from active work in 1905. He was also a member of the American Medical Association and of the South Boston Medical Society.

Dr. I. S. Curtis of Brunswick, Maine, died at his home on June 9, aged seventy years. Dr. Curtis was graduated from Bowdoin College in 1867, and from the Maine Medical School in 1872.

Dr. Joseph Spiegelhalter of St. Louis, Mo., died at his home on June 7, aged seventy-four years. Dr. Spiegelhalter, who was born in Germany, came to this country in 1854, and after a short service in the Union Army was graduated from the Humboldt Medical Institute of St. Louis in 1862, after which he again entered the army. At the close of the war he began his practice in St. Louis, where he served as health officer in 1865, and as coroner from 1866 to 1870. He was a member of the American Medical Association, the St. Louis Medical Society, the American Association for the Advancement of Science, the American Public Health Association, and the St. Louis Microscopical Society.

Dr. Andrew M. McCabe of Pittsburg, Pa., died after a short illness, on June 13, aged thirty-eight years. He was graduated from the medical department of the Western University of Pennsylvania in 1867.

Correspondence.

THE SUPPRESSION OF YELLOW FEVER IN CUBA.

To the Editor of the Medical Record:

Sir: I feel very sure that no one more than yourself would be anxious to correct any injustice committed by your publication as a result of erroneous information. Your correspondents in Cuba have not reported correctly the yellow fever situation in that country. The crowds of tourists that you speak of in your editorial of June 5 came this spring, and remained much longer than usual because the United States did not quarantine against them. They are proof that there was no yellow fever in Cuba.

The seeds of the fever, as you call them, are not lurking there. The last case of yellow fever occurred in December of last year. I am myself, perhaps, one of those most responsible for giving the mild, unrecognized cases of acute infectious diseases the capital place that belongs to them among the factors in the propagation of epidemics. But there is a limit to the bearings of this doctrine. You can't keep mild cases of yellow fever continuously running in a series, in the midst of a very nonimmune population, without having an explosion. No one has had a better opportunity than ourselves to study this matter. With Colonel Kean, U. S. A., and Drs. Finlay, Agramonte, Lebredo, and others we have been, during the last three years, studying with special care the manner of dying out of outbreaks of yellow fever—an interesting study. Three months in Cuba (a tropical country), and with the conditions of watchful and well-organized vigilance that there prevail, is sufficient time to make sure that we have seen the last case, and that we have destroyed the last infected stegomyia, provided that at least two of the months of the said period of three, fall within the semester from April to August. Three months, I say, should be enough, and we are now about completing our sixth month without a case. Fortunately, during this last visitation of the fever in Cuba, the disease worked itself only exceptionally into the Cuban families of children. It followed very generally groups of men, mostly laborers and rather recent arrivals, who live generally apart from the Cuban families. The recent visitation of three years duration in Cuba has been kept all along well under control, both before and during the American intervention. Comparing with the old annual epidemic that characterized the amarillic infection during the Spanish regime, the recent outbreaks were but insignificant manifestations. Now, under such circumstances, it is not easy for the disease to affect extensively the non-immune native children. The child in the Cuban home is protected by a screen of immune persons, so that, even when an infected insect comes into such a house, the chances of its picking out the nonimmune child are small.

There is no reason why you should feel apprehensive of importation from Mexico. In the first place, the chances

of outwanderings and importations of the disease are growing every day less and less; because there are no more great centers of yellow fever infection existing—the disease is dying out; and, secondly, because the maritime quarantine in Cuba has been very successfully managed We have had but one importation in Cuba since the disease disappeared in 1901, to two importations in the United States during the same period.

I have myself, with my colleagues Drs. Finlay, Agramonte, Lebredo, Albertini, Martinez, and Lainé examined personally, or studied carefully, all cases that might be considered as at all suspicious of yellow fever, during the last five months, and none of them has left in our minds the least apprehension.

We are starting with the budget of four million dollars for Public Health and Charities, under the direction of a Secretary in the President's Cabinet, Dr. M. Duque, a very able and enthusiastic physician; we are consolidating and broadening at the same time the operations in Preventive Medicine that were started during the American intervention, and the MEDICAL RECORD, an American paper, would I am sure be the last to withdraw from us, upon information that has not been substantiated, that encouragement that the Cuban people have learned to expect always from American institutions.

JUAN GUITERAS, M.D.,
HAVANA. Director of Public Health.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BERIBERI—RUPTURE OF UTERUS—OFFICIAL RESEARCHES—CONGRESS OF CHEMISTRY; NEXT MEETING IN AMERICA—INDIAN MEDICAL SERVICE—TUBERCULOSIS EXHIBITION—TROPICAL MEDICAL ENDOWMENT—OBITUARY.

LONDON, June 4, 1909.

THE Tropical Society's discussion on beriberi was concluded on May 21. A report of the first part of this important debate appeared in my London letter in the MEDICAL RECORD for May 22. Dr. C. W. Daniels opened the adjourned discussion. He said the "cured rice" spoken of by Dr. Braddon was not prepared as in India, being steamed for eight minutes, not boiled until it split, and could not be correctly called sterilized. It was soaked well in water and the grain often sprouted; it was dirty and mouldy. He had himself cultivated innumerable bacteria from it. The Chinese said they could not eat it, as it gave them dysentery, but they ate "uncured" rice, which looked, smelt, and tasted very well. Touching statistics, he said, the variations in prevalence were as great before as after the "cured rice" days. In one gaol rice was used for many years, when no beriberi occurred, then suddenly 35 cases, mostly fatal, occurred in a single month. Did that rice take years to affect the prisoners? But in other gaols cases occurred almost immediately on admission and it could not be due to chronic poisoning by the uncured rice, which, in fact, was used in England and all over the world.

Sir W. Treacher, K.C.M.G., said as a layman he might say he had had great experience of outbreaks. He saw instances of one class only being affected in a community in which all fed alike, e.g. in Labuan a company of Malays were stationed as a guard and beriberi broke out and nearly all died, though none of the other inhabitants had it, yet all ate the same rice brought in a sailing ship from Singapore.

Dr. Beddoes said malignant beriberi prevailed on the Amazon, where rice was not eaten, the chief food being cassava, which was prepared from the same root as tapioca.

Dr. Hartigan said in Hongkong some of the schools suffered much, others not, but the diet was just the same.

Dr. Macfarlane added to this that at St. Paul's College, Hongkong, outbreaks occurred every year and all sorts of rice have been tried, with no effect. Change of place, not of diet, was the means of arresting the disease.

Professor Ronald Ross urged that further experiments in feeding should be made on more exact lines. There was certainly a case for careful research

Sir Patrick Manson remarked that most of the speakers had opposed the rice theory, although it had been upheld by competent observers who had previously regarded it as untenable. His own position was that of suspended judgment.

After the discussion Dr. Sandwith called attention to the paper of Bontius of Batavia in 1624, in which the disease was fully described. The Royal College of Physicians lent the volume of Bontius, "De Medicina Indorum," for exhibition at the meeting, which interested many of the members.

Rupture of the uterus was pretty fully discussed by the Section of Obstetrics and Gynecology of the Royal Society of Medicine on May 13. Dr. T. W. Eden opened with a paper on the operative treatment, in which he related three cases, two of recovery and one fatal. Abdominal hysterectomy was performed in all three. In 1900 there was a discussion at the Obstetrical Society, now absorbed in this section, when Dr. Spencer related four cases treated by gauze packing, and advocated that method. In 1901 Varnia condemned all conservative plans and urged removal of the uterus by abdominal section in all serious cases. Dr. Eden considered the three risks of rupture as shock, hemorrhage, and sepsis, and said deep bleeding occurred more frequently than had been supposed whether the rupture were complete or incomplete. The hemorrhage, which immediately followed the accident, usually ceased spontaneously, but was apt to recur, for the uterine contraction could not control it, and it might be partially extrauterine. About 50 per cent. of the mortality (which totals some 70 per cent.) was due to sepsis. The mortality of expectant treatment had been estimated by different observers variously as 60 to 90 per cent. In severe cases Dr. Eden held that operation offered the best chance, as it was the only certain way of controlling bleeding, as the uterus had often been infected and if the organ had not been removed the risk of subsequent pregnancy and fresh rupture was high. He thought laparotomy and suture of the rent had a higher mortality and vaginal hysterectomy did not permit full exposure of the injury and bleeding vessels might escape notice in that operation.

Dr. Lionel Smith gave an account of ten cases and discussed the cause and symptoms.

Dr. Herbert Spencer said though rupture sometimes happened in careful hands it was oftener due to bad and dirty midwifery. He could not accept supravaginal hysterectomy as routine treatment in complete rupture, still less when the peritoneum was not involved.

Dr. Hubert Roberts related four cases. One died before anything could be done. In one the rent was plugged and recovery ensued. In two the abdomen was opened and the rent sutured, and one of them recovered and three years later was delivered of a full-term child. He thought sutures and drainage often would give as good results as removal.

Dr. Drumond Robinson had had five cases. One died soon after rupture. In two gauze packing was used and both recovered. In two others the fetus was *in utero* when the rupture was discovered and abdominal hysterectomy was performed, but both died. In such cases there was no option, he thought, and removal by abdominal section was necessary.

Dr. J. S. Fairburn had treated six cases by three several methods—plugging, suture, and hysterectomy. Selection of the plan should be aimed at. He had had three cases in which nothing was done and two recovered. Another case in which child and placenta had been delivered before admission suffered from so profound shock and bleeding that the abdomen was opened and the rent so sagged hysterectomy was done, but she died in a few hours. These and other cases showed that no treatment was suited for all cases.

The Local Government Board has authorized nine researches out of the annual Parliamentary grant. Five are continuations of investigations into protracted and recurrent infection in typhoid; the same in diphtheria; into flies as carriers of infection; into sewage bacteria and defensive mechanism of the body against infections; milk pollution and Gaertner's bacilli in prepared foods. The other four are (a) changes undergone by milk on infection by bacteria and relation of pancreas to epidemic diarrhea (Drs. Sholberg and Wallis); (b) records of lying-in hospitals as to nutrition of mother and other factors influencing vitality of infants in the first fourteen days (Dr. Darwell Smith); (c) mixed infections in phthisis (Dr. Inman); (d) importance of certain types of cells in defense against the tubercle bacillus and effect of tuberculin on their activities (Dr. J. Miller)

The International Congress of Applied Chemistry has concluded its rather elaborate programme. Its eleven sections have discussed innumerable questions and given us the last word on many. Of course, hygiene and sanitation were first in medical interest Food

and adulteration, fuel and the enormous waste of heat in unconsumed smoke (one expert calculated this waste would pay off the national debts of most countries), ventilation, disinfection, and many other topics have occupied attention. Among the social functions the banquet in the central transept of the Crystal Palace, at which over 2,000 guests assembled under the presidency of Sir William Ramsay, presented a remarkable spectacle and was pronounced most successful. It is true that the speeches could only be heard by those near the speakers, but all were taken as a happy demonstration of the unity of science. The trip to Windsor Castle, at the invitation of the King, although somewhat marred by unfavorable weather, was also greatly appreciated, four special trains being required to convey those who went. At the closing meeting the American Ambassador brought an official invitation that the next year's meeting should be held in the United States. In one of his happy speeches he told us the President had approved the joint resolution of the House of Representatives and Senate as to this invitation and he described some of the attractions for scientists. Dr. Wiley added words of welcome and the invitation was accepted. It was remarked that this is the first time the Congress has received a direct message from the ruler of a great nation to hold a meeting in his country.

An exhibition has been opened at the East End by the Association for the Prevention of Tuberculosis and will remain open until the 19th. Admission is free, the object being to interest and instruct the populace. The most striking exhibit is a room—dirty, dark, stifling—and beside it a duplicate as it ought to be—light, airy, clean.

The General Medical Council continued its sittings through the week. The chief business was the trying of cases of alleged "infamous conduct in a protessional respect." The sordid details will scarcely interest you, but I may say that some names were removed from the register, after a full inquiry. From the point of view of an observer, the Council is not a body well adapted to undertake judicial proceedings, but members seem anxious to do their best.

Some anxiety is felt in the Indian Medical Service at the renewal of a proposal to establish a civil profession, independent of the officers who have hitherto filled many positions, which such a plan might take away and which almost certainly would be detrimental to the service and to the natives. Lord Morley seems in a hurry, though the unrest among the natives since he took office might have warned him that it is easy to pull down if the question of consequences be ignored. The Indian Government is not in such a hurry and wishes to proceed slowly.

Lord and Lady Stanley of Alderley have endowed the London School of Tropical Medicine with a sum producing £50 a year in memory of their son, who died at Sokoto last November. He was only thirty years old and during six years had attained an exceptionally high position in the Colonial service. He was greatly esteemed by his superior officers and specially trusted by the natives.

Dr. Simeon Holgate Owen, whose sudden death was reported on the 21st ult., at the age of 64, was consulting physician to the Manchester Northern Hospital for Women and Children and had served on the staff of the Royal Infirmary. He was M.D., R.U.I. 1872, M.R.C.P. 1888 and had been president of the Clinical Society. He wrote a work on "Fevers," another on "Work and Recreation," and contributed to the societies and journals.

Another sudden death is that of Dr. Thos. Fred. Hopgood, aged 62, surgeon to the Sunderland Infirmary and to the Durham County Eye Infirmary and the Orphan Asylum. He had a stroke last July, but had apparently recovered and resumed his work. He was in the infirmary on the day preceding the fatal seizure.

The Urine in the Diseases of Infancy.—In an analysis of the urine in 667 children, Morse and Crothers of Boston have found that, putting aside diseases of the gastrointestinal tracts, albuminura and casts are more often found in pneumonia and meningitis than in other acute diseases of infancy. They disagree with other writers on the frequency of nephritis following otitis media and eczema. They also show that in infancy nephritis rarely produces edema, while, conversely, edema in infancy is usually due to some cause other than disease of the kidneys.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

CEREBROSPINAL MENINGITIS—PRACTICAL METHOD FOR THE RAPID EXAMINATION OF THE BILIARY AND INTESTINAL FUNCTIONS IN THE CHILD BY THE ACETIC SUBLIMATE REACTION UPON THE STOOLS—THE ULTRA-MICROSCOPE AND ITS ESSENTIAL RÔLE IN THE DIAGNOSIS OF SYPHILIS—UTILITY OF MICROSCOPIC EXAMINATIONS IN THE DIAGNOSIS OF SYPHILITIC ACCIDENTS AND ESPECIALLY CHANCRE—ATTEMPT TO TREAT SOME CASES OF EPITHELIOMA OF THE ESOPHAGUS BY THE DIRECT LOCAL APPLICATION OF RADIUM.

PARIS, May 15, 1909.

At the recent meeting of the Hospitals Medical Society Netter and Debré made an interesting communication on the development of the epidemic of cerebrospinal meningitis at Paris. The epidemic of cerebrospinal meningitis occurred principally in the months of March, April, and May. The cases observed presented apparent relations which caused the contagion to be recognized, and the disease tended to take on an epidemic character. The authors reported seven cases personally observed. Aside from the decisive diagnostic points furnished by lumbar puncture, meningitis shows its presence by two valuable signs, stiffness of the neck and flexion contraction (Kernig's sign), but the changes in the neck do not begin until the second day and their occurrence is sometimes even later. The treatment should consist of intraspinal injections of antimeningococcic serum repeated at high dosage. The serum must be introduced into the spinal canal within the membranes, and we should inject each time 30 to 40 cubic centimeters. It is best to repeat these injections daily, sometimes twice a day. Before making the injection as much liquid as possible should be withdrawn, up to 100 or 110 c.c. We are no longer helpless in the treatment of cerebrospinal meningitis, and by the methodical employment of the antimeningococcic serum we possess a means of defense of undoubted efficacy.

Triboulet describes a method of practical value in the examination of the biliary and intestinal functions in the infant, by the acetic sublimate reaction upon the stools. From the examination of a large number of specimens he concludes that when one finds the existence of a stercobiline in the stools of a patient, whether sick or no, this patient is normal in his biliary functions. To recognize stercobiline in the feces a piece of a fresh stool the size of a small nut is placed in a test tube filled two-thirds full of distilled water; this is well shaken up, and then with a dropper there is added eight or ten drops of an acetic solution of sublimate of the following formula: Distilled water, 100 cubic centimeters; sublimate, 3½ grams; acetic acid, 1 cubic centimeter. Under this reaction a true precipitation occurs and there is formed a deposit, for the formation of which we must wait about a quarter of an hour to get the maximum reaction. The colors obtained are four—a red reaction indicates the presence of stercobiline and a normal condition of the intestinal content; a yellow color indicates abnormal biliary functions connected with an infectious condition; a green color is normally met with in infants at the breast; a gray color occurs in very grave abnormal conditions in dystrophic nurslings. From this method of examination we may draw very important conclusions with reference to a large number of questions of alimentary hygiene in the nursling. This very simple and practical test, brought forward by Triboulet, allows of examination of the biliointestinal function, and these are considerations that should not escape either the physician, the surgeon, or the accoucheur.

Gastou and Comandon read an interesting paper on the ultramicroscope and its essential rôle in diagnosis of syphilis. The diagnosis of syphilis, often difficult and uncertain, may be made absolutely by the use of the ultramicroscope. With this apparatus the examination for the spirochete is rapid, immediate, almost always certain, easy, and may be made in his office by the physician. The ultramicroscope is based on the principle of lateral illumination of the preparation. The light reflected by mirrors traverses obliquely the layers of the liquid situated between the slide and the cover glass. It does not penetrate directly into the microscope, but the particles in suspension in the preparation themselves become luminous. The examination is made with an immersion lens and the ultramicroscope, upon which, by means of a lens, are concentrated the rays from a powerful

source of light. The parasite of syphilis examined in this way has a special motility, which allows it to be not only recognized but differentiated. The spirochete shows a helicoidal movement and a sinusoidal movement, like a needle. Further, there is a sort of wave of contraction passing from one end of the organism to the other. The preparation of exudates for examination is simple: If we have an erosive lesion it is first washed with sterilized cotton soaked in serum, and is then lightly curetted with a spatula, especially upon the edges. If it is a skin lesion, it is first washed with alcohol, wiped with cotton, then lightly scarified, and a small vacuum bulb of Bier is applied. With this technique the spirochete is generally very easily found in primary or secondary lesions. The search for the spirochete is easiest in hypertrophic mucous patches. In the blood and urine it is found only in heredosyphilities. Lastly, the discovery of the spirochete in the saliva is of the utmost importance for the prevention of syphilitic contagion. Following this communication Milian insisted upon the value of the ultramicroscope in the diagnosis of syphilitic lesions and especially chancre. This is of value to the physician whenever he finds himself in presence of a suspected ulceration. The use of this instrument should become generalized.

Guisez and Barcat reported several attempts in the treatment of several cases of epithelioma of the esophagus by direct local applications of radium. When by esophagoscopy the authors had ascertained the presence of cancer of the esophagus, they applied in contact with the growth a No. 15 or 16 sound, the end of which carried a tube of radium protected by two screens of silver four-tenths of a millimeter in thickness. The application continued for from two to three hours. As a result of these applications the esophagus, which was absolutely impermeable, became permeable to soft bougies after three or four applications of radium. The dysphagia was not diminished, and the spasm even increased after the application. The results of the first attempts at the treatment by radium of these neoplastic tumors of the esophagus seems encouraging; the rays produce an amelioration of symptoms and should be further tested, especially in comparison with the ordinary treatment of cancer, and its discouraging results.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

INDIGENOUS TYPHOID FEVER—CHOLERA ENDEMIC—PERSONAL NOTES.

MANILA, P. I., May 8, 1909.

HERETOFORE many medical men have seriously doubted whether cases of typhoid fever, especially those among natives, ever occurred here which could not be traced to infection introduced into the islands from the outside, that is to say, from a foreign country. Cases among the American soldiers were attributed to infection brought from the United States either in food, clothing, or the intestines of individuals. Cases among the Japanese, which, by the way, are exceedingly common among the members of that race who reside in the Philippines, were ascribed to the same causes, and those which occurred among the Filipinos themselves were thought to be due to contact direct or indirect with the Americans, Japanese, or other races that introduced the disease here. Lately, however, two cases were encountered at Taytay by the Hookworm Commission, of which mention was made previously in these columns. These cases presented the pathognomonic symptoms of the disease and the diagnosis was further confirmed by positive Widal reactions. Both were in Filipinos who had not been outside of their town for many weeks prior to being stricken and who ate and drank only the food and water which was common to the remainder of the inhabitants. They denied partaking of any food introduced from the outside, with the exception of the rice and fish, which, however, are used by all of the residents. There were no Americans, Japanese, or other foreign residents in the town, with the exception of the members of the Commission. On account of the daily sanitary inspection which had been made since the advent of the Commission in the town, more than five weeks before these cases came under observation, it was not likely that any cases of a recognizable form at least existed in the town during these five weeks. Some of the drinking water was obtained from a spring, but most of it probably came from shallow surface wells, but the water used by the typhoid patients was used commonly by many other persons. There were practically no flies nor mosquitos in the place. This experience, at least, would indicate that the disease exists among the Filipino people themselves.

The reason that typhoid fever does not spread more in the Philippines is probably due to the fact that there are no reservoirs or other common sources of water supply, hence infection on a large scale is not possible and the use of milk, which may have been infected with typhoid organisms by water or other means, is practically unknown among the bulk of the Filipino people. From the foregoing, then, it may be observed that the cases afford ample room for speculation as to their origin.

As the American administration in the Philippines comes into closer and closer touch with the actual conditions in these islands, it is more and more apparent that cholera must have been prevalent in the islands for many years. With the sources of information that were available only a few years ago it would probably be stated now that no cholera prevailed at the present time. But with the improved communication, the increasing confidence, and the result of the educational campaign which has been so persistently carried out, it is now known that cholera in sporadic form is present in a number of provinces. The number of cases reported does not reach more than 20 or 30 per week among 7,000,000 people, and is generally encountered among the most poorly nourished members of the community.

In the past it has been customary to diagnose such cases as enteritis, diarrhea, cholera nostras, dysentery, etc., but it now seems probable that it is in this benign form that the disease is carried along from year to year, and when conditions, as yet not understood, are favorable the disease increases in virulence and assumes epidemic proportions. When it is remembered that these cases occur over an area that comprises a territory equal to that of the States of New York, Pennsylvania, New Jersey, and Maryland, and that less than 25 experienced medical men are available to combat this condition, and that the transportation over much of the territory is as difficult as it would be to walk and carry supplies from New York to Pittsburg, it will be readily understood that the complete eradication of cholera can scarcely be hoped for in the near future.

When other unfavorable factors are taken into consideration, as, for instance, the fact that the climate is favorable to the development of the cholera organism throughout the four seasons of the year; in other words, that there is no winter season which would at least stop the disease for a time, that a large proportion of the people are extremely superstitious and inherently indifferent to sanitary measures, and believe that by observing them they thwart the will of the Almighty, that the cost of food is comparatively high, thus making the use of boiled water and cooked food difficult for the masses, that eating with the fingers from a common family receptacle is practically universal, that the Filipinos as a race are physically weak and unresistant, it will be still more apparent why cholera cannot be more successfully combated, and cannot help causing admiration for the brave medical men who hopefully battle on against such heavy odds.

Dr. Paul C. Freer, Director of the Bureau of Science, and also the Dean of the Philippine Medical School, has left for the United States, via Europe, for a six months' vacation. During his absence Dr. Richard P. Strong, the Chief of the Biological Laboratory, will be the acting Director of the Bureau of Science, as well as the acting Dean of the Philippine Medical School.

Captain and Assistant Surgeon Harry Nichols, who was relieved as a member of the Army Medical Board for the study of tropical diseases, has been ordered to remain with it for another period of three months. The vacancy caused by the expiration of his tour of duty in the islands will be filled by Captain and Assistant Surgeon Kilbourne.

Tobacco Amblyopia in a Woman.—A case is reported from California of a refined and educated woman, fifty-two years of age, who suffered from severe tobacco amblyopia. For two years the patient had smoked six to eight cigars a day.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 10, 1909.

Comparison of the Guaiac and Benzidin Tests for Invisible Hemorrhage in Diseases of the Digestive Organs.—F. W. White describes these tests and the mode of their application. He emphasizes the following points. Tests for invisible hemorrhage in diseases of the digestive organs are very valuable and will come into use more and more. A preliminary step with both the tests described, is to exclude sources of error from food ferments. This is more important for gastric contents than for feces. Acetic ether extraction is best for the guaiac test and boiling in the benzidin test. Metallic salts, iodide of potash, and charcoal must not be given when the stomach contents are to be tested by the benzidin method. Before using these tests, meat, fish, and their juices must be excluded from the diet, and no hemoglobin derivatives used as a drug for two days before the guaiac test, and three or four days for the benzidin test. Gastric contents should be examined when available, but feces are the best material for examination, as they alone are available for the repeated examination which is usually necessary for diagnosis, and they are free from the source of error introduced by the use of a stomach tube. The Weber method (described) is the best guaiac test for routine clinical work, using several amounts of guaiac as recommended by Schroeder. The original Adler (described) benzidin test is too delicate for clinical work. This objection has been overcome in the Schlesinger and Holst's modification of the test, which is about five to seven times as delicate for blood in gastric contents as the guaiac test and only about twice as delicate for blood in the feces. This last test is consequently the best for clinical work. It has all the clinical value of the guaiac test with somewhat greater delicacy, greater clearness and more simple technique, and, as carried out, acts as a control on the cleanliness of the reagents and glassware. Good results with the benzidin test depend on careful technique, exclusion of oxidizing ferments in raw food, fresh material, clean glassware, and quality, strength, and proportion of the reagents used. A negative benzidin test has a greater value than negative guaiac test in ruling out hemorrhage, and if both tests be used as a control much time will be saved by using the benzidin test first, which takes only two minutes, and, if negative, renders any further tests for blood unnecessary. It is wise to control the benzidin test with the guaiac test when positive results are found until the technique is learned and tested individually.

The Relation of the Spleen to Resistance against Infection.—J. C. Hubbard introduces his subject by reference to a boy with splenic anemia from whom the spleen had been removed. Some three weeks later appendicitis developed and in spite of prompt operation the boy died in about twenty-four hours, the appendix having been found perforated and gangrenous. The question is asked, was the ability to withstand infection decreased in any way by the splenectomy? A series of experiments was undertaken on guinea pigs to determine if possible this inquiry. The results are thus summarized: Two splenectomized pigs died of general infection (after operation and artificial inoculation pus cocci), the controls surviving. One operated pig died of general infection, there being no control. One operated pig died of a local infection not at the point of inoculation, and some time later its control died of a general infection. A control died of a general infection, while the operated pig lived until killed. Both the operated pig and the control lived until killed. It would appear, therefore, from these experiments, that there is no marked difference in the ability of splenectomized pigs and normal guinea pigs to withstand infection artificially produced by *Staphylococcus pyogenes aureus*. A review is given of recent literature on the subject, and the history of one man referred to by the author, who removed the patient's spleen because of rupture, some three years and nine months ago, would seem to indicate that removal of the spleen does not lessen a man's ability to withstand infection. The protective function of this organ in this particular respect seems to be taken up by other organs after its removal.

New York Medical Journal, June 12, 1909.

Diet as a Prophylactic and Therapeutic.—H. W. Wiley says that the debasement of the diet, the addition of injurious substances thereto, or the abstraction of valuable substances therefrom diminishes the power of that diet to maintain the body in a state of hygienic equilibrium. The proper quantity to maintain that equilibrium is a condition of efficiency. The daily ration may vary temporarily without any apparent change in efficiency, but a continued variation will certainly show itself. In the United States the amount of protein ingested is usually in excess of bodily needs, although some silly ideas have been advanced along this line. Another fault is improper mastication. This is a mechanical necessity preliminary to deglutition and hydrolysis in the process of digestion. But this mattetr may be carried to an extreme. In regard to the therapeutic value of diet we must remember that in sickness the use of food is regulated by entirely different conditions from use of it in health. The introduction of drugs of any kind into foods intended for invalids is criminal. Some persons can drink pasteurized milk in health but not when diseased. The author does not believe in the Metchnikoff theory that sour milk is the elixir of life. A theory of this kind would have to be demonstrated before it could meet with universal acceptance, and it would take one hundred years to demonstrate it. The treatment of tuberculosis is largely conditioned on diet. While diet is only one of the factors in prophylaxis and treatment, it is one of the most important.

The Treatment of Pneumonia with Special Reference to the Use of Quinine.—J. A. Keown gives abbreviated histories of fifteen cases. He says that if the consolidated area could be prevented or limited, the number of germs would be lessened, there would be less absorption of toxins, the patient would have greater lung space for oxidation, the temperature would be lowered, and the patient's general condition would be much improved. He believes that quinine will accomplish all these results. Of the series of cases here presented, fourteen recovered and one died. The dose of the remedy was, in some instances, so small that recovery could not (in the abstractor's judgment) be attributed to the remedy. In no instance were more than 12 or 15 grains given in twenty-four hours. The author says, however, that his experience with quinine leads him to the belief that if sufficient quinine is given the consolidation can either be prevented from coming at all, or arrested where one commences to give the quinine in sufficient doses. At first this seemed an unwise interference with the natural pathological process of the disease, but continued experience with the use of quinine has led him to believe that this can bring only good results. In addition to this effect of the drug, quinine in the blood is considered to be an antiseptic. It is supposed to limit metabolism which is a good thing in pneumonia and it is a good reducer of the temperature. It also acts as a tonic, and stomachic. Quinine does not seem to shorten the course of a case of pneumonia, but certainly does limit the amount of consolidation, and converts the disease from a dangerous and painful one into one of mild severity and practically no danger. Large doses of quinine are not necessary, but sufficient quinine should be given to control the process of consolidation, which can be ascertained by careful examination of the chest by auscultation and percussion, and it is also indicated by the temperature, quinine reducing the temperature, acting as an antipyritic. When sufficient quinine has been given the temperature is normal or nearly so.

The Treatment of Tuberculosis by the Administration of Mercury.—B. L. Wright again refers to his twelve patients on whose condition he reported in this journal, August 29, 1908. From a comparison of the conditions of the respective patients with that previously reported it will be seen that of the two patients not on mercury in the previous report, but who have since taken it irregularly and indifferently, one is improving and one is failing, the latter having had a rather severe typhoid fever in August, 1908. Of the ten patients reported as being on mercury, six have been cured, two markedly improved, one improved, and one failed, this latter man having had typhoid in August, 1908. All of these men were in the United States Navy and were carefully observed. The bulk of the paper is occupied with detailed notes of the cases, and must be consulted in the original by those interested.

Ureteral Calculi.—J. F. Erdman describes cases in which he has operated, and considers the operation as a whole. Symptoms consist of pain, of lumbar and abdominal varieties, testicular, penile, and vesicular, tenesmus, and frequent desire to urinate. When these are present we should make a careful uranalysis, have an *x*-ray picture taken, and occasionally search by the cystoscope. The microscopical evidences in urine analyses that weigh in the diagnosis of possible stone are the presence of blood, crystals of oxalates and urates in excess, and epithelial elements from the hilum and ureters. Blood may be present in the urine in cases of appendicitis due either to a toxemic nephritis (acute) or to some associated condition, such as acute nontoxic and chronic nephritis or floating kidney, embolic infarcts, etc. Blood without other renal

elements, and in the absence of other pathological lesions of the bladder, urethra, etc., is the best diagnostic sign of stone we have, barring the evidences of a definite shadow in a radiograph, or the scratch marks, made by contact with the stone, found upon a waxed ureteral catheter or probe that has been introduced into the ureter. Blood in the urine obtained by catheterism or after ureteral catheterism should be given the weight of evidence of trauma rather than that of calculus, although no trauma may have occurred by either of these methods. In operation the peritoneum is incised sufficiently to admit one or two fingers to palpate the ureter. The ureter is located, and then rapidly followed in its course until the object of the search is found. The outer flap of the peritoneum is then rapidly dissected away from its contiguous structures, and in a small enough well to expose the stone, which is held or raised by the intraperitoneal finger, the ureter is incised longitudinally over the stone just long enough to allow of the expulsion of the calculus. Ordinarily, unless one finds a very large calculus, no sutures are required in the closure of the ureteral incision. A wick drain is placed down to the ureteral trauma, the peritoneum closed, and a final closure of the remainder of the abdominal wound to the emergence of the drain is made. Several patients in whom this no suture of the ureter method has been followed by me had practically no urine leakage, the wound drain being removed in four to six days.

Symptoms and Diagnosis of So-called Chronic Rheumatism.—C. Ogilvy discusses infectious arthritis, typhoid infection, gonorrheal arthritis, the effects of influenza bacillus, rheumatoid arthritis, arthritis deformans, hypertrophic arthritis, Still's disease, villous arthritis, and gout, in all of which there are symptoms which have led to a diagnosis of chronic rheumatism. The various diagnostic points which lead to a proper diagnosis in the various conditions named are systematically presented. Nothing new is said, but that paper is a protest against the all too prevalent habit of labeling any case of obscure joint pain one of chronic rheumatism.

Journal of the American Medical Association, June 12, 1909.

The Physician and Public Health.—Walter Wyman discusses the duties of the physician engaged in private practice in his relations to public health, and emphasizes the fact that no physician can separate himself from his fellows and their general interests. A most natural sequence of a doctor's practice is an interest in general sanitation and hygiene, and he illustrates his ideas by the modern movements against epidemic diseases which are now so prominently to the fore. He gives particulars as to what the government is doing by regulations for its own employees, for emigrants, seamen, etc., and dwells on the need for instruction of the tuberculous in hygienic rules to be observed by them for the welfare of their fellow citizens. The responsibility of the general practitioner in this matter is not a small one. Wyman goes at some length into the history and functions of the Public Health and Marine Hospital Service, its importance to the country's welfare, its relations to local State governments, etc. In conclusion, in addressing those who are just starting into professional life, he urges them not to be delinquent in observing and attending to the general physical welfare of the communities in which their lot may be cast.

Gallstones and Heart Disease.—R. H. Babcock calls attention to the gastric and digestive tract symptoms of gallstone disease and their association with cardiac derangements, which often overshadow those pointing directly to the hepatic disorder. This last was the case in eleven of the thirteen cases he reports. The symptoms referable to the heart predominated, the gall-bladder becoming an object of suspicion either on account of digestive troubles or something in the history of the case. In each of the cases, however, careful palpation detected a swelling over the gall-bladder which in most cases was shown by operation to be a Riedel's lobe. He divides the cases into four groups: 1. Five cases of pronounced cardiac incompetence showing considerable dilatation with arrhythmia and feebleness of heart's action with murmurs. 2. In two cases there had been attacks of pain, of anginoid character followed by evidences of cardiac muscular inadequacy, and one case in which there was dull infracardiac pain together with irregular pulse and a moderate degree of dyspnea on exertion, both dependent on recognizable, though not great, cardiac dilatation. 3. In this group were three cases of intermittent pulse of long standing and very intractable, but without dyspnea or other marked subjective symptoms of myocardial inadequacy. Patients in this group were greatly benefited by operation, more so than by any other line of treatment. 4. This group includes two cases of valvular disease in which cardiac competence was destroyed, either by evident attacks of hepatic colic, or by distressing symptoms attributed to the stomach, at first, but later referred to the gall bladder, because of the recognition of a Riedel's lobe. The cases are reported in detail, and the question arises how to explain the effects of gall-bladder disease on the heart and why all persons with chronic gall-bladder disease do not develop cardiac symptoms. Babcock admits his inability to answer the first of these questions, but suggests a preexisting myocardial condition as accounting for the occurrence of the symptoms in some and not in other cases. Several theories may be advanced for the bad effects of gall-bladder disease on an already predisposed cardiac muscle; such as (1) the circulation in the blood of bacteria or their toxins; (2) the depressing influence of bile constituents on the heart muscles; (3) disturbance of the splanchnic circulation, and secondarily of the systemic circulation, of the heart; (4) reflex inhibition through the vagus. Each of these are taken up separately and their probability or possibility shown. Babcock closes with a discussion of the literature of the subject.

Pain and Pott's Disease.—C. C. Wholey reports a case of Pott's disease showing how the symptom of backache may mislead a physician, and how the symptom of pain may divert one from important signs that would aid in making an earlier correct diagnosis. The case was specially characterized by backache, this giving rise to three mistaken diagnoses: calculus, rheumatism, and neurasthenia. Backache is a symptom of so many conditions that it has comparatively little value in itself, taken alone. It is probably of overestimated significance in nephritis, except in the acute processes, and when symmetrical is of far less diagnostic importance than when unilateral. Ulceration of the stomach or large intestine is a not uncommon cause and chronic prostatitis is an often overlooked factor. The observations of Head are of value in estimating the significance of pain of obscure types and origin. Wholey believes that Pott's disease would be much more frequently and earlier diagnosed if its initial manifestations, of which pain in the form of backache is often conspicuous, were looked for and recognized. Other symptoms of diagnostic importance and the special location of the backache should be carefully observed when utilizing this symptom in clinical diagnosis.

Chloroform in Hemoptysis.—Joseph B. Fish after referring to a previous paper on the successful use of chloroform in pulmonary hemorrhage (*Journal A. M. A.*, March 13, 1909, page 883), says that he has continued his experiments and now practises this treatment alone in such cases. The effect of chloroform on the circulation is chiefly to decompress the vasomotor system, causing an extraordinary fall of blood pressure. Complete vascular relaxation follows and the patient, so to speak, is bled into his own vessels. There is also some cardiac enfeeblement and dilatation, which also contribute to lowering the blood pressure. Chloroform has also a depressant effect on the respiration, and, as it produces the coagulation of the blood *in vitro*, it is possible that some direct contact with the bleeding point by the vapor may also have some effect. He describes his mode of administration of from 2 to 4 c.c. of chloroform on an ordinary inhaler or wad of cotton held near the nostrils of the patient. The hemorrhage will cease within five or ten minutes, and during the following twenty-four or forty-eight hours the patient will be bringing up blood clots. The inhalation of from 15 to 20 drops every hour is continued for a few days and ammonium chlorid, with small doses of codein, is given internally every four hours to expel the retained secretions and prevent excessive coughing. It is a good plan, he says, also to give a teaspoonful of magnesium sulphate to keep the bowels free. In the limited number of cases in which he has used this treatment the results have been all that could be desired, and he recommends it to further trial by others.

Partial Constant Epilepsy.—W. G. Spiller and E. Martin report a case of a type of epilepsy that has been but scantily noticed, even by the most recent writers, except in Russia, where it has been called "epilepsia continua." Oppenheim (Lehrb. der Nervenkr., ed. 5, p. 1389) mentions it in a few lines, by stating that cases occur in which during the interparoxysmal period muscular twitchings of short duration and without loss of consciousness are observed in one or another part of the body. In the case here reported, the patient, a young colored man with a positive syphilitic history, had convulsions of the Jacksonian type followed by persistent paresis confined to the right side of the face and the right upper limb. Independently

of the typical attacks he had twitchings, confined to the right side of the face, almost constantly present and resembling a tic movement of fibrillary twitching. After persisting some weeks in the face, they changed to the right arm, where they were continuous. There was no impairment of consciousness. The name "epilepsia partialis continua" seems to have been first used by Koshewnikow, who reported four cases in 1894. The condition has since been called by some writers Koshewnikow's epilepsy. Because of the failure of specific medication in this case, and the apparent progressive character of the disease, operation was deemed advisable. It revealed separate gummatous masses in the portion of the brain corresponding to the centers for the face and upper limb, the syphilitic nature of which was confirmed by microscopic examination. The operation was attended by only trifling shock, but very little benefit was obtained.

The Phthisical Chest.—W. L. Niles notices the old teaching that the consumptive chest is flat, and says that it remained for Woods Hutchinson to show that, instead of being flat it is abnormaly round. Since his first publication on the subject others have confirmed, to a more or less degree, his findings. Niles takes up the subject of the cause of this peculiarity, and shows how an examination of the human chest from fetal to adult life gives us, in the earlier stages of development, a chest considerably deeper than it is broad, *i.e.* a tendency to the type of the quadrupedal animal. With only two exceptions (whales and bats) all animals below the anthropomorpha have chests that are deeper than they are broad. At birth the chest is practically round in man, and after birth it gradually flattens out until the normal index of seventy is reached at about the eighteenth year. It seems a fair conclusion that the typical tuberculous chest is one that has been arrested in its development at puberty, and Hutchinson seems to think that this has some influence on the prognosis of pulmonary tuberculosis. Niles states his conclusions as follows: "1. The typical tuberculous chest is more nearly round than the normal chest. 2. The increased index precedes development of tubercle infection in the lungs. It is due to an arrest of development at or about puberty and predisposes to pulmonary tuberculosis. 3. Abnormally high-indexed chests in children should be corrected by proper exercises."

The Lancet, June 5, 1909.

A Tropical Form of Adenitis Apparently Due to an as yet Unrecognized Organism.—R. L. Ley reports three cases of this disease, the characteristics of which appear to be (1) that it may lie latent for a long time, so that cases acquired in the tropics may develop anywhere; (2) that the glands attacked are those of the groin and popliteal space indicating the probable route and mode of infection, viz., from sores on the feet and from an organism living in the soil, and (3) that animals contract the disease and probably inoculate human beings. The chronicity and the locality of the glands attacked are the two main features. The condition is to be distinguished from syphilis, tuberculous tumor, septic processes, and Hodgkin's disease. The author suggests that the disease may bear the same relation to the bubonic plague that cowpox does to smallpox, and that it may, in the same way as cowpox, be transmitted to man.

British Medical Journal, June 5, 1909.

Facial Paralysis Following Emotional Shock.—The patient of P. C. Fenwick, a woman of thirty-eight years, read in the paper an account of a shipwreck with great loss of life, and immediately felt a sense of "clawing" in her left cheek. Two hours later the left side of her face was completely paralyzed. When seen by the reporter next day, the whole side of the face was motionless. All nerve branches were involved, taste and hearing remaining normal. Galvanism and faradism evoked no response and there was no R. D. The treatment was high frequent currents, continuous current (anode behind ear) and massage, potassium iodide being given internally. In about two weeks the patient was able to wrinkle the forehead slightly; in a few days more the forehead could be moved a little, and at the end of a month facial movements were normal. Trauma and drafts of air could be ruled out as possible causes of the paralysis.

Treatment of Facial Paralysis Due to Division of the Facial Nerve in the Mastoid Operation.—F. Marsh gives the histories of two cases. They show (1) that if division of the facial nerve is recognized at the time of operation, careful adjustment in the manner indicated (the use of strands of chromicized catgut) will probably result in the restoration of function; (2) that if division has not been recognized the wound should be reopened and the nerve ends adjusted at the earliest opportunity; (3) that if a careful adjustment has been made, a second operation should not be undertaken within three or four months; (4) that this method of adjustment should be tried before anastomosis with the hypoglossal or spinal accessory nerves is attempted, the results of which are not always gratifying.

Resection of the Trachea for Cicatricial Stenosis.—In the case of the patient of G. G. Turner, a man of twenty-five years, the trachea had become infiltrated with a considerable mass of cicatricial tissue, and it seemed to the author to be in accord with surgical principles to excise the involved segment when dealing with a non-collapsible tube of large caliber like the trachea. In a fit of depression following alcoholic excess the patient had cut his throat. The usual course was followed in attempting to restore the severed parts to a normal shape, but the later course of the disease showed that the left recurrent nerve had been permanently injured and that the trachea was beginning to contract just above the tracheotomy wound which had been required on account of dyspnea. It was decided to resect the section involved. The cricoid and the upper part of the windpipe were accordingly thoroughly exposed through a vertical incision, and a complete segment of the trachea excised. The resulting gap was very wide, but the trachea was freed without fear until it could be easily approximated to the cricoid, to which it was fixed by several No. 1 chromic catgut stitches passed around the upper ring of the trachea and through the cricoid, care being taken to tie the knots on the outside. The posterior and lateral surfaces were brought into perfect opposition, but there was a little irregularity of the union in front. A vertical opening was made into the trachea about 1-2 inch below the line of suture for the introduction of a small silver tracheotomy tube. The skin incision was then carefully closed by silkworm stitches. The part removed consisted of a complete transverse section of the trachea with two rings, the lumen being completely obliterated by a mass of scar tissue. For five days the patient went on very well, but there was then a little suppuration with rise of temperature, and the skin wound gave way. On the eighth day, without any warning, he had a sudden profuse hemorrhage. The bleeding clearly came from the left side of the wound from a recess by the side of the trachea, and, after resisting all the efforts of the house surgeon, it stopped spontaneously. As the source of the hemorrhage was doubtful, and its spontaneous arrest probably only temporary, it was thought wiser to give an anesthetic, and, if possible, deal directly with the bleeding point. As a matter of fact, it was possible only to curette a small cavity, which was packed with gauze soaked in turpentine. As one or two of the sutures in the front part of the tracheal wound had given away, two silkworm stitches were introduced and subsequently removed. After this the patient made a straightforward recovery and was soon able to leave the hospital, the wound healing completely in the sixth week following the resection operation.

Case of General Paralysis of the Insane with Extraordinary Lymphocytosis in the Cerebrospinal Fluid.—W. Boyd observes that in tabes and general paralysis of the insane the cerebrospinal fluid usually, and perhaps always, contains an excess of lymphocytes, and that this lymphocytosis may be of considerable value in the diagnosis of the parasyphilitic diseases of the nervous system. Under normal conditions the number of lymphocytes in a field of 450 diameters in a film made after centrifuging 5 c.c. of the cerebrospinal fluid for ten minutes, is two or three. In the two diseases named the number is greatly increased. In the case here presented the number of lymphocytes under the conditions was 3,450, counted in a single field of the size named. In the non-centrifuged fluid the number was no less than 285 per c.mm. The full history of the case is given.

Berliner klinische Wochenschrift, May 24, 1909.

The Treatment of Glycosuria.—Rosenfeld discusses both alimentary glycosuria and true diabetes. He says that the best way to find the tolerance of the body to sugar is to give a free carbohydrate diet, and then gradually reduce this until the urine is sugar free. This is much safer than the complete cutting off of carbohydrates usually employed. In many cases an entirely sugar-free urine cannot be obtained. In such case the starchy food should be reduced to the point at which the maximum is oxidized for the minimum excreted. The amount of bread in such cases should not be reduced below 60 grams *per diem*. In the severe cases of diabetes in which more dextrose is eliminated than there is carbohydrate ingested the extra energy is supplied by fat. As to the role of

carbohydrates and fat, experiments show that a complete withdrawal of carbohydrates causes acetonuria. The carbohydrates are needed for the oxidation of fat. The fat burns in a fire of carbohydrates. Complete loss of power on the part of the organism to oxidize carbohydrates completely inhibits fat combustion and fatty degeneration occurs. A partial destruction of carbohydrates oxidation causes a partial combustion of fat, the result of which is acetone, diacetic, acid and β-oxybutyric acid. It is therefore important to find a carbohydrate which will be oxidized by diabetics. Levulose is not excreted immediately, being converted into glycogen. It does, however, appear in the urine the next day as dextrose. Lactose is also excreted as dextrose, as are alcohol, mannose, and mannite. The administration of the carbohydrate acids as glycuronic, glyconic, oxalic, and mucic acids increase neither the dextrose elimination nor the acetone formation. Sugar given per rectum is absorbed and not excreted. It does, however, not decrease the acetone. Intravenous sugar injection possibly acts better. Probably the best treatment is that lately described by Von Noorden, the oatmeal cure. The use of oatmeal decreases both the glycosuria and the acetone.

Alimentary Lipemia.—J. Leva describes a new method of estimating the fat in the blood and so judging of the absorbing power of the alimentary tract. It is very simple, merely consisting of making a thick blood smear and examining it with the dark field microscope. Between the corpuscles are seen the actively dancing Müller's hematoconian bodies. These bodies are present only after fat feeding. The greater the fat absorption the greater the number of these bodies and the earlier they appear. The author makes four classes of findings. In class 1 the hematoconian bodies are scattered; in class 2 they are so numerous that they cannot be counted; in class 3 the entire field is covered, and in class 4 the field is crowded. Twelve hours after a meal they are still numerous, and only in sixteen hours is class 1 reached. His routine is as follows: In the evening a small fat free meal is given. The next morning a drop of blood is examined, and if it is comparatively free of Müller's bodies the test meal is given. This consists of a slice of bread and 20 grams of butter. In one and a quarter hours the blood is examined, and again in two to two and a half hours. At the first examination class 2 should be found, and at the second class 3. Any variation means an abnormal absorption of fat. The author gives a table showing one hundred cases examined. They are too few to allow the drawing of definite conclusions.

Münchener medizinische Wochenschrift, May 18 and 25, 1909.

What Factors Regulate the Size of the Heart.—Oskar Bruns takes up the history of our knowledge of this subject. The two theories are that the size is directly proportional to the muscle work done, and the other that it varies with the size of the skeletal muscles. He refers to the finding of Grober that the heart of the gull is smaller in proportion to the body weight than that of the wild duck, though the former flies more rapidly and farther. This he explains by the better arrangement of wing feathers, making the method of flying easier. He discusses the various factors which affect the heart size as beer drinking, nourishment, blood-pressure, and metabolism. Then he describes a series of experiments in which he took young dogs, in each series the dogs being of one litter. Some he allowed to rest and others to "climb mountains" in a tread mill three hours a day. On the dogs being killed and the skeletal muscles dissected carefully it was found that the heart weight in the trained animals bore exactly the same ratio to the weight of the skeletal muscles as it did in the untrained ones. The size of the heart is not proportional to body weight but to body musculature. This, of course, applies only to healthy individuals. He considers that the large heart of athletes, as bicycle riders, is due to right-sided hypertrophy due to the difficulty of forcing the pulmonary circulation resulting from the fixation of the chest walls during violent exercise.

The Danger to Typhoid Carriers from Their Own Typhoid Bacilli.—Wilhelm Kamm under this title discusses typhoid carriers. He refers to Kayser and Park, who found in a routine examination of patients who had had the disease a year previous, that from five to six per cent. still carried the organism. Kamm examined 136 individuals and obtained a positive Widal reaction in eight of them, four of whom had had the disease from four to eight years previously. In these he was unable to find typhoid bacilli in the stools or urine and so concluded that the Widal reaction is no test for bacilli carriers. Schneider and Forster state that in the cases in which the source of typhoid can be definitely proven that from five to twenty-seven per cent. can be traced directly to contact with typhoid carriers. The author then states that typhoid carriers may be a source of danger to themselves as well as their neighbors, and reports cases which he considers prove typhoid autoinfection. The patients were inmates of an insane asylum. Case I. This woman had typhoid fever in March, 1906, and remained a carrier. In October cholecystectomy was attempted on the patient, but given up, and a few days later she died of pneumonia. At autopsy the gall-bladder was normal, the spleen enlarged and soft, pneumonia. Typhoid bacilli were found in the liver, gall-bladder, and duodenum. Case II. The patient in 1901 had typhoid fever and continued to have the bacilli in the stools. She also had tuberculosis and died in 1908 of a cerebral hemorrhage. At autopsy gallstone and carcinoma of the gall-bladder and liver, as well as tuberculosis and cerebral hemorrhage, were found. Typhoid bacilli were isolated from most of the internal organs. The author fails to show in what way the presence of the typhoid bacilli in the organs in these two cases caused the final illness. His next two cases are the more common ones of post-typhoid rib abscesses.

The Treatment of Paralysis of the Upper Extremities.—Vulpius refers to the marked similarity in symptoms between the true birth palsies of the arm due to injury to the brachial plexus and the pseudoparalyses from separation of the epiphysis at the head of the humerus. In both cases there is marked internal rotation of the humerus—in one case from paralysis of the external rotators, in the other from dislocation of the bone. The loss of function is especially marked by an inability to raise the arm above the horizontal or to reach the face with the hand. Heusner devised an apparatus to rotate the arm mechanically, but this was not very successful. Cutting the pectoral muscles has also been attempted. Neuroplastic operations hold out some hope in the cases of true paralysis. Vulpius then describes a new operation to relieve the deformity. This consists of an osteotomy of the surgical neck of the humerus with external rotation of the lower fragment. Two cases are reported, one of true, the other of false paralysis. In both the results were perfect, the arms, after removal of the bandages and sufficient time to enable the strengthening of the muscles, showing as free motion as on the well side.

French and Italian Journals.

Primary Cancer of the Urethra in Women.—André Boursier gives two cases of primary cancer of the urethra, a somewhat rare disease. These cancers are usually of pavement epithelium, which may be tubular. It is accompanied by pain, difficult urination, pollakiuria, and final retention of urine. In some cases incontinence and pain in coitus have been observed. The treatment varies with the depth to which the disease has invaded the tissues along the urethra. When it has involved only the tissues below the symphysis, that is from ten to twelve millimeters in length, it may be removed by the bistoury, an incision being made wide of the growth, and the mucous membrane of the urethra sutured to the vaginal wall to reconstitute its orifice. When the whole urethra is involved the growth may be still removed, but the operation is much more difficult. When the growth has involved the neck of the bladder operation becomes impossible. In any case the results are that incontinence remains to a greater or less degree.—*Journal de Médecine de Bordeaux*, March 8, 1908.

Prolapsus Uteri in Nulliparæ.—Paul Reclus says that prolapsus uteri in young nulliparæ who are unmarried is generally of congenital origin. It is seen in girls of infantile aspect, with irregular menstruation, ill developed muscles, and ptoses of the abdominal organs. Here the peritoneum is not at fault and its repair or suture is of no value as a therapeutic measure. The origin of the trouble is due to a bad development and weakness of the uterine ligaments, especially the round ligament. This allows the uterus to descend and the Alexander operation is found to give no benefit because the ligament is found to be weak and to stretch easily. The only operation that is of benefit is that of ventrofixation, one that is not generally advisable in women who may marry and become pregnant.—*Gazette des Hôpitaux*, March 12, 1908.

Book Reviews.

Orthopedic Surgery for Practitioners. By Henry Ling Taylor, M.D., Professor of Orthopedic Surgery and Attending Orthopedic Surgeon, N. Y. Post-Graduate Medical School and Hospital; Assistant Surgeon, Hospital for the Ruptured and Crippled, New York; assisted by Charles Ogilvy, M.D., Adjunct Professor of Orthopedic Surgery, N. Y. Post-Graduate Medical School and Hospital; Attending Surgeon, New York City Children's Hospital; and by Fred H. Albee, M.D., Instructor in Orthopedic Surgery, N. Y. Post-Graduate Medical School and Hospital; Assistant and Skiagrapher, Hospital for the Ruptured and Crippled, New York. New York and London: D. Appleton & Co., 1909.

This book, as its title implies, has been written for the benefit of the general practitioner, and in many respects the author's purpose has been well carried out. Theoretical discussions and masses of statistics have been omitted; most of the illustrations are entirely new and unusually good; and the reader has laid before him, in a practical manner, the results of a long and ripe clinical experience. The arrangement of the book, with its division into three parts, viz., General, Special, and Technical, is excellent, and makes for clearness. The chapter on the foot, and the division on technique are especially good, as is also the section on examination and general diagnosis. It is to the writer's credit that he maintains an attitude of scientific scepticism towards fads in his specialty, as, for instance, mechanicotherapy and elaborate systems of exercise. But, on the other hand, there is perhaps a little too much repetition of good practical ideas on the subject of correct habits of life, too much of a "hopeful, happy, and tranquil mind." In differential diagnosis the book is rather weak, and in this respect will be a disappointment to the general practitioner who turns to it for help in looking up a case. The great fault of the book, however, is in the subject of pathology, especially of minute pathology. No amount of clinical experience or familiarity with the writings of others can altogether atone for this fault, which is a common one in orthopedic textbooks. It is apparent throughout the book and is especialy noticeable in the description of Potts' disease and of hip-joint disease. A ganglion of the wrist is called "a collection of gelatinous fluid in a dilated bit of tendon sheath," and the pathology of "angina cruris" is inexact. In discussing sarcoma of the long bones, the author avoids the subject entirely, and advises removal of a piece of the tumor and its examination by a pathologist. In a number of the illustrations, the name of the assistant who holds the patient is given. "Posed by Smith," or by Jones, is hardly dignified in a medical work. Hysterical scoliosis is mentioned, but not carefully described, and the pathogenesis of scoliosis in general does not seem to agree with the most modern views. On the other hand, the general remarks on postural deformities of the spine and on atrophy, ankylosis, and massage are excellent; and the exposition of the principles governing the application of braces is unusually complete and satisfactory. The eminently practical qualities of the book, and the sincerity and earnestness of its author make it a real addition to orthopedic surgery.

Marriage and Disease, Being an Abridged Edition of "Health and Disease in Relation to Marriage and the Married State." Edited by Professor H. Senator and Dr. S. Kaminer (Berlin). Translated from the German by J. Dulberg, M.D., Manchester, England. New York: Paul B. Hoeber, 1909.

The translator does not intercede for divine or professional mercy upon his rendition, and it is beyond the reviewer's province to do it for him. Yet the temptation becomes almost irresistible when he makes Posner mention, on page 307, "a discharge from the urethral orifice of a thin, *rubber*-like, viscid fluid." The translator probably knows that we Americans speak of rubbers as our English cousins mention their "gums." We have heard of a hardy Briton "cleaning his gums on the front door mat," but have naturally never seen the heroic, albeit unesthetic, performance. Our translator evidently intended to make his work comprehensible to us when he converted Posner's "gummi-artig" (mucilaginous) fluid into one of a rubber-like consistency. Several other small slips could be cited, but they do not materialy obscure the text, and moreover do contribute in some measure to the gaiety of nations. In the preface we learn that the translator was commissioned by the publishers to prepare an abbreviated edition of the work mentioned in the sub-title, which would be intelligible to the ordinary reader. It seems questionable whether in abridging the original he did well to instruct the lay-reader in sexual perversions, as he does in his translation of Moll's chapter. In it are mentioned (p. 375) "the cases of ladies of the highest rank who fall in love suddenly with their coachmen, or where ladies persecute with passionate proposals negroes or other uncommon people." On the same page are presented "married women who, after having for years loved their husbands, and faithfully performed their conjugal duties, are suddenly seized with a passion for some entirely unworthy individual into whose arms they throw themselves unreservedly." That husbands of such females need not remain unconsoled appears in the next sentence: "Sometimes this infatuation disappears after a few months or even weeks, making room again for the normal married life." It seems more than debatable whether the knowledge of certain appliances should be brought to young wives who seek information from the present work, by reproducing, in Fürbringer's contribution (p. 159), the latter's condemnation of "the so-called exciting cundoms," which "serve no other purpose than to increase the sexual sensation." Certainly no prudishness evokes the wish that the translator and editor had eliminated those parts without which the usefulness of the work to the layman, for whom it is intended, would not have suffered. However, the imgressions beyond the border-line of pornography will doubtless increase the sale of the book. If the readers would take advantage of its really valuable contents, written by most eminent German specialists for the original work from which the present volume has been condensed, it would still accomplish a good purpose. It may be hoped that the editor, in preparing a new edition, will eliminate such information as can be of no benefit, and may be pernicious to the lay reader. In a work for physicians, as is the original, the indecent verbal illustrations are unfortunately inseparable from clinical descriptions.

Intestinal Autointoxication. By A. Combe, M.D., Professor of Clinical Pediatry at the University of Lausanne (Switzerland); Chief of Clinic for Children's Diseases; President of the Swiss Pediatric Society. Together with an Appendix on the Lactic Ferments, with Particular Reference to Their Application in Intestinal Therapeutics. By Albert Fournier, formerly Demonstrator at La Sorbonne, Paris. Only Authorized English Adaptation by William Gaynor States, M.D., Clinical Assistant, Rectal and Intestinal Diseases, New York Polyclinic; Member of American Medical Association; Member of State and County Society of New York, West Side Clinical Society, etc. With 18 figures in the text, 4 of which are colored. New York: Rebman Company.

Autointoxication is a subject of growing importance to the physician, and the literature bearing on it is none too great, especially in quality. The present work, while it is the latest pronouncement, can hardly be said to add much to our knowledge of the subject. It begins with an introduction, which deals with toxemias, intoxications, and autointoxications, these last being subdivided into "dycrasic" and gastrointestinal. Why the translator uses the term "dycrasic" and "dycrasia" (presumably for dyscrasic and dyscrasia) we do not know; but he is consistent and persistent in his preference for the former terms. Then come sections on toxic substances, the antitoxic functions of the organism, and experimental pathology. So far, the book is a fair *résumé* of present knowledge on the subject. The next portion treats of the causes of intestinal autointoxication, its pathological physiology, pathogeny, symptomatology, and diagnosis—and is disappointing. The author does not sufficiently distinguish between scientific fact and mere hypothesis, and old opinions are restated and put forward without any investigation as to their value. The last and largest part of the book is on treatment; and this is the most valuable portion of the whole work; perhaps this is not to be wondered at, as the author's opening sentence is, "The object of this book is to make my methods of treatment known." The term autointoxication has a very satisfying sound, and has long served as a cloak for ignorance; and the present work, while containing some things of value, particularly in the section on treatment, contains also so much that is of little use, that it can hardly appeal to readers who appreciate the writings of Albu, Bouchard, Herter, and others on this subject. The volume would benefit much by a thorough and critical revision. Besides "dycrasia" (noted above), "ileus" is used for ileum, "salycilic" and "salycilate" for salicylic and salicylate, and "specie" for species; these all appear over and over again. On page 36 part of a sentence is omitted; "evolution" occurs for ovulation; "bacillus anthracosis" does duty for bacillus anthracis; "cephalgia" is used instead of cephalalgia; expressions like "its almost totality," "a same ferment," etc., indicate lack of care in translating or in revision.

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held May 24, 1909.

The President, Dr. H. Seymour Houghton, in the Chair.

Home for Dr. Carroll's Widow.—It was reported from the Comitia Minora that the sum of $150 had been voted from the general funds of the society for the fund for the purchase of a house for the widow of the late Major Carroll, Surgeon, U. S. A.

Further Studies on the Presence of the Tubercle Bacillus in the Circulating Blood.—Dr. Randle C. Rosenberger of Philadelphia read this paper. He said that following the preliminary report of fifty cases of pulmonary tuberculosis in which the tubercle bacillus was demonstrable in every instance, he continued the study of the phenomenon until at the present time the number of cases was over 300. That tubercle bacilli were suspected as being present in the circulating blood was a well-known fact. In the present study he included (together with pulmonary types) tuberculosis of other structures, to determine, if possible, whether the bacillus could be demonstrated in the blood. Glandular, osseous, and peritoneal tuberculosis, together with three tumors of the nervous system (cerebellar) and one case diagnosed as transverse myelitis came under observation. In several cases of meningitis tubercle bacilli were demonstrated in the blood; one of these cases came to autopsy, and a pig inoculated with the cerebrospinal fluid developed tuberculosis. In a case where a tumor was present just above the clavicle and the diagnosis rested between sarcoma and tuberculosis the bacillus was present in the blood, and when the tumor was removed it proved to be a mass of tuberculous glands. In Pott's disease of the spine a long search was necessary, but tubercle bacilli were eventually detected in the blood, as well as in the feces and urine. Epididymitis, cystitis, and orchitis also showed tubercle bacilli in the blood. Acute pleurisy, especially pleurisy with effusion, was diagnosed as tuberculous time and again by resorting to an examination of the blood. In three cases where the tubercle bacillus was found in the blood of a tuberculous mother the organism was found in the blood of the child. Fifty-seven cases diagnosed as incipient tuberculosis and nine cases of acute miliary tuberculosis were proven by finding tubercle bacilli in the blood. The technique for the demonstration of the bacillus in the blood was by the citrated blood method; sometimes the specimen was centrifugalized, but usually it was allowed to deposit a sediment by standing in the refrigerator over night. After spreading and drying upon a clean, new slide it was thoroughly laked, then dried, fixed and stained by the ordinary routine technique, as for sputum. As in his work on the feces, he used Pappenheim's solution as a decolorizer and counter-stain. He advised this for the blood work also, insisting upon an immersion of at least twenty minutes to an hour. In some of his preparations he found acid fast bacilli after two hours' exposure to 25 per cent. sulphuric acid in absolute alcohol. In applying carbol fuchsin to the preparation he simply allowed it to act in the cold for ten or fifteen minutes to twenty-four hours, and very rarely, if ever, heated it except when in haste. In these investigations he made use of citrate of soda solutions made at five different laboratories. Some of the spreads were made in one laboratory and laked and stained in another. In the preparation of the blood he never made a diagnosis of a tubercle bacillus unless it was absolutely acid fast. The organisms were of the morphology noted in cultures or in sputum, but none of them would be mistaken by a bacteriologist for granules of debris. In some preparations the organisms were very easily detected, requiring only a very short time; but on the other hand, a search lasted a couple of hours a day for two days, and in one or two cases three days, before the bacilli were detected. As a rule, two spreads were made from each specimen. If the case came to autopsy and they failed to find the organism before death, additional smears were made from the original tube. In two cases a month intervened between the time that the blood was obtained and a second preparation made, and the bacilli were plainly demonstrable. In his own series of 312 cases of tuberculosis an acid fast bacillus was demonstrable in every case which was indistinguishable from the tubercle bacillus. No attempt to grow the organism from the blood had as yet been made. In the majority of the frank, tuberculous cases the diagnosis was always corroborated by finding the tubercle bacillus in the feces, sputum, and sometimes in the urine. Two series of cases might be cited as being of very great interest. In the first series 80 cases were studied, in which the tubercle bacillus was found in the blood. Forty-eight specimens of feces were obtained and 45 were positive; 56 specimens of sputum were studied and tubercle bacilli were found in 33 and none at all in 23; of six specimens of urine studied, tubercle bacilli were found in five; of miscellaneous materials, such as pleural fluid, pus from joints or sinuses or from empyemata, 23 were studied, with positive results in 22. In the second series, comprising 42 cases of tuberculosis, the bacillus was found in the blood in all, and of 19 specimens of feces submitted for examination all showed tubercle bacilli. As a final corroborative test, autopsies were held upon 27 cases, and all of these showed some tuberculous lesion or lesions. From 50 of these cases, after pouring off the citrate solution, the sediment of the blood (about 2 to 3 c.c.) was inoculated into the peritoneal cavity of guinea pigs. One of the animals died in a month with miliary tuberculosis of both lungs. Three other pigs died in two months, one with miliary tuberculosis of both lungs and spleen, and another dying of a frank pneumonia developing into a tuberculous condition of the upper lobe of the right lung. Four pigs showed a few scattered tubercles in the lung as well as in the liver. The remainder of the animals did not present any gross lesions, but the blood of each pig contained acid fast bacilli resembling those found in human blood. As a result of these studies, Dr. Rosenberg said he was more than ever convinced that tuberculosis was a bacteremia, and that the tubercle bacillus could be demonstrated in the blood in every case where there was an active tuberculous process. He also believed that the bacillus was present in the blood in a certain percentage of apparently healthy individuals at some period, and perhaps might be there for years in an attenuated form, and when the general resistance was lowered, or the resistance in some viscus or anatomical structure was lessened, the bacillus became pathogenic, at once lodged at this point, and brought about the disease, tuberculosis. If the bacillus was not present in the blood how could instances of the disease be explained as resulting from injuries of various kinds, or even after surgical operations? Surely the greatest care was exercised by the surgeon as regards antisepsis, and yet tuberculosis was said to follow operations, as for appendicitis, where absolute cleanliness was exercised. He also believed that the bacillus was transmitted from mother to child through the placenta, as the examination of a large number of specimens of blood from umbilical cords showed these same acid fast organisms.

Some Problems Connected with Tuberculosis.—Dr. Henry G. Piffard said that in 1864 Bazen and Hardy taught substantially the same doctrine, namely, that the cutaneous affection commonly known as "lupus" was the offspring of the so-called strumous or scrofulous diathesis, which at that time was regarded as the parent of consumption. Twelve years of observation and reflection led him to accept the French rather than the opposing German views. Further observation led him a year later to write, "Another peculiarity is its gradual extension and involvement of new regions by an apparently infective process, similar to, but less in degree than, that manifested by cancer." (Medical Record, July 21, 1877.) Two weeks later an article from the pen of Mr. Jonathan Hutchinson appeared, in which was stated: "The mode in which lupus extends itself, and more especially in which multiple patches are developed, is well worthy of investigation. My impression is that the processes are by cell infection and very similar to what we observe in cancer." These dates here given were four years prior to the discovery by Koch of the actual infecting agent, and it was worthy of note that the same fundamental idea should have occurred simultaneously to two men living three thousand miles apart. Koch's discovery and isolation of the organism cleared up this mystery. Many others, however, awaited an equally satisfactory solution, to wit: What is the tubercle bacillus of Koch? What are its allies among similar organisms met with in other mammalian species? What are its allies in the avian kingdom? What relationship did it bear to similar organisms met with in the reptilian and piscine orders? The features common to the organisms met with in the animal kingdom were few but positive. As usually seen, they were little rods, which, when stained with fuchsin, resist the decolorizing action of acids and alcohol, and hence were termed "acid-fasts." This fact alone distinguished them from a great majority of other microorganisms met with in the animal body, but not from all. No one had explained either the light or dark particles seen in the bacillus. By some the light ones were supposed to be spores, but Dr. Piffard looked upon them rather as degenerate or degradation forms or perhaps a stage leading merely to fragmentation either with or without loss of vitality. The darkly stained granules, if not true spores, were thought by some to be daughter forms. These were mere superstitions and constituted another of the mysteries connected with tuberculosis. The importance of bovine tuberculosis was second only to that of human tuberculosis. The possibility of its etiological relation to human disease maintained by v. Behring and denied by Koch was at present *sub judice*. Personally, he believed that while possible it was very infrequent, as the number of cases in which human tuberculosis could with any probability be traced to bovine infection was extremely limited. On the other hand, the vast number of consumers of milk from tuberculous cows who did not develop the disease would point strongly to its innocuousness. There was no doubt, however, as to the inroads that tuberculosis was making in the dairy herds, and if unchecked it would lead to great financial loss to the dairyman and to personal inconvenience by lessening the milk supply. It was, therefore, an economic question to which legislators and administrative officials should give their most earnest attention. Swine also rarely became victims of the disease, while sheep and goats suffered to a much less degree. Wild animals in a state of nature were wholly or comparatively free from tuberculosis, but suffered greatly from it in confinement. Tuberculosis was not confined to warm-blooded animals, but had been met with in reptiles and fishes. In the vegetable kingdom acid-fast bacilloids were to be found, possessing the characteristic reactions of the animal germs, and most of them were capable of producing tuberculous nodules, or miliary lesions in laboratory animals. The bacillus of leprosy was acid-fast, difficult of direct cultivation on laboratory media, latent in the system for long periods of time, and finally made its presence known by unmistakable signs and was vastly less amenable to remedial agencies than the tubercle germ. Yet there were many points of similarity between the clinical behavior of the two diseases. Perhaps the most striking and possibly essential difference between the two was the difficulty experienced in the artificial cultivation of the lepra bacillus and the, thus far, unsuccessful efforts to transfer the disease to the lower animals. Tuberculin injected into lepers was followed by the customary reaction thought to be peculiar to ordinary tuberculosis. The etiological factors in human tuberculosis certainly presented problems that demanded most careful examination. Broadly speaking, three main causes had been prominently advocated and considered to be the *focus et origo* of the trouble. (1) Milk fed to infants was the chief cause of consumption. (2) Droplet infection. (3) Dust particles in the air carrying the virulent germs. He did not think that with the present knowledge they were justified in giving preeminence to any of the foregoing. Each undoubtedly had a greater or less influence in the spread of the infection. Tuberculin as a diagnostic aid indicated the presence or absence of tuberculous foci, but it did so, he believed, at the risk to the future welfare of the patient and greatly impaired the patient's resistance to infection. Yamanouchi brought forward an ingenious test. He inoculated a rabbit with the serum of a suspected subject, and after a suitable time followed this with an injection of tuberculin. If the rabbit reacted he considered it as positive evidence of tuberculosis in the patient. Rosenberger claimed that in tuberculosis the bacilli might be found in the blood, but how far this method of diagnosis could be made practical remained to be seen. Attempts to secure an artificial immunity in animals offered a promising field for investigation by the agricultural experiment stations and veterinary laboratories throughout the country. One of the most important objects of laboratory research that should receive early attention was the determination of the relation that existed between the various acid-fast and acid-semi-fasts, if, indeed, such relations did exist. Next, to determine the relative pathogenicity of each, and whether the same was increased or otherwise by passage through animals; this to be followed by efforts to determine positively the question of the transformation of species or types into each other; and finally to determine if they had a common ancestor that could be reached, and whose activities could be curtailed.

The Clinical Diagnosis of Tuberculosis of the Tonsil.—Dr. Lee Maidment Hurd read this paper (see page 1089).

Dr. George B. Wood of Philadelphia said he would confine his remarks to tuberculosis of the tonsil and the possibility of systemic infection from disease of this organ. Dr. Hurd had called to their attention the dangerous tonsil, the submerged tonsil, and tuberculosis of this offered a greater danger than did tuberculosis of ordinary tissues that were regarded as dangerous. He did not think that clinically it was possible to recognize tuberculosis of the tonsil, except in very rare cases in which there was ulceration. In the examination of 38 cases *post mortem*, patients who were supposed to have died of pulmonary tuberculosis

of advanced form, in 32 positive evidences of tuberculosis of the tonsils were found; and yet in none of the cases had the pathologist at the time of the *post mortem* reported any tuberculous disease of this organ. He said he had seen a few cases of tuberculosis of the tonsil secondary to pulmonary disease easily recognized clinically by the ulcerative process. In speaking of tonsils one should remember that they were simply glands with a very intimate relationship to the epithelium. They were so constructed that they retained bacteria very readily and 5 per cent. was about the ordinary average in which tuberculosis was found in the faucial tonsil if removed. At least that was the percentage given after investigating 1,300 cases which were reported by twenty different authors. He thought that the pathological diagnosis of tuberculosis of the tonsil rested largely upon its histology. Was it possible for the disease to start in the throat, and invade the apices of the lungs, or bronchial lymph glands directly through the lymph current? He described the anatomy of the lymph current and showed that this was possible; a retrograde current could affect the parietal apical pleura.

Dr. Bond Stow said that for three months he had been devoting all his spare time to studying the presence or absence of tubercle bacilli in the blood, the kind of bacilli spoken of by Dr. Rosenberger, the bacilli absolutely acid-alcohol-fast, conforming to the morphology and stain of the classical type of Koch's bacillus. The cases were studied clinically and *post mortem*. After describing the technique in which he endeavored to obtain a non-contaminated blood, he reported 18 cases of chronic tuberculosis which were diagnosed clinically as tuberculosis. In seven of these positive tubercle bacilli were found in the blood; in 10 cases of incipient tuberculosis all diagnosed clinically, the bacilli being found in the sputum, in not a single instance was he able to find the bacilli in the blood. A full report of this work he said he would give later.

Dr. Benjamin White reported his results after following the technique of Dr. Rosenberger exactly, and in none of the cases was he able to find the tubercle bacilli in the blood. A guinea pig was inoculated with the human bacilli. Six weeks after the liver was found to be riddled with tubercles; the liver was necrotic, the spleen was studded with tubercles, as was the diaphragm, pleura, peritoneum, etc. From the right heart were withdrawn 5 c.c. of blood, and, following Dr. Rosenberger's method, only one tubercle bacillus was found. It seemed strange that an animal with such a severe infection should have so few bacilli in the blood. The bile was also examined, but no bacilli were found. He thought that the results of their experiments were very suggestive.

Dr. William H. Park said that in their laboratory one of the men, a very careful worker, had examined half a dozen cases, and his results were the same as Dr. White's. He thought it would be a very good thing to have Dr. Rosenberger come to New York and demonstrate his technique so that they could get together in this matter. It was very hard to understand how animals got this bacteremia and yet did not develop tuberculosis; he could not see how the tubercle bacilli could exist in the blood and not produce tuberculosis. However, one not familiar with the technique should hesitate in giving judgment.

Dr. Bernstein had followed the technique of Dr Rosenberger very carefully, but with negative results.

Etiology and Treatment of Diarrhea.—Dr Joseph E. Winters said that of 22,476 cases of fatal diarrhea 88.8 per cent. occurred under the age of one year; of 10,886 fatal cases occurring in one year, nearly 70 per cent. were under six months, and 90 per cent. under one year of age. Fatal diarrhea occurred almost solely in the nursing period. It was never seen in a child fed exclusively at the breast of a healthy mother. Artificial feeding was the cause of the fatal diarrheas. It was a disease of the heated term. At the Yale University Agricultural Station it was shown that fresh milk cooled at once to 40° F. and kept at that temperature prevented the growth of bacteria. Of the fatal diarrheas but 1.2 per cent. occurred among the higher classes; this was because they were able to care for the milk properly. With the fresh milk kept at 40° F. there would be no more diarrhea in summer than in winter. The injurious bacilli required a certain temperature in which to develop; they would not develop in milk if it was kept at 40° F. Pasteurization destroyed these germs; but the spores and toxins were still present and were not affected by the heat. The high temperature, marked prostration, delirium, coma, convulsions, etc., were caused by these toxins; the nervous collapse seen for days after the diarrheas had ceased, together with the lesions in the various organs, were the effects of these toxins; the vomiting and purging were caused by these toxins acting on the splanchnic nerves. The spores would develop into germs unless the milk was kept at a low temperature. After their ingestion the spores developed into germs and produced toxins. Even after pasteurization the toxins possessed the same toxicity as the organisms. It was stated that the mortality in infants under one year of age at the Berlin Charity Hospital was from 89 to 92 per cent, and that no amount of pasteurization or sterilization had the slightest effect in preventing or controlling the diarrheas. Of 634 fatal cases over 58 per cent. died in less than seven days. Of those that died after the second week one-half had bronchopneumonia, bronchitis, pleural exudations, etc. After the second week certain lesions supervened which were caused by the toxins. The millions of villi in the small intestine offered an enormous absorbing surface for the toxins, and food laden with bacilli certainly should be avoided; food in such cases was as sand to an inflamed eye. Rest to the intestine must be assured until the fermentation ceased. A dose of castor oil was advised, to be followed by water of ammonia. If high temperature was present, cold water could be given with benefit. When there was a dry tongue, fever, fast pulse, etc., rhubarb and bicarbonate of soda were advised Dr. Winters then took up a consideration of the feeding for infants under one year, and under two years, when diarrhea was present. Beef juice should never be given. The giving of cereals to infants under six months of age was pernicious. If irrigations were required to aid the action of castor oil in clearing out the intestines, glycerin and warm water should be used But it should be remembered that repeated irrigations were exhausting and dangerous.

AMERICAN MEDICAL ASSOCIATION

Sixtieth Annual Meeting, Held at Atlantic City June 8, 9, 10 and 11, 1909.

(Special Report to the Medical Record.)

SECTION ON DISEASES OF CHILDREN

(*Continued from page 1083.*)

Thursday, June 10—Third Day

Election of Officers.—The following officers were elected for this section for the year 1910: *Chairman* Dr. William J. Butler of Chicago; *Secretary* Dr. Godfrey R. Pisek of New York; *Delegate*, Dr. Charles Douglas of Detroit.

The Child's Breakfast.—Dr W. C. Hoffheimer of

Philadelphia read this paper. He said that about 30 per cent. of the children of New York and Chicago were sent to school without breakfast. He claimed that poverty was not the sole cause of this condition, but that investigation showed that bad hygiene and overcrowding in the homes were the factors most responsible. In his opinion many of the children did not have an appetite for breakfast, due to the conditions just enumerated. He believed that the lack of proper food for the day's work seriously handicapped the child physically as well as mentally. It was frequently good food improperly taken, as well as essentially bad food irregularly consumed, that showed evil results in the child's development. To remedy the matter he advised education of the mothers as to the importance of personal and general hygiene of the home, ventilation of the sleeping rooms, and the necessity of good food properly taken at regular intervals.

Conditions of the Public School Child.—Dr. J. W. Van Derslice of Chicago presented this paper, based upon a study of school conditions existing in the Middle West. The data presented covered an investigation of 904 schools in 31 cities, ranging in population from 50,000 to 2,000,000, and the conclusions were as follows: 1. Twelve per cent. of the pupils in the first grade and 31 per cent. of the pupils in the fourth grade were average. 2. One child out of every 200 pupils was compelled to leave school on account of ill health. 3. Nineteen per cent. of the schools had no playgrounds. 4. Eight per cent. of the first grade pupils had no outdoor recess. 5. Twenty per cent. of the school toilets were in an unsanitary condition. 6. Twenty-two per cent. of the schools were improperly ventilated. 7. Fifty-three per cent. of the schools used free text books and had no means of sterilizing the same. 8. In the first and seventh grades the number of pupils in each room ranged from 31 to 40. 9. In the first grade 7 per cent. of the teachers required home work of the pupils. 10. Seventy-six per cent. of the cases of nervousness in children of the first grade were caused by too much school work. 11. The curriculum of nearly every school investigated was overcrowded. 12. The medical inspection of the schools was inadequate. 13. As a remedy for these evils the establishment of a supervising board of competent physicians in every city and town was advised.

Dr. L. T. Royster of Norfolk said that no school board was competent unless one of its members was a physician. He believed that the physical and moral welfare of the child was superior to the intellectual training, and advocated more physical culture and manual training among school systems. He stated that the education of the masses was best accomplished in the homes, and urged that physicians act as missionaries in this respect. A plea was made for broadminded principles in regard to public instruction.

Dr. Charles Douglas of Detroit thought that our most urgent duty consisted in the education of the public. We were now dealing with the results of ignorance on the part of mothers and others who had the welfare of the children in charge. The establishment of a department for the education of young women on the subject of nutrition was sadly needed in every college.

Dr. George F. Little of Brooklyn said that the discussion of this subject among physicians was useless. In his opinion best results were obtained by an education of the public at large.

Dr. Charles Gilmore Kerley of New York said that it was first necessary to educate the physicians as to the needs of the child. Physicians were urged to become more interested in the subject of the school child. It was his belief that a department of hygiene was necessary in every large town.

Dr. Helen Putnam of Rhode Island said that hygiene was not taught by text books, but by personal, practical instruction of parents and physicians. Medical inspection of schools was inefficient, and better trained medical inspectors were urgently needed. School fatigue was commonly noticed among children, and to overcome this condition the establishment by the school boards of the various cities of such departments as domestic science and nature study was advised.

Dr. Henry I. Bowditch of Boston said that the medical student in college was neglected, as he received practically no lectures on the subject of ethics, and that the average medical graduate knew little or nothing concerning the duties of the physician to his State and country.

Dr. J. W. Van Derslice of Chicago closed the discussion. He agreed that the education of physicians as to the particular requirements of the school child was important and necessary. He said that all questions which pertained to this subject deserved careful consideration before any drastic action was taken.

Help the Mother Nurse Her Child. A Plea to Physicians Not to Begin Artificial Feeding Without First Trying to Help the Mother Maintain Her Milk Supply.—Dr. Maurice Ostheimer of Philadelphia read this paper and drew the following conclusions: 1. The fact that all women were able to nurse their children appeared to be forgotten recently since artificial feeding had proved so successful. 2. Physicians were advised to prepare, encourage, and aid every pregnant woman to nurse her child. 3. During pregnancy it was necessary that attention be paid to breasts, exercise, fresh air, sleep, regular bowel movements, correct food, and plenty of water. 4. After confinement the mother was instructed to take two or three quarts of water daily, cornmeal and gruel between meals, and perhaps milk, cocoa, iron, and brown stout. 5. When this was correctly carried out the mother was enabled to nurse her child to nine or ten months, at the end of which time diluted cow's milk was given from a cup. 6. By this method no bottles or nipples were required. 7. The treatment was only contraindicated in advanced tuberculosis in the mother and in those nervous women who continued to grow stout on it without improvement of their breast milk supply.

Dr. H. M. McClanahan of Omaha said that careless physicians were partly responsible for the wholesale weaning that now existed. Many mothers weaned their children in the first two weeks of life because the child cried a great deal, and therefore believed that the breast milk was insufficient for the needs of the infant. He believed in mixed feeding, and supplemented the breast feedings by one or two bottles of modified milk mixtures daily in those cases where the supply of breast milk was found inadequate for the child's nourishment. He condemned the practice of weaning for trivial causes, and said that nothing but serious organic disease in the mother exempted her from nursing her offspring.

Dr. J. P. Sedgwick of Minneapolis said that there was no need for so much weaning, inasmuch as the majority of mothers had breast milk. He agreed that in some instances physicians were responsible for this evil, and believed that the subject of maternal nursing deserved more consideration.

Dr. L. A. Bulkley of New York advocated more maternal nursing, and dwelt upon the importance of caring for the mother before the birth of her child. In his opinion brown stout was not good for the nursing mother, as in many cases it disturbed digestion. He advised the employment of milk which was diluted one-third with boiling water. He administered one glassful of such milk three times daily, one hour before meals, and found that it improved the appetite and increased the supply of milk in the breasts.

Dr. A. F. Fur of Cleveland said that babies were fed at too frequent intervals. He believed in feeding infants four ounces of milk mixture every four hours.

Dr. J. W. Van Derslice of Chicago did not approve of

long distance feeding. The average baby's stomach had a capacity of two ounces, and four ounce mixtures were therefore contraindicated. He said that in many cases obstetricians were responsible for the early weaning of infants, as they usually had charge of the child during the first two or three weeks of life.

Dr. Charles Douglas of Detroit said that a careful consideration of the child's age and digestive powers was necessary before any milk mixture was advised.

Dr. John Lovett Morse of Boston said that the proper place for a discussion of this subject was before the Obstetric Society, since the obstetrician usually had charge of the child during the first few weeks of life.

Dr. F. P. Gengenbach of Denver said that he was a firm believer in breast feeding because it increased the child's resistance powers. In place of bottle feeding he advocated wet-nursing, and deplored the fact that the number of wet-nurses was so small.

Dr. Thomas S. Southworth of New York said that milk as a milkmaker stood first in the nursing mother's dietary. He believed that supplementary feedings improved the supply of breast milk.

Dr. Maurice Ostheimer of Philadelphia closed the discussion, and said that in his experience large quantities of milk in the dietary of the nursing mother had not proved satisfactory.

Opacities of the Cornea: Their Frequency in Children from Preventable Causes and Their Effect on Vision.—Dr. C. W. Cutler of New York presented this communication. His conclusions were as follows: 1. A knowledge of the structure of the cornea and familiarity with the methods of examination was important. 2. Early recognition of lesions of the cornea was important, so as to prevent blindness. 3. Externally, the causes of opacity of the cornea were traumatism, gonorrhea, and trachoma, and, internally, tuberculosis and syphilis. 4. Phlyctenules were sure signs of latent tuberculosis in the patient. 5. In the treatment of ophthalmia neonatorum Crede's method was preferred. 6. Mothers were permitted to nurse infants afflicted with ophthalmia neonatorum, provided great care was exercised.

Suppurative Conditions in Joint Regions in Infants.—Dr. Linnæus E. La Fétra of New York read this paper. He said that young infants were susceptible to joint infections, and that in children over five years suppurative conditions were more commonly found. Infection in these cases was due to the streptococcus, staphylococcus, gonococcus, pneumococcus, typhoid bacillus, osteomyelitis, epiphysitis, deep cellulitis, and perinephritic abscesses. He believed that rheumatism occurred rarely in very young infants, and that gonorrheal arthritis was more frequently seen in male children. Cases of scurvy in children sometimes stimulated joint affections, and were differentiated by a careful examination of the gums and a history of the course of the disease. The diagnosis between tuberculous and rheumatic affections was made by exclusion. The treatment depended largely on the cause of the infection, but in general it consisted of immobilization of the joint with the application of compresses of equal parts of alcohol and alum acetate. If these procedures were not effective, surgical measures were advised.

Dr. Charles N. Dowd of New York said the subject of suppurative conditions of the joints in infants deserved more attention on the part of the profession. He stated that in some instances a correct diagnosis of the particular type of infection was made with great difficulty.

Exhibition of a Patient with Achondroplasia, with Notes on the Disease.—Drs. M. H. Fussell, R. S. McCombs, and G. L. De Schweinitz of Philadelphia presented this patient, and the notes on the disease were read by Dr. Fussell. He said that achondroplasia affected only the bones that were laid in cartilage. These cases were all dwarfs, and the patient exhibited, although 16 years of age, was but 35 inches in height. Pathologically, this disease was at first confounded with rickets; however, the *x*-ray now made it possible to differentiate between the two conditions. Achondroplasia was characterized by a recession of the bones of the nose, a large vault as compared to the base of the skull, marked bowing of the legs, dwarfism, enlargement of the ends of the bones, and fingers all of the same length. The case exhibited was a boy who, in addition to his achondroplastic condition, was also suffering from congenital syphilis, and this was the only case on record where a combination of these two diseases existed in the same individual.

Syphilitic Pseudoparalysis.—Dr. L. T. Royster of Norfolk read this paper and defined syphilitic pseudoparalysis as a manifestation of inherited syphilis exhibited by failure on the part of the infant to move one or more of its extremities. The ends of the long bones were enlarged and the bones usually affected were the ulna, radius, humerus, and tibia, and in areas affected, in some cases, pus was formed. The diagnosis of this condition was plain in the presence of a syphilitic history, but at times it was found necessary to distinguish between pseudoparalysis, scurvy, birth palsies, fractures, and dislocations. The treatment was antisyphilitic, and in cases where pus had formed surgical measures were employed.

Vaccine and Serum Therapy in Diseases of Children.—Dr. Charles Gilmore Kerley of New York read this paper and drew the following conclusions: 1. The object of this treatment was to produce immunity. 2. The treatment was most satisfactory in staphylococcic infections. 3. Streptococcic cases did not show favorable results under this treatment. 4. The dose for a child under three years was from seven to twenty millions of dead cocci, and it was repeated every sixth day. 5. Cases of furunculosis showed marked improvement under treatment of staphylococcic vaccine. 6. Cases of gonorrheal vaginitis showed no favorable results when injected with dead gonococci. 7. Cases of pneumonia had not shown any improvement when treated with pneumococcic serum. 8. Local tuberculous lesions were treated with injections of tuberculin with doubtful results. The dose employed was 1/5000 milligram, and it was given every second day.

The Antibodies in Tuberculosis: Their Relation to Tuberculin Inoculation and Vaccination.—Dr. William J. Butler of Chicago read this paper. He said that the object of these experiments was to produce antibodies in the blood stream, and that all the cases employed in these experiments were suffering from tuberculosis. The subject was still in the process of evolution, but thus far no antitoxin effect had been observed from the injection of tuberculin.

Persistent Thoracic Sinus Following Empyema.—Dr. Charles N. Dowd of New York presented this paper, which was based upon a study of fifteen cases. He concluded as follows: 1. Persistent thoracic sinuses were cured by decortication of the lung and partial resection of the chest wall in 80 to 90 per cent. of the cases. 2. After the operation patients showed no lateral curvature of the spine. 3. The lung capacity remained much diminished. 4. The patients had good health and were not materially inconvenienced. 5. The mortality was probably more than 5 per cent. and less than 10 per cent. 6. The after treatment consisted of pulmonary gymnastics.

Dr. F. G. Beck of Chicago said that he operated only as a last resort. He thought 80 per cent. of the cases were cured by the injection of bismuth-vaselin paste.

Dr. Charles Gilmore Kerley of New York inquired as to the efficiency of Bier's hyperemic method in the treatment of these cases. He believed in employing pulmonary gymnastics, and asked if vaccine therapy had been productive of good results in this class of cases.

Dr. A. Jacobi of New York said that he had had good results from the use of bismuth-vaselin paste in the treatment of fistulæ. He had used a solution of iodine in many cases, but the results were not favorable.

Dr. Charles N. Dowd of New York closed the discussion. He said that bismuth-vaselin paste gave satisfactory results in some cases. He believed that all cases of empyema demanded early operation. Bier's method was not satisfactory in his hands. The treatment here was a mechanical problem, not a question of bacteria, and he therefore thought that vaccine therapy was out of place as a remedy for these conditions. The average duration of the cases reported was fifteen months.

The Treatment of Diabetes Mellitus.—Dr. Julius Rudisch of New York read this paper, and summarized as follows: 1. Contrary to accepted theories, a strict protein diet maintained over a long period was not only beneficial as to sugar excretion, but there was an improvement of the general nutrition, with an increase in body weight. 2. The presence of acetone, diacetic, and β-oxybutyric acids in the urine was no contraindication to a strict protein diet with the exclusion of fats. 3. In some cases of emaciation vegetable fats were substituted for animal fats with great advantage. 4. In nonemaciated subjects the administration of fats was unessential and occasionally detrimental. 5. Medicinally, atropin sulphate, of which large doses had been borne, not only had an undoubted influence on the excretion of sugar, but also had increased the tolerance for carbohydrates. Bicarbonate of soda was also used with beneficial results.

Dr. A. Jacobi of New York said that sixty years ago diabetes was a rare disease. He had seen but fifteen cases of diabetes in children, and the result was fatal in every case. He believed heredity played an important part in the etiology of diabetes in children. He thought that many cases of transitory glycosuria existed. In the treatment he had employed arsenic in slowly increasing doses, and he had also resorted to the use of atropine and codeine. In feeding these cases he believed that fat was digested only in certain quantities, and that in some instances it produced irritation of the kidneys. He very frequently employed olive oil in the treatment of diabetes, and he claimed that it always produced excellent results.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Wednesday, June 9—Second Day.

The Remote Results of Conservative Surgery of the Ovaries.—Dr. J. O. Polak of Brooklyn gave a study of the results of three hundred operations, with resection of one or both ovaries, and forty-one secondary operations for recurrent disease. The object of conservative surgery had been to preserve ovulation and possible pregnancy, the internal secretion of the ovary, and to avoid an operative menopause. Pregnancy had followed the conservative operation in 10 per cent. of the cases. In one case in which, at the age of eighteen, he had removed one ovary and resected a monocyst from the other ovary, there had followed five pregnancies with three living children. The postponing of the menopause was in itself sufficient ground to do conservative surgery if possible. The results of the resection of the ovary were at times shown in premenstrual pain and in some cases enlargement of the ovary. If the ovary was carefully sutured so as to cause coaptation but no pressure, and attached high in the pelvis, so as to remain free from peritoneal adhesions, it was frequently possible to avoid some of the early postoperative swelling and pain in the ovary. Ablation of the tubes and ovaries tended to displace the uterus. Retention cysts of the ovaries when punctured were usually cured without further trouble. Microcystic ovaries, when resected, usually caused further trouble and needed secondary operation; monocysts could usually be removed and no further trouble in the ovary need be anticipated. Of six dermoid cysts in which the ovary was resected, only one required further operation. Papilloma of the ovary recurred.

Dr. J. G. Clark of Philadelphia said that in the cases of artificial menopause the postoperative state was worse than the preoperative. In inflammatory cases, if it was necessary to operate in the acute stage, radical removal was necessary, but it was much more satisfactory to wait for the acute conditions to subside and leave a small residuum of disease, after the method of Senger, and then remove that small residuum and preserve the portions of the ovaries, menstruation, and leave at least a hope in the patient's mind that a pregnancy might follow.

Dr. Howard Kelly of Baltimore said that the conception of conservatism changed as time advanced. Formerly it was considered conservative to save one ovary; now he punctured ovarian cysts, leaving behind parts of both ovaries, and even such marked conservatism was not, as a rule, considered important enough to be mentioned in the case histories. There were several factors that had to be considered in the question of conservatism. One was the age of the patient. He did differently in girls from what he did in old women. Another factor was the occupation of the woman. In the working woman who wanted to take no chances of recurrence of her condition he did radical work, whereas in the woman who did not have to work for a living, and who was willing to take the responsibility of return of the disease and come back for another operation if necessary, he did conservative work, and made the woman report frequently for examination and observation. In the cases of Graffian follicle cyst and corpus luteum cyst he did resection of the ovary. If the hematoma left only a shell of ovarian tissue he took out the whole ovary. In malignancy he took out the diseased ovary, and if there was any suspicion of the other ovary he took that out also. In the dermoid cysts he saved what he could. In pelvic inflammation he saved the ovary, at times supporting it free from the pelvic floor.

Dr. Albert Goldspohn of Chicago said that he had been among the first to do conservative surgery in the West. Some men objected on purely empirical grounds; with them he had no patience. Other doctors objected to conservatism on clinical grounds, and them he respected. The resection of some ovaries not only did not cause any bad symptoms, but might save trouble to the patient. He thought the consistency of the ovary very important—more important than the size in determining its future value to the patient. The point most to be considered in leaving in the ovary was whether or not it would discharge more ova, and, if so, whether that would cause pain and inflammation. If the follicles were deeply situated beneath a fibrous covering, or if there were cicatrices in the ovary which made it probable that the nerve fibers were involved in the scars, then the ovary should be removed. He did not think that operations should be done in the presence of acute inflammation in the pelvis, and for that reason would have the gynecologist treat appendicitis in the female.

Dr. R. B. Hall of Cincinnati had resected monocysts, and in cases of multicysts removed the whole ovary, and possibly the second ovary also; yet he thought it desirable to preserve menstruation, if possible, in every woman under thirty.

Dr. C. E. Frederick of Buffalo had tried to save the ovary and preserve the tone of the nerves. But he was becoming more radical in the cases where the disease was primarily of the ovary. If the pelvic disease was primarily of the tube and the ovary implicated secondarily, he might leave the ovary even though it looked pretty ragged. He considered that if the disease had started in the ovary, and the ovary was resected that the same causes that started the

disease in that ovary in the first place might reproduce it again in the part that was left. He cited one case in which there had been a monocyst in one ovary and a multicyst in the other. He had removed the multicyst ovary in toto and had resected the monocystic ovary. Ten years later the patient came back with an inoperable cancer of the part of the ovary that he had left in.

Dr. H. O. Panzer of Indianapolis reported the case of a woman of twenty-seven years, in whom he had done an ablation of all the pelvic organs. This was followed by senile atrophy of all the organs of the body. He admitted that this was an extreme case, but still taught the value of conservatism.

Dr. Philander Harris of Paterson, N. J., called attention to the entirely different anatomy of the tube and ovary and therefore the improbability that the ovary was more than accidentally involved in the tubal disease. Therefore he saved the ovaries whenever possible, and not more than 3 per cent. of his operative cases had an artificial menopause. Not more than 1 per cent. of his cases had trouble from the fragments of ovary that he left in, and most of those troubles were abscess, that could be easily drained.

An Ovarian Abscess Containing a Lumbricoid Worm.—Dr. Henry D. Fry of Washington, D. C., described this case, which occurred in a colored woman, who gave no history of nausea, vomiting, or lack of appetite before admission to the hospital. On admission she had a temperature of 103° and a pulse of 132. There was a mass in her left side. After admission she vomited a lumbricoid worm, and examination of the stool showed that she passed eggs of the same worm. After the acute symptoms had subsided she was operated on, and the mass in the left side was found to be an abscess of the ovary. There were no adhesions to the intestines. The walls were thick everywhere except at one point, and there they were smooth and nonadherent. It is well known that the lumbricoid worms enter through the drinking water, travel over all mucous membrane surfaces communicating with the alimentary canal, and penetrate lumbar, psoas, and abscesses. The female genital tract is also frequently involved, and the worms passed with the urine. Entrance may be gained by fistulous tracts to the intestine, or by passing over the perineum. A case of a lumbricoid worm in an ovarian abscess had been reported in which the worms were alive, but there were adhesions to the intestines. In this case the worm was dead, flattened, six or seven centimeters long. It was identified by the pathologist. The author thought that in this case the worm had passed externally over the perineum into the vagina and then through the uterus and tube to the Graafian follicle.

The Present Status of Irrigation and Drainage in Obstetrical and Gynecological Operations.—Dr. Horace G. Wetherill of Denver said that the older methods of irrigation and drainage were being simplified. The powerful antiseptic drugs had been shown to be inefficient and possibly harmful, either by their own toxicity or by the mechanical diffusion of the infection. Irrigation was still considered good for certain mechanical effects, but should be used with the minimum efficient force, and never used if it was possible to avoid it. When irrigation was used it should be to wash out débris. Drainage had also been simplified. The old glass tubes were rarely used. And gauze was used only to wall off infection or to control hemorrhage or to prevent leakage from hollow viscera. Drainage was still considered useful after rupture of a localized abscess or after the pouring out of food, pus, or urine into the abdominal cavity. Irrigation might do good in the abdomen in extrauterine hemorrhage by washing out the blood clots and its remnants being absorbed to add to the body fluid. An old tubal abscess might be turned out into the abdomen without bad effect if it were merely mopped out. Similarly, an appendiceal abscess locally ruptured and mopped clean produced no bad effects. The peritoneum was able to take care of moderate quantity of pus, but the tissues of the abdominal wall might need drainage, as they were not so well prepared to cope with infectious material. Abdominal drainage whenever needed was to be down hill through the vaginal vault. Intrauterine irrigation was still abused. Its routine use after uncomplicated labor was bad. Physicians and obstetricians in particular were very reluctant to accept the proofs from the experience of others. Intrauterine drainage at times was needed. A gauze wick was inefficient for all except thin discharges. The drainage should be free and capable of carrying off thick fluids. The author demonstrated a drain made from ordinary rubber tubing that he had found most useful. The intrauterine douches were liable to cause a reinfection of the uterus if they were frequently repeated, just as was seen after the frequent catheterization of the bladder. For irrigation of the uterus he inserted his double tube drain made from plain rubber tubing, and irrigated with 33 per cent. alcohol, permanganate, boric acid, tincture of iodine, salt solution, or sterile water. With his tube inserted at the time of starting treatment the intrauterine irrigation could be carried on with the patient asleep.

Dr. W. W. Golden of Elkins, W. Va., said that he had used irrigations of dilute solutions of iodine with great benefit in some uterine cases, where proper aseptic precautions had not been possible.

Dr. H. D. Fry of Washington, D. C., protested against the use of intrauterine douches in normal labor cases. They increased both morbidity and mortality. In the sapremic cases they might be allowable, and in the cases of infection with *Bacillus coli*. In the streptococcic infections irrigations only did harm. He said that in one set of cases he knew of no efficient drain. These were the cases of vaginal operation for extrauterine pregnancy. The cases where this operation was indicated were limited, but almost always after drainage the patient developed fever, which she should not do if the drainage was efficient.

Dr. Ill of Newark said that he did not think any rubber tube would keep the inner surfaces of the uterus sufficiently apart so that drainage would be efficient. Hence he packed the sides of the uterus with gauze and then put Dr. Wetherill's rubber tube drain into the center of the cavity and irrigated with 25 per cent. alcohol. If this was instituted within two days of the onset of uterine sepsis he saved most of the cases. The gauze and tubes could be removed after five or six days and would be found as clean as on insertion.

Dr. Jack of Genesee, N. Y., believed in the treatment described by Dr. Wetherill. In some cases the apparently moribund patients got well. He thought that the alcohol injections gave constitutional stimulation as well as local disinfection.

Dr. Wetherill, in closing, said that in the vaginal operations for ruptured ectopic pregnancy gauze was more effective than a rubber tube, but here it acted as a tampon rather than as a drain. In the case where the gauze drain or tampon was not satisfactory he did an abdominal operation. In place of Dr. Ill's gauze packing of the uterus in addition to the tube, Dr. Wetherill used half-inch thick walled rubber tubing, which was most efficient.

Fibromata of the Uterus.—Dr. Eliot McDonald of New York had studied 700 cases statistically and pathologically in relation to cancer, degeneration, and complications. Five per cent. of the cases showed malignant changes. Of these adenocarcinoma was present in 2.9 per cent.; squamous celled epithelioma of the cervix in 0.8 per cent.; sarcoma in 1 per cent., and chorioepithelioma. Special stress was laid on the ratio of adenocarcinoma being three times that of cervix cancer, which is just the reverse of the condition in the nonfibroid uterus, showing the unusually great tendency of adenocarcinoma formation in the fibroid

cases. There was an increasing risk to life as the age of the woman increased from the increasing prevalence of malignancy. In view of the sarcomatous changes, carcinomatous associations, and complications of the tumors, early removal was indicated when they were of sufficient size to produce symptoms. The menopause, as shown by the relation of the age of the patient to the complications and degenerations, instead of bringing a cure to the fibroid, was but a precursor of more dangerous complications. Thorough pathologic examination should be made of all excised fibroids for evidence of malignancy.

Enucleation of Uterine Myomata; Why and When Performed.—Dr. E. E. Montgomery of Philadelphia uttered a plea for myomectomy in place of hysterectomy under appropriate conditions. If the uterus were removed the effect of the premature establishment of the menopause could not be predicted. If enucleation was done and was not effectual in relieving abnormal symptoms, or preventing the recurrence of growths, it was always possible to remove the pelvic structures at a subsequent operation. Enucleation should be done by the vaginal route if the tumors were accessible that way and there was no excessive bleeding. The author had operated on five cases during pregnancy without interference with the course of the pregnancy. In one case he had done a myomectomy the suture material in the fundus of the uterus had sloughed off with a part of the fundus. Later the woman had a child without trouble, but during a second pregnancy the uterus had ruptured and the woman died. Removal of myomatous growths by enucleation should be considered when the tumors were few and the uterine structure little involved, when the growths were readily accessible, when the woman was under forty and childless, or with only one or two children, and when the tubes and ovaries were free from complicating conditions. Enucleation should not be considered when the woman was over forty years of age, when the uterus was so spread out by the disease that reconstruction of a functionating uterus would not be feasible, or when the tumors were so distributed that in the necessary suturing the circulation of the uterus would be interfered with.

Dr. Herman J. Boldt of New York endorsed the limited indications for myomectomy. He considered the figures given by McDonald of tubal complication of fibroids as very low. In his own cases they had occurred in over 40 per cent. of the cases, against McDonald's 27 per cent. Malignant changes or suspicion thereof in women over forty were indications for panhysterectomy. Appendicitis had been found in the vast majority of cases when they had been removed and examined.

Dr. G. Betton Massey of Philadelphia approved of Dr. McDonald's exhibitions, but not of his conclusions. He did not think that calcareous degeneration of a fibroid added to its danger, but rather was a sign of physiological absorption, and not an indication for operation. He considered that the differential diagnosis between degenerations and neoplasm was very much needed.

Dr. Howard Kelly of Baltimore said that he had studied some 1,600 cases of fibroids with Dr. Cullen, and in about 2 per cent. there were changes of a sarcomatous nature. He therefore thought that all such cases should be studied carefully microscopically after operation, and the operation revised later if necessary. He thought that myomectomy was the operation par excellence, if feasible, in the cases of fibroids. But it had a greater danger than hysterectomy on account of infection, but more especially from hemorrhage. In the operation he preferred to bisect the uterus, enucleate the masses, clamping and tying the pedicle, and suturing with a tight lockstitch to prevent any hemorrhage. He closed the wound, leaving in a very small telltale cigarette drain, which would indicate the presence of hemorrhage. This drain was removed on the third day.

Dr. Chase of Brooklyn would have the general practitioner educate himself in the pathology of the changes that proceeded in the later stages of fibroids.

Dr. Tracy of Philadelphia said that the increasing dangers of degeneration as the woman got older was certainly an argument in favor of removal of all fibroids except the small ones in young women that gave no symptoms. He considered the diseased ovaries and tubes in a large proportion of the cases simply an associated process, not a factor, in the fibroma causation. He thought the fibromata often merely a part of the general arteriosclerotic process.

Dr. Ill of Newark did not believe in the indiscriminate removal of all fibroids. Statistics taken from general hospital autopsies showed the presence of fibroids in a large percentage of all women, so that hundreds of thousands of women in the vicinity of Philadelphia, for instance, must have fibroids, and if 5 per cent. of these were undergoing malignant degeneration there must be thousands of women dying of such conditions annually, which surely is not the true proportion, so that the statistics of Dr. McDonald needed careful interpretation.

Dr. C. C. Frederick of Buffalo said that the cases should be operated on when they gave symptoms. Of those that refused operation, many died of degeneration of the fibroid. He preferred myomectomy whenever it was applicable. To lessen the hemorrhage he usually tied off one ovarian and the uterine artery on the opposite side, in addition to the myomectomy.

Dr. Lawrence of Columbus thought that this section of the American Medical Association should not allow the teaching to go out that any form of neoplasm could be negligently left in the body without provision for the future. There were certain general symptoms, such as neurasthenia, toxemia, and so on, which were at times due to fibroids without any localizing symptoms. If fibroids were treated early, more myomectomies would be possible, in place of hysterectomy. He thought that every fibroid when found should be removed.

Dr. Montgomery appreciated the pathological histories of Dr. McDonald, but in spite of that would not have every fibroid removed, though he would have those cases that were not operated on watched very carefully. The mortality from operation was, of course, not from the easy case of early fibroid, but from the old complicated cases, and therefore the early operation should be preferred and the watching not prolonged until too late.

Dr. McDonald did not wish to convey the idea that adenocarcinoma was a direct degeneration of the fibroid, but that it was of much more frequent occurrence in cases with fibroids than in those without. Calcareous degeneration, while in itself not serious, was almost characteristic of dead tissue, which was dangerous. When a fibroid took on new and rapid growth the probability of its being sarcomatous was very great and the need for operation very urgent. In women between forty and fifty with fibroids 8 per cent. had malignant degeneration; between fifty and sixty, 13 per cent., and between sixty and seventy, 25 per cent. were undergoing malignant changes. If the cases were diagnosed and then neglected, the physician was responsible for the final results. If this work in his hands had come to have any value the thanks were due to the inspiration and work of his former teacher, Dr. Charles P. Noble.

Ovariotomy and Myomectomy Early in Pregnancy, with Full Term Delivery.—Dr. H. Grad of New York City took up the question of sterility and fibroids. Fibroids might tend to produce sterility, but when pregnancy occured in a uterus containing fibroids the growth of the fibroid was liable to increase. He cited one case of fibroid occurring in a woman who had never menstruated, and another of a woman who had one child in a fibroid uterus, and

then, after a period of thirteen years, there came four months of amenorrhea, followed by a bloody discharge for six weeks and then a miscarriage. Instead of the fibroid subsequently undergoing involution with the uterus, it kept on bleeding and a panhysterectomy had to be done. In this case a dormant tumor had been started up by pregnancy. Fibroids might interfere with conception by mechanical hindrance of the entrance of the semen or by the chronic congestion of the uterine mucosa preventing the lodgment of the ovum. Operations for fibroids causing symptoms should be undertaken during the pregnancy if the fibroid was pedunculated, or if it was liable to obstruct the birth canal, but a certain number of fibroids that were implanted low in the uterus or cervix could be lifted out of the pelvis. In interstitial fibroids with marked symptoms operation might be indicated during pregnancy.

Dr. Howard Kelly of Baltimore said that there was a growing tendency to noninterference in fibroids during pregnancy unless they were producing symptoms if the fibroid was in the fundus of the uterus. In the lower portions of the uterus attempt should be made to push the fibroid up out of the pelvis; with a fibroid in the cervix it was usually best not to wait for a normal delivery, but to do a Cesarian section at term, yet even in these cases it is possible at times for the uterus to be emptied without operation. He had had one case come to him just after labor in which there was a cervical fibroid so large and hard that he would have said positively that a normal labor was unquestionably impossible.

Dr. Henry Fry of Washington, D. C., believed in waiting for labor if possible, but after labor the puerperium should be watched most carefully. In one of his cases after labor the fibroid had necrosed, and the woman suddenly developed symptoms of collapse, and never again could be gotten into condition good enough to allow of operation.

Dr. A. E. Benjamin of Minneapolis considered central necrosis of the fibroid during pregnancy or immediately thereafter so liable to happen, and the danger of absorption from operation so small when carefully done, that he considered operation during pregnancy preferable to waiting in the appropriate cases.

Dr Carstens of Detroit thought the mortality of operations during pregnancy not greater than in women not pregnant, so that he would operate during pregnancy

Dr Grad of New York, in closing, said that he did myomectomies during pregnancy in those cases also where there were painful contraction not due to the uterine contents.

Curettage for Uterine Hemorrhage.—Dr Howard Kelly of Baltimore considered the cases of metrorrhagia (occurring especially at the two ends of the woman's normal menstrual life) in which the bleeding was persistent and profuse, often cutting the hemoglobin contents of the blood down below 50 per cent., and in which there was no evident adnexal disease or physical evidence, clinically, of change in the uterus further than enlargement of the organ. He recognized that the bleeding might be due to changes in the endometrium, in the myometrium, in the blood vessels of the uterus, or in the condition of the blood, but thought the curettage applicable to those cases in which the changes were in the endometrium. The curettage had to be repeated frequently at first, just before the expected menstrual flow, but if the hemorrhages continued then he curetted every time the flow came on and began to be excessive on the second day of menstruation if the flow on the first day was excessive. He cited one case in a woman of forty-eight years, on whom he had done a curettage before menses three times, and then over and over again during the menstrual flow every time she bled for two years. The patient had now been free from hemorrhage for over a year, and hysterectomy had been avoided. He cited another case of a girl with hemorrhages, apparently from a hypertrophic endometrium, who was well after six or eight curettages in one year. He would continue the treatment as long as the woman did not show signs of getting worse.

Dr. G. Betton Massey of Philadelphia treated such cases by electrochemical curettage. He coated the copper anode with mercury and inserted it inside the uterine cavity and then turned on 100 to 200 milliamperes of current. This controlled the bleeding in ten seconds, coating the endometrium with a copper mercury amalgum. He did not think a sharp instrument safe. The electrochemical treatment had the same effect as Dr. Kelly's treatment, and saved the blood loss. This treatment needed repetition once a month between periods for about a year. Such conditions in the old woman aroused suspicions of cancer, and in the girl of fibroid.

Dr. Hermann J. Boldt of New York thought that the cases were so suspicious of grave trouble that he treated most of them by hysterectomy, but when sure that no cancer was present after a curettage he made intrauterine applications on gauze, or, better, injected pure phenol with a syringe into the uterine cavity. The gauze strip he inserted with the tip of the intrauterine syringe and left it in place for an hour. Then he removed it. He placed a cotton tampon in the vagina to catch any excess of phenol. This treatment must not be used if other complications were present. He had never seen necrosis, though he had seen one or two cases of subsequent amenorrhea from excessive effect. It was always a cure.

Dr. Carstens of Detroit was always suspicious of malignancy. He called attention to the very marked recuperative powers of the endometrium, and had seen the condition recurrent after applications of phenol on a cotton swab. In girls he now uses pure nitric acid and does not get recurrences.

Dr. Henry D. Fry of Washington said that such frequent repetitions of a curettage would not be allowed by many of his patients. He thought the best time for the curettage just after the flow. The general prejudice against operations during the menstrual flow was gradually being overcome, but curettage would probably be the last operation to get beyond this prejudice. The advantages of repeated curettage were not evident unless there was some distinct disease of the endometrium. In many of these cases arteriosclerosis in the uterus was probably the basis of the trouble. He believed in the introduction of phenol as excellent, but used it through an intrauterine speculum. He had found a boroglyceride tampon in the vagina for two weeks before the flow a great aid. He thought the frequent repetition of the curettage would bring it into disfavor not only in this condition, but in all others.

Dr Shoemaker of Philadelphia said that the cause of these hemorrhages was so likely to be malignant disease or fibroid that the greatest laboratory care must be exercised to exclude them. In one of his cases it was the twentieth slide examined that showed malignancy.

Dr W. S. Gardner of Baltimore called attention to the result of the studies of the endometrium as shown in the paper by Dr Novak and himself on this subject. Hypertrophic endometritis was present in many normal cases and simply represented a premenstrual endometrium found at an improper time. The cause of the bleeding in these cases was not in the endometrium, and perhaps not in the uterus, but in the conditions causing the congestion of the uterus, and that cause, not the endometrium, should be removed.

Dr Novak of Baltimore said that in metrorrhagia and in menorrhagia there was no marked variation in the endometrium from the normal, and the changes in the pathology were not primary in the endometrium, but elsewhere.

To be continued.

thesia by means of, 1078; death from, 448; light equipment for operating in private houses, 585.
Electricity and light in medicine, 575; in genitourinary diseases, 982; injury by, 870; in treatment of fractures, 279.
Elephantiasis of male genitalia, 122; prospective cure for, 156.
Ely, L. W., treatment of Pott's disease at the Sea Breeze Hospital, 1096.
Embolism, pulmonary, following operation, 45.
Emmanuel movement and its relation to the medical profession, 406; movement, the church and the, 807
Empyema, tuberculous, treatment of, 1041.
Endoaneurysmorrhaphy, indications for obliterative in contradistinction to reconstructive, 284.
Encephalitis, acute (hemorrhagic), 223.
Endocarditis, chronic infectious, 1044; histology of, 984; ulcerative, with necropsy and blood findings, 34.
Endometrium and some variations, 1041.
Enteroclysis in typhoid fever, 582.
Enterospasm, 577.
Enterostomy in intestinal obstruction, value of, 283.
Epidemics, prevention of, 393.
Epilepsy, 198; acute pulmonary edema as terminal event in, 993; calcium lactate in, 984; partial constant, 1113; problem of, 430; structural side of, 994; surgical treatment of, 122, 775; treatment of, experiment in, 325; visual auras of, 578.
Epileptic voice, 857.
Epiploitis following radical cure of hernia, 323.
Epithelioma of penis, 825; treatment of, by pure radium salts, 531.
Epsom salts as a poison, 859.
Erdmann, J. F., cholecystectomy vs. cholecystotomy, 263.
Erysipelas, carbolic acid in, 322; medical and surgical treatment of, 995.
Erysipelas, treatment of, 408; treatment of, by means of carbolic acid and alcohol, 268; vaccine treatment of, 494.
Esophagoscopy, direct, 659.
Esophagus, idiopathic enlargement of, 124; stricture of, early recognition of, 102.
Ethmoiditis, acute suppurative, 815.
Ethylchloride as general anesthetic, 982; economy in, 892.
Etiology of pain, 917, 950.
Eucalyptus in leprosy, 615.
Eunuchoidism, study of, 581.
Europe, post-graduate study in, 704.
Evans, T. H., hypochloridization in treatment of exophthalmic goiter, 24.
Evolution, doctrine of, 275.
Examinations, 20.
Exophthalmus in chronic nephritis, 987.
Extremities, traumatic injuries of, conservative treatment of, 761.
Eye, cataract of, spontaneous absorption of, 154; cataract, technique of extraction of, 106; hemorrhage into vitreous body, 27; in mental defectives, study of, 541; of yesterday and of to-day, 213
Eyelid, fibrosarcoma of, in child, 1072.

F

Facial deformities, 616.
Far Eastern Association of Tropical Medicine, 852.
Farmer, J. C., prophylactic circumcision, 191.
Fat-splitting ferments in lymphocytes, 402.
Feces, diagnostic value of examination of, 1075; diagnostic value of stained specimens of, in cancer of stomach, 1074, examination of, in clinical work, 736; occult blood in, clinical tests, for, 496; tubercle bacilli in, 1103.
Feeding, infant, determination of calorie value in, 1080; infant, Huebner's system of, 1080; infant, relation between science and art of, 1080; of sick infant, 933.
Femur, fracture of neck of, 204; fractures of, bone pegs in, 205; neck of the, injuries of the, 1.
Fernandez, F. M., contribution to study of thiosinamine in otology, 1103.
Fetal membranes, suppurative lesions within, 84.
Fetterolf, George, symptomatology of, tuberculosis of the larynx, 143.
Fetus, typhoid infection of a, 452.
Fever, alimentary, 485; glandular (Pfeiffer's), 196; hemoglobinuric, 241; hysterical, 105; in infectious disease, effect of, 894; spotted, Rocky Mountain, 280; syphilitic, 766.
Fibroid phthisis in childhood, 410; tumors and pregnancy, 121.
Fibromata, of uterus, 1123; pylorectomy for, in infant, 539.
Fibromyomata, uterine, aseptic sloughing of, 849.
Fibrosarcoma of eyelid in child, 1072.
Fibula, sarcoma of, 286.
Filariasis, 76.
Fishberg, M., the inadequacy of the sanatorium treatment of tuberculosis, 1001.
Fistulæ, ureteral, 955; vesicouterine, 123; vesicovaginal, 36.
Fleas and plague in the Old Testament, 484.
Flies and milk contamination, 850; relation of to spread of disease, 820.
Florida Medical Association, 771.
Floyd, R., two unusual cases of influenza-pneumonia, 521.
Fluoroscopy and radiography, hints on, 764.
Food containing benzoates injurious to health, is?, 16; intoxications in childhood, 1039; preservatives, 407; preservatives, evil of, 321.
Foot, flat, 736.
Football injuries of Harvard squads for three years, 192; Pres. Eliot on, 748.
Foot-and-mouth disease, nature of, 201; origin of recent epidemic of, 935.
Forceps for removal of tags, etc., on posterior pharyngeal wall after adenoid operations, 606; Tarnier, 774.
Forehead, pulsating tumor of, 782, 949.
Formalin in extirpation of cancer, 405.
Fox, Howard, the principles and technique of the Wassermann reaction and its modifications, 421.
Fracture, Colles', 289; compound, radical conservation in treatment of, 204; diagnosis and treatment of plea for more careful, 1078; electricity in treatment of, 279; of femur, bone pegs in treatment of, 205; of neck of femur, 204; operative treatment of, 1078; simple, diagnosis and operative treatment of, 203; simple, operative treatment of, 203
Freezing as a therapeutic measure, 633, 664.
Friedreich's ataxia, 314.
Frontal sinus, disease of, operation in, 278; sinus obliteration, operation for, 991.
Fulguration treatment of cancer, 191,
Funiculitis, endemic, 280.

G.

Gall-bladder, removal of, 288; spontaneous rupture of the, 29.
Gallstone disease, 983.
Gallstones and heart disease, 1113; value of turpentine in, 75.
Ganglioneuroma, retroperitoneal, 30.
Gangrene, carbolic acid, 768.
Garvin, A. H., some points on the early diagnosis of pulmonary tuberculosis, 179.
Gastrectasia, atonic, diagnosis and treatment of, 328.
Gastric and duodenal ulcer, 288; perforated, 1068; contents, trypsin in after oil test meals, 1075; contents, uses and limitations of examinations of, 1074; disease, indications for surgery in, 290; hemorrhage, blood transfusion for, 457; juice, secretion of, in nongastric malignant disease, 428; neuroses, 289; secretions, effect of injection of salt solution into intestines on, 1070; secretion, mechanism of, 861; tetany, experimental study of, 1043; ulcer and carcinoma, relation of, 988; ulcer, chronic, diagnosis and treatment of, 577; ulcer, cure of, 951; ulcer, diagnosis of, 454, 549; ulcer, hour-glass stomach, 867; ulcer, Roentgen rays in treatment of, 249; ulcer, treatment of, by immediate feeding, 738.
Gastroenteroptosis, radiographic examination in, 248.
Gastrointestinal autointoxication, a disease or a symptom? 565.
Gastroptosis, diagnosis and treatment of, 583.
Generative organs of women, restoration versus removal, 122.
Genitourinary complications of typhoid fever, 410; diseases, electricity in, 982.
Goelet, A. H., concealed appendix, 1017.
George Washington Memorial Association, 1037.
Gibson, C. L., pulmonary embolism following operation, 45.
Glanders, acute, in man, 193.
Glands, sweat, destruction of, by Roentgen rays, 860.
Glandular fever, 196.
Globular resistance of new-born, 606.
Glycogen in sputum, 1000.
Glycosuria, alimentary, 1114; and diabetes, 867; in pregnancy and the puerperium, 148.
Goiter, cause of, 1061; exophthalmic, 658; exophthalmic, hypochloridization in treatment of, 24; exophthalmic, loss of hair in, 860; exophthalmic, in girl of ten years, 667; exophthalmic, surgical treatment of, 119; exophthalmic, treatment of, 63; mortality in operations for, 120; operations, accidents and complications in, 288; parenchymatous, nature and treatment of, 413
Goldberger, J., report of a case of hydrophobia, 1018.
Golley, F. B., two cases of cancer treated with trypsin, 814
Gonorrhea and syphilis, Iowa's endeavor to control, 108; chronic, pathology and treatment of, 278; chronic, vaccine treatment of, 496; influence of congenital abnormalities of the penis on, 49

Gonorrheal conditions in women, 645.
Goodhue, E. S., American School of Tropical Medicine at Honolulu, 109.

Gout and rheumatism, 904; chronic, 72; treatment of, by thyminic acid, 75.
Graef, Charles, headaches of ocular and nasal origin, 11.
Granuloma from foreign body, rare, 1069.
Graves' disease, treatment of, with milk of thyroidless goats, 777.
Greek for physicians, 531.
Grocco's sign, explanation of, 657.
G. R. S., a word for the outcast, 774.
Guaiac and benzidin tests for blood, 1112.
Guiteras, Juan, suppression of yellow fever in Cuba, 1108.
Gynecology, cystoscopy in, value of, 1049; disinfection in, without soap and water, 618; Roentgen rays in, 1069.

H

Hair-ball in stomach in children, 1039.
Hair, loss of, in exophthalmic goiter, 860.
Hand, foreign body cyst of, 80.
Hands and feet, webbed, 332.
Harbin, R. M., methods and results of drainage in 22 cases of abscess of the appendix, 54.
Harbors, tidal, pollution of our, 247.
Hare, H. A., unauthorized use of a name, 1064.
Hare-lip, technique of operations, 286.
Harrigan, A. H., combined operation for radical cure of inguinal hernia and appendicitis, 1099.
Harrower, H. R., study of the urinary acidity and its relations, 966.
Hartford County Medical Society, 732.
Hassin, G. B., acute (hemorrhagic) encephalitis, with report of cases, 223.
Hay fever and other rhinological causes of asthma, 920.
Headache, indurative, 816; of ocular and nasal origin, 11; of puberty, 734.
Health matters, 105.
Heart, arrhythmias, 833; beat, dropped, 411; beat, points of origin of, 904; cardiovascular diseases, 201; clinical improvements in methods of studying diseased, 418; complications in pneumonia, 1043; disease and gallstones, 1113; disease, baths and exercise in treatment of, 202; effects of baths on, 403; in puerperal state, 252; insufficiency, 417; lesion, sudden death from unsuspected, 943; massage of, in apparent death, 936; murmurs, postural, 533; orthodiagraphy in study of, 948; size of, 1115; sound, third, 948; stenosis at pulmonary orifice of, 987; tricelian, and transposition of viscera, 184; wounds, suture of, 324.
Heart-block, 970; case of, 860; in man, 75.
Heat, new disorder from, 902; spasm, muscular, 737.
Heath operation, so-called, cases illustrating the, 468.
Hebotomy, prognosis and indications, 157.
Hecht, D'Orsay, treatment of syphilis and parasyphilis of nervous system, 1012.
Heckmann, Jacob, etiology of arthritis deformans, 958.
Heels, painful, 615.
Hematoma of vulva, 660; rare forms of, 119.
Hematuria during purpura, pathogenesis of, 157; following nephrectomy for tuberculosis, 502.
Hemiplegia resulting from cerebral apoplexy, 345.
Hemoglobinuric fever, 241.
Hemolymph nodes, hyperplasia of, 990.
Hemolysis in diagnosis of carcinoma, 241.
Hemolytic properties of cancer serum, 61.
Hemophilia, observation of the hematology of, 413.
Hemoptysis, chloroform in, 1113; treatment, of, by galvanization of thorax, 944.
Hemorrhage, cerebral, 27; cerebral, following arteriosclerotic granular nephritis, 846, 864; gastric, blood transfusion for, 457; in newborn, 74, 332; internal and pulmonary as complication of tuberculosis, 559; internal concealed, 323; into the vitreous body, 27; intracranial in newborn, 815; pulmonary, 533; uterine, curettage for, 1125; vaginal, in infant, 766.
Hemorrhoids in the child, 114; methods of excision of, 736.
Henock's purpura and intussusception, 450.
Hermaphroditism, case of, 585; pseudo, case of, 615.
Hernia, congenital false diaphragmatic, 942; epiploitis following radical cure of, 323; inguinal, and appendicitis, combined operation for radical cure of, 1099; inguinal, left-sided, containing vermiform appendix, 194; inguinal, oblique, repair of internal ring in, 287; oblique inguinal, repair of internal ring in, 659.
Herrick, C. B., the railway surgical service, 688.
Hillsborough County Medical Society, 732.
Hip, injuries of the, 1; operation for congenital dislocation of, 664.
Hip joint, disease of, due to streptococcol invasion, 817; tuberculous, resection of, 578.
Hippocrates, the modern, 486.
Holmes' nautilus, anatomy of, 753.
Hospital patients, transfer of moribund, 187, 238; practice vs. private practice, 592; system, public, of Greater New York, 665.
Hospitals for rational treatment of inebriates, 795.
Hot air in treatment of acute purulent inflammations, 903.
Hubbard, S. D., freezing as a therapeutic measure; liquid air and carbonic acid snow, 633.
Heubner's system of infant feeding, 1080.
Hulst, Henry, examination of lungs by Roentgen rays, 798.
Humerus, cancer of, 459; supracondyloid, fracture of, 459.
Hunger, alcohol in, 618.
Hurd, L. M., clinical diagnosis of tuberculosis of tonsils, 1089.
Hydatid moles, 399.
Hydronephrosis, infected, 375; intermittent, 857; nephrectomy for, 536.
Hydrophobia, 28; report of a case of, 1018.
Hydrotherapy, 321; claims of, 337.
Hygiene, administrative, some serious lapses in, 220, 454.
Hyperalimentation, nitrogenous, 157.
Hyperemia, Bier's, in dermatology, 18; Bier's, dangers of, 1021.
Hypernephroma and carcinoma, simultaneous occurrence of, 241; of serratus muscle, metastatic, 623.
Hypochloridization in treatment of exophthalmic goiter, 24.
Hypophysis cerebri, 1079; function of, 916.
Hypoplasia, hereditary, in man, 365; in its relation to health and disease, 120.
Hysterectomy clamp, improved, 606; effect of, 451; for carcinoma of cervix, 121; indications for, 334.
Hysteria, blindness of, 817.
Hysterotomy, bloodless, 533.

I

Icterus, xanthoma in, 327.
Idiocy, amaurotic, three cases of, 946.
Ileocolic circle, 980.
Ileosigmoidostomy for relief of inveterate constipation, 242.
Ileum, lipoma of, 623.
Ileus, 955; paralytic, 776; postoperative, 1067.
Illinois State Medical Society, 937.
Immunity after injection of antidiphtheritic serum, duration of, 759; and anaphylaxis, 555; and infection, catalytic theory of, 749.
Indicanuria and its significance, 1073.
Indigestion, intestinal, 280.
Inebriates, hospitals for rational treatment of, 795.
Inebriety in Great Britain, 103.
Infancy, urine in diseases of, 531.
Infant feeding, 416; feeding, determination of calorie values in, 1080; feeding, Heubner's system of, 1080; feeding, relation between science and art of, 1080; feeding, vagaries of, 103; mortality, 883, 1080; mortality: comparison of past and present, 333.
Infantile pseudoparalysis, 902.
Infants, premature, water as diet for, 450.
Infection and immunity, a catalytic theory of, 749.
Infectious diseases, biological foundation for specific therapy of, 665; diseases, prophylaxis of, 155.
Inflammation, acute purulent, hot air in treatment of, 903.
Influenza, epidemic of, characterized by edema of the eyelids, 30; pneumococcus, 487; pneumonia, two unusual cases of, 521; unusual aspects of, 371.
Infusoria in stomach contents, 327.
Injured and crippled, care of, in Germany, 781.
Injuries, traumatic, conservative treatment of, 761.
Inoculation accident in Manila in 1906, 942.
Insane diathesis, 901; voluntary patients in State hospitals for, 199.
Insanity in the sixth and seventh decades, 19.
Inspection of schools, medical and sanitary, 480.
Institutional work for young physicians, 694.
Insurance examiner, the, 686.
International American Congress of Medicine and Hygiene, 938.
International Congress of Medicine, Sixteenth, 937.
Intestinal and omental adhesions, 955; gases, surgical importance of, 285; indigestion, 280; localization, 658; obstruction, 622; obstruction, enterostomy in, 283.
Intestine, foreign body in, 457; foreign

body in, further report on, 536; large, acquired diverticula of, 328; large, physiology and pathology of, 904; large, traumatic rupture of, 648; obstruction of, 118, 411; resection of, 118.
Intoxications, food, in childhood, 1039.
Intrascapulothoracic amputation for sarcoma, 78.
Intrathoracic operations, apparatus for, under differential pressure, 62; physiological and technical studies, 1042.
Iodine for sterilization of skin of operation areas, 365; in surgical tuberculous disease, 413; tincture of, and iodine catgut in major surgery, 99.
Iodophilia of leucocytes, 450.
Iowa State Medical Society, 979.
Iowa State Society of Medical Women, 978.
Iridotomy, 364.
Irrigatine and drainage in obstetrical and gynecological operations, 1123.
Isaacs, A. F., calculus in lower segment of ureter in the female, 1054; free suppurative peritonitis, 306.
Isthmuses, ureteral, the three, 593.

Phlebitis of leg, after laparotomy, 766.
Phosphatic index, research regarding, 763.
Phosphorus as brain food, 858.
Phthisis, fibroid, in childhood, 410; some nontuberculous throat complications of, 934.
Physical basis of life, 946; training, 1061.
Physician and lawmaking, 195; and public health, 1113.
Physicians' Mutual Aid Association, 359.
Physiology and infant feeding, correlation of, 416.
Pierce, Paul, the evil of food preservatives, 321.
Placenta of eclamptics, 618; prævia, 1066; previa, cesarean section in, 906.
Plague, rat-flea theory of, 234; treatment of, 916.
Plasmodia, malarial, classification of, 1026.
Pleura, surgery of the, 120.
Pleural effusions, 660; pains and adhesions, 534.
Pleuritis, fibrinous and serofibrinous, treatment of, 775; serofibrinous, autoserotherapy in, 318; tuberculous, treatment of, 1041.
Pneumococcus and meningococcus infections, resemblance between clinical effects of, 988; influenza, 487; lung abscess, 864; peritonitis, due to, 577.
Pneumonectomy with aid of differential pressure, 1041.
Pneumonia, a bedside and laboratory study, 669; cardiac and vascular complications in, 1043; efficient treatment for, 242; influenza, two unusual cases of, 521; meningitis in, 852; treatment of with quinine, 1112.
Poisoning by egg, a note on, 438; egg, case of, 1066; ivy, 73.
Poliomyelitis, acute anterior, epidemic of, 412.
Polycythemia, splenomegalic, fatal case of, 902.
Polypus, fibroid of uterus, 369.
Porro-Cesarean section, 117.
Porter, R. H., the problem of epilepsy, 430.
"Post hoc ergo propter hoc," 1081.
Post-graduate study in Europe, 704.
Post-mortem examinations, attitude of public towards, 728.
Posture, postoperative sitting, 568.
Potassium bichromatic in treatment of cancer, 534.
Pott's disease, pain and, 1113; treatment of, at Sea Breeze Hospital, 1096.
Poultry, cold storage of, 278.
Pregnancy, eclampsia and toxemia of, pathology of, 1081; ectopic, 496; ectopic, analysis of eighty cases of, 37; extra-uterine, immediate versus deferred operation for, 100; fibroid tumors and, 121; interstitial, with report of a case, 230; myomectomy in, case of, 328; opthalmoreaction in, 326; pyelitis of, treated with coli-vaccines, 325; tuberculosis and, 585.
Presbyterian Hospital to move, 319.
Prophylaxis among children, 1038; of infectious diseases, 155.
Prostate, excision of, seven years after Bottini's operation, 503.
Prostatectomy, 297, 778; and calculi of bladder, 1072; present status of, 973; problems relating to, 198; suprapubic, 117.
Prostatic vesicle, cyst of, 101.
Proteid metabolism in obesity cures, 76.
Proteins, fats, and carbohydrates, resorption of, in chronic alcoholic, 1074.
Pseudo peritoneum, 1079.
Psoriasis, etiology of, 412.
Psychology, medical, 176.
Psychoneuroses and gastric disturbances, 578.
Psychosis, zoophil, 381.
Psychotherapeutics and religion, 316.
Psychotherapy, 154; some aspects of, 153.
Public Health and Marine-Hospital service, 683.
Public Health service, year's work of, 607.
Public health work, publicity in, 449.
Puericulture, 976.
Puerperal fever, etiology of, 1029; infection, essence of turpentine in prevention and cure of, 603; sepsis, 153; state, heart in, 252.
Puerperium, pyrexia during, 113.
Pulmonary abscesses of obscure origin, 784; affections of infancy, 933; apices and tuberculous infection, 354; complications in one thousand laparotomy cases, 1041; embolism following operation, 45.
Pulse wave, retardation of, in aortic retardation, 75.
Pulsus bigeminus, note on, 860.
Purpura hæmorrhagica; is it caused by the colon bacillus? 482; Henoch's, and intussusception, 450; infantile, paroxysms in the course of, 933.
Pyelitis of pregnancy treated with coli-vaccines, 325.
Pyelocystitis in infancy, 809.
Pyelonephritis, calculous, nephrectomy for, 502.
Pylorectomies, series of thirteen, 353.
Pylorectomy, partial, for fibromata in infant, 539.
Pylorus, deverticulum at, 1072; stenosis of, 140; stenosis of, congenital, 372; stenosis of, congenital hypertrophic, 539; spasm of, congenital, 1080; stenosis of, hypertrophic, in infants, 1080.

Pyocyanase in diphtheria, 366.
Pyonephrosis, hematogenous origin of, 916.
Pyosalpinx, series of cases of, 910.
Pyrexia during puerperium, 113.

Q.

Quackery, ancient, 533.
Quick, E., renal tuberculosis, 562.
Quigley, Dr., the late, 190.

Tongue, cancer of, 156, 450; mouth, and jaw, cancer of, 901; philosophical anatomy of, 858.
Tonsillectomy, otitic significance of, 1027.
Tonsils, carcinoma of, 80; dangers associated with removal of, 383, 493; enlarged, results of, 1000; functional relation of, to teeth, 982; operation for removal of, 943; palative, 413; toxic secondaries of chronic disease of, 857; tuberculosis of, diagnosis of, 1089, 1118.
Tories, smoked, a menace to health, 893.
Townsend, T. M., Iowa's endeavor to control gonorrhea and syphilis, 108.
Toxemia of gastrointestinal origin, 81, 82.
Toxins of erysipelas and B prodigiosus in inoperable sarcoma, value of, 621.
Trachea, resection of, for cicatricial stenosis, 1114.
Tracheotomy cases, 1068.
Trachoma, excitant of, 651.
Tray for holding instruments during surgical operations, 605.
Treatment, simplicity in, 1106.
Trembles and milk-sickness, cause of, 839.
Treponema pallida in syphilis, 167.
Tropical diseases, 364; diseases, America's opportunities and obligations, 1076; medicine in United States, 748.
Tropics, conquest of, for white race, 1045; sanitation of, 658.
Trypsin in stomach contents after oil test meals, 1075; in treatment of cancer, 804; in treatment of surgical tuberculosis, 64.
Tubercle bacilli, dead, ingestion of, 949; found in human tuberculosis, 949; in circulating blood, 568, 1117; in feces, 1103; in glandular tuberculosis, 609; in human ovum, 64; in milk, 616; the cause of cancer, 27.
Tuberculides, clinical and histological features of, 823; of the skin, 821.
Tuberculin injections in diseases of the skin, 823; in tuberculosis of infants and children, 487; reaction, cutaneous, diagnostic use of, 265; reaction, cutaneous, studies with, 949; reaction, demonstration of, 33; reaction, inunction in cutaneous tuberculosis, 823; reaction ophthalmo, in pregnancy, 326; treatment, 241.
Tuberculosis, abdominal, 242; abdominal, surgical types of, 287; acute miliary, diagnosis of, 73; among syphilities, 114; and carcinoma of stomach, 868; and climate, 113; and pregnancy, 585; and tuberculides, clinical and histological features of, 823; and tuberculides of the skin, 821; animal, 851; antibodies in, 1121; bovine, 147; bovine, transmission of, to children, 1080; cutaneous, clinical and histological features of, 823; cutaneous, diagnostic value of inunction tuberculin reaction, 823; frequency of, at autopsies, 577; general movement of in last twenty-five years, 987; genitourinary leucocytes in urine in, 366; glandular, tubercle bacilli in, 609; hemorrhage as a complication of, 559; hip-joint, resection of, for, 578; history of, 604; human and bovine, 616; in childhood, 157; in childhood, hygienic and climatic prophylaxis of, 471; in children, 440; increase in, 149; in early childhood, 894; inflammatory, 76; inhalation treatment of, 651; inoculation, following ritual circumsion, 668; in New York, 866; Kuhn's mask in treatment of, 442; localized subphrenic, 1041; miliary, 373; mercury in treatment of, 1112; nephrectomy for, 622; problems connected with, 1118; renal, 562; responsibility of family physician toward, 112; sacroiliac, 451; saliva in transmission of, 817; sanatorium treatment of, inadequacy of, 1001; sensitization in, 948; serum diagnosis and prognosis in, 28; sexual factor in, 193; superalimentation in, passing of, 354; surgical, iodine in, 413; surgical, trypsin in treatment, 64; vs. paresis, 364; war against in Great Britain, 1104.
Tuberculosis of appendix, resection of colon for, 78; of breast, 348; of cervix uteri, 893; of children, tuberculin in, 487; of kidney, 871; of larynx, 72; of larynx, symptomatology of, 143; of larynx, treatment of, by means of sunlight, 1070; of tonsils, diagnosis of, 1089, 1118.
Tuberculosis, pulmonary, apical, 354; pulmonary, blood in, coagulability of, 341; pulmonary, body weight in relation to, 243; pulmonary, chest in, 1113; pulmonary, classification of, 279; pulmonary, climatic treatment of, 532; pulmonary, clinical index of thorax associated with, 866; pulmonary, diagnosis and therapy of, 419; pulmonary, diet in, 253; pulmonary, early diagnosis of, 179; pulmonary, exercise in, 1066; pulmonary, experimental, with formation of cavities, 941; pulmonary, fibroid, in childhood, 410; pulmonary, graduated rest in treatment of, 738; pulmonary, incipient, and its diagnosis, 241; pulmonary, laryngeal examinations in, 205; pulmonary, some non-tuberculous complications of, 934.
Tuberculous arthropathies, errors of diagnosis in, 232; joints, 858; patients, agglutinating power in, 28.
Tubes after resection, obliteration of, 916.
Tuboovarian abscess with complications, 369.
Tumor, experimentally produced, 526; pulsating, of forehead, 782, 949.
Typhoid agglutinins in meningitis, 113.
Typhoid bacilli carriers, 578; carriers, dangers to, 1115; carrier, treated with typhoid vaccine, 325; carriers, 192.
Typhoid bacilluria, 1020.
Typhoid fever, 983; and shellfish, 365, 808; atypical, 650; diet in, 936, 1072; etiology of pulmonary affection in, 269; general movement of, in last twenty-five years, 987; genitourinary complications of, 410; milk-free diet and enteroclysis in, 582; modern conceptions of, 146; neuroretinitis due to, 737; prophylactic inoculation against, 323; renal suppuration in, 991; short duration, 198; two unusual cases of, 658; vaccine treatment of, 93; vaccines in, 815; what is? 316.
Typhoid infection of a fetus, 452; meningitis, 235; perforation, 449.

U.

Ulcer, carcinomatous, of vagina, 368; chronic, of stomach and duodenum, diagnosis and treatment of, 577; gastric and duodenal, 288; gastric and duodenal, perforated, 1068; gastric, cure of, 951; diagnosis of, 454; gastric, large, 867; gastric, Roentgen rays in diagnosis of, 249; gastric, treatment of, by immediate feeding, 738; leg, Unna's method of treatment, 450, 778; of the upper digestive tract, new method of recognizing and locating, 549.
Umbilical cord, surgical treatment of, 859.
Unauthorized use of a name, 1064.
Uncinaria infections, 820.
Uncinariasis in the army, 977; prevalence and importance of, 820.
Unna's method of treating leg ulcers, 450.
Ureter, calculi of, 754; calculus in lower segment of, in female, 1054; method of detecting injuries of, during operation, 370; stones in the lower end of, 476.
Ureteral calculi, observations upon, 245; calculus, 242; calculus, cystoscopic aid in diagnosis and treatment of, 246; calculus, operative technique, 246; calculus, surgical anatomy and pathology of, 245; calculus, x-ray aid in diagnosis of, 247; fistulæ as sequelæ of pelvic operations, 955; isthmuses, the three, 503.
Urethra, cancer of, 1115.
Urine, acidity of, estimation of, 111; acidity of, study of, 966; extravasation of, 536; findings, transitory, in some diseases of childhood, 1039; incontinence of, in children, 981; in diseases of infancy, 531, 1110; in pregnancy, constituents of, 1018; Luys separator, 815; phosphatic index, 763; starch in the, 411; sugar in, Benedict method of estimating, 848; typhoid bacilli in, 1020.
Urobilin, significance of, 860.
Urobilinuria not a sign of hepatic insufficiency, 145.
Uterus, acute inversion of, 325; cancer of, 533; cancer of, causes of mortality in, 157; cancer of, inoperable, treatment of, 76; cancer of cervix, 1026; fibroids of, and malignant disease, 576; fibromata of, 1123; ganglionic nervous system of the human, 353; hemorrhage of, curettage for, 1125; lower segment of, 1103; ganglionic nervous system of the human, 353; myomata of, enucleation of, 1124; perforation of, by curette, 910; polypus, fibroid, of, 369; prolapse of, in nulliparæ, 1115; puerperal abscess of, 369; retrodisplacements of, operation of choice in, 1030; retroflexion of, 104; sacral suspension of the, 370; tuberculosis of cervix, 893; ventrosuspension of, 122

V.

Vaccination, so-called "dangers" of, 193.
Vaccine treatment of acne vulgaris, 777; treatment of erysipelas, 494; treatment of typhoid fever, 93, 815; virus, action of radium on, 439.
Vaccines, antigonococcal, 496; homologous, clinical experiments with, 947; in diseases of children, 1121.
Vagina, carcinomatous ulcer of the, 368.
Valentine, F. C., Iowa's endeavor to control gonorrhea and syphilis, 108.
Valk, Francis, the eye of yesterday and to-day, 213.
Van Buskirk, E. M., paramyoclonus multiplex (Friedreich), 314.
Vandegrift, G. W., case of retinitis due probably to acute lead poisoning, 399.
Van Fleet, F., misleading antivivisection literature, 23.
Vascular degeneration, case of, 817.
Vegetarianism for inebriates, 1103.
Venereal disease in infancy, 1019; diseases, state control of, 238; diseases, the professional secret in relation to, 239.
Venom, rattlesnake, therapeutic value of, 775.
Vertigo, aural, 777.
Vesicovaginal fistula, 36.
Vienna, letters from, 71, 900.
Vincent's angina, 280.
Viscera, disease of, exact areas of pain in, 952; Roentgenographic study of motion in, 248; transposition of, 184.
Visceral crises in erythema group of skin diseases, surgical importance of, 537.
Visceroptosis as a constitutional anomaly, 451.
Vital statistics for 1908, 403; of New York, 66; Philadelphia, 66.
Vitreous body, hemorrhage into, in the adolescent, 27.
Vivisection, anti, condemn, 65; peril, a new, 235.
Voice, epileptic, 857.
Volkmann's ischemic paralysis and contractures, 204.
Vomiting, periodic, in children, 194.
Voorhees, I. W., Dr. Bull's farewell to his students, 735.
Vulva, hematoma of, 660.

W.

Wackenheim, F. L., hygienic and climatic prophylaxis of tuberculosis in children, 471.
Wakefield, Homer, etiology of common colds, 408; some serious lapses in administrative hygiene, 220.
Wakley, Mr. Thomas, death of, 491.
Warbasse, J. P., some common injuries of the elbow, 170.
Washer, wholesale baby, 805.
Wassermann reaction, 30; in cardiac and vascular disease, value of, 990; in congenital syphilis, 660; in surgical syphilis, 452; in syphilis, 281, 618; in syphilis and other diseases, 657; principles and technique of, 421; specific therapy and, 861.
Water as a therapeutic agent, claims of, 337; as diet for premature infants, 450.
Walters, W. H., vaccine treatment of typhoid fever, 93.
Weather changes and subjective symptoms of disease, 895.
Weight, body in relation to pulmonary tuberculosis, 243; standard, for women, 13.
Weisse, F. S., table of standard weights for women, 13.
Wells and Darwin and the doctrine of evolution, 275.
Wells, W. A., danger signals in inflammation of the ear, 311.
Whiting, A. J., two important angioneuroses, 8.
Whiting, Fred, adequate drainage the essential step in the successful surgery of brain abscess, 133.
Whitman, Royal, further observations on injuries of the neck of the femur in early life, 1.
Widener industrial school for crippled children, 780.
Wiener, A., a forceps for removal of tags, etc., on the posterior pharyngeal wall after adenoid operations, 606; clinical and anatomical manifestations of otitic brain abscess, 137.
Wiley, Dr., and referee board, 185; should be retained, 65.
Williams, T. A., rational treatment of tabes dorsalis in relation to its pathogenesis, 591.
Women, gonorrheal conditions in, 645.
Wolf, H. E., hydrotherapy, 321; mental alienation and abdominopelvic disease in, 1039; table of standard weights for, 13.
Wood, P. R., smoked torics a menace to health, 893.
Wood, Wallace, cerebral lobules, 753.
Wood, W. G., salaried positions open to medical men in larger cities, 696.
Wounds, blue rays in treatment of, 904.
Wright, J., diagnosis of tuberculosis of tonsils, 1089.
Wrist, Madelung's deformity of, 79; old standing injuries of the, 194.

X.

Xanthoma in icterus, 327.
X-ray diagnosis, 844; see Roentgen ray.

Y.

Yellow fever and mosquito, 73; blood pressure in, 821; Cuba free from, 1064; diazo reaction in, 1069; etiology of, 944; in Cuba, suppression of, 1108.

Z.

Zoophil-psychosis, the, 381, 448, 615.
